Spin–Lattice Relaxation in Imperfect Cubic Crystals and in Non-cubic Crystals

BY E. R. ANDREW AND D. P. TUNSTALL

Department of Physics, University College of North Wales, Bangor, Caernarvonshire

MS. received 19*th December* 1960

Abstract. An examination is made of the spin–lattice relaxation in the solid state of nuclei whose energy level spacings in a magnetic field are rendered unequal by quadrupole interactions with the crystalline electric field. Attention is directed to two special cases: (1) when the main magnetic field is suddenly increased from zero, and (2) after saturation of the central line of the resonance spectrum; in the case of imperfect cubic crystals this is the only observed line. In general, $2I$ relaxation times characterize the relaxation behaviour, though in the two special cases the effective number is reduced. Detailed calculations of the relaxation behaviour have been made for spin number $\frac{3}{2}$ and $\frac{5}{2}$ for a quadrupolar relaxation mechanism. The behaviour in the two special cases differs and to a degree which depends on the relative strength of quadrupolar relaxation by transitions involving $\Delta m = 1$ and 2. The relevance of the results to the experiments of Day and Squire on potassium iodide is discussed. Magnetic relaxation is also treated and an expression is found for the $2I$ relaxation times.

§ 1. INTRODUCTION

THIS paper is concerned with the spin–lattice relaxation in solids of nuclei of spin number $I > \frac{1}{2}$, whose $2I$ energy-level spacings in an applied magnetic field are rendered unequal by quadrupole interactions with the crystalline electric field. This situation arises whenever the nuclei are found on sites having non-cubic symmetry, and is encountered in cubic crystals in which the cubic environment is destroyed by imperfections and in other crystals in which the nuclear environment has less than cubic symmetry. In these crystals the inequality of the level spacings excludes the rapid first-order spin-exchange transitions discussed by Abragam and Proctor (1958), which, when present, serve to maintain a Boltzmann distribution of level populations. In the absence of spin-exchange transitions the spin–lattice relaxation of the nuclei is in general not characterized by a single relaxation time. The approach of the spin system to equilibrium with the lattice can be described by the $2I$ rate equations which determine the differences in population between adjacent levels, and is therefore described in general by $2I$ relaxation times. The relative importance of the different relaxation times depends on the nature of the relaxation process and on the initial conditions.

Among the many initial conditions which might be encountered, there are two cases of particular interest to which we shall give special attention. In the first, which we call case 1, the entire system is initially in thermal equilibrium in zero magnetic field, and then an external field is suddenly applied. The growth of the nuclear magnetic resonance signal is registered as a measure of the approach of the spin system to a new equilibrium with the lattice. In the second situation, which we call case 2, the spin system is initially in equilibrium with the lattice in an external magnetic field, and is then saturated by a strong radio-frequency field. The return of the spin system to equilibrium with the lattice is then measured through the regrowth of the nuclear magnetic resonance signal. We shall find that in general the relaxation behaviour is different in the two cases. This work was in fact stimulated by the observation of Day and Squire (1959) that the relaxation of ^{127}I nuclei in monocrystalline potassium iodide at 4·2°K was exponential for both case 1 and case 2, but that the relaxation time for case 1 was about 2·6 times longer than that for case 2.

In a perfect cubic crystal the electric quadrupole moments of the iodine nuclei cause no perturbation of the six nuclear Zeeman levels, and all five transitions contribute to a single resonance line. However, imperfections in an actual crystal can create a range of electric field gradients which displace the satellite lines over a wide frequency range, leaving only the central line observable. Watkins and Pound (1953) found that even with well annealed potassium iodide crystals of optical quality at room temperature a sufficient degree of imperfection remained to remove all but a few per cent of the satellite intensity from observation. Apart from this small residual contribution of the satellites, only the central line was observed, and this is therefore likely to be the situation generally with potassium iodide crystals, and with potassium bromide also. We may therefore expect that saturation will equalize the population of the two central levels $m = \pm\frac{1}{2}$ only, while modifying the populations of the other four levels; the initial conditions thus produced for case 2 therefore differ from those of case 1 in which initially all six populations are equal. On the other hand, for a hypothetical perfect cubic crystal saturation would equalize the populations of all six levels, and the relaxation behaviour of cases 1 and 2 would then not differ. It should be noted that after removal of the saturating radio-frequency power, a coherent precession of the transverse magnetization persists for a time of order T_2 (about 10^{-3} sec). This free induction decay is thus completed in a very short time compared with the spin–lattice relaxation processes considered here.

In the next section we consider the relaxation behaviour for imperfect crystals, such as potassium iodide in which $I = \frac{5}{2}$ for ^{127}I and potassium bromide in which $I = \frac{3}{2}$ for ^{79}Br and ^{81}Br; in both crystals the spin–lattice relaxation mechanism is quadrupolar. The analysis equally applies to non-cubic crystals exemplified by corundum and sodium nitrate which in a general orientation give a spectrum of five ^{27}Al and three ^{23}Na resolved lines respectively (Pound 1950); it will not apply in special orientations at which lines overlap since the level spacings will then not be unequal. In § 3 we consider the relaxation behaviour for crystals whose effective relaxation mechanism is magnetic.

§ 2. QUADRUPOLAR RELAXATION

2.1. $I = \frac{5}{2}$

For a system of nuclei having spin $\frac{5}{2}$ the nuclear transitions which may be effected by the lattice through interaction with the nuclear quadrupole moments are shown in Fig. 1 (*a*). We assume that the spacing between the levels is sufficiently unequal to suppress spin-exchange transitions. If in an actual imperfect cubic crystal the imperfections are not sufficiently severe to obliterate the satellites completely, there may be some residual spin-exchange which will have the effect of reducing the differences we calculate between cases 1 and 2. We return to this point later. The relaxation behaviour of the central line, corresponding to transitions between $m = \pm\frac{1}{2}$, is calculated for both case 1 and case 2, since in imperfect cubic crystals this is the only resonance line which is observed. For good non-cubic crystals the relaxation behaviour of the satellites also could be examined experimentally and the analysis is easily extended to cover this case.

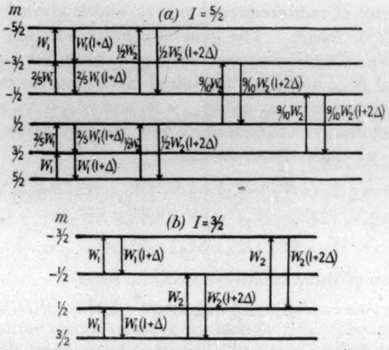

Fig. 1. Transitions effected by the quadrupolar spin–lattice relaxation process: (*a*) $I = \frac{5}{2}$, (*b*) $I = \frac{3}{2}$.

The actual values of the transition probabilities depend on the detailed form of the quadrupolar relaxation mechanism. However, all the upward transition probabilities for $\Delta m = 1$ are simply related to each other and so are those for $\Delta m = 2$ (Pound 1950). Following Yosida and Moriya (1956) the upward transition probabilities may conveniently be written as

$$W_{m\to m-1} = W_1(2m-1)^2(I-m+1)(I+m)/2I(2I-1)^2 \qquad \ldots\ldots(1)$$

$$W_{m\to m-2} = W_2(I+m)(I+m-1)(I-m+1)(I-m+2)/2I(2I-1)^2, \qquad \ldots\ldots(2)$$

leading to the transition probabilities shown in Fig. 1 (*a*) for $I = \frac{5}{2}$; the downward transition probabilities are given by (1) and (2) multiplied by the Boltzmann factors $1+\Delta$ and $1+2\Delta$ respectively, where $\Delta = h\nu_0/kT$ and ν_0 is the unperturbed nuclear resonance frequency. The quantities W_1 and W_2 are a measure of the transition probabilities for $\Delta m = 1$ and $\Delta m = 2$ respectively and are functions of temperature and crystal orientation. Quadrupole relaxation theories of van Kranendonk (1954), Yosida and Moriya (1956), Kondo and Yamashita (1959) and Kochalayev (1959) all lead to the view that W_1 and W_2 are of the same order, and this is consistent with such experimental evidence as there is (Pound 1950, Goldburg 1959, Andrew and Swanson 1960). In most cases of interest the quadrupolar splitting is small compared with the Zeeman splitting. Consequently the Boltzmann factors relating equlibrium populations of adjacent levels are very nearly equal, and this simplifies the following analysis.

If the populations of the levels are N_m, and the difference in population $N_{m+1} - N_m$ between adjacent levels is called $N_{m+\frac{1}{2}}$, we can write down the following differential equations governing their differences:

$$\begin{aligned}
\dot{N}_2 &= -\tfrac{1}{2}N_2(4W_1+W_2) + \tfrac{2}{5}N_1(W_1+W_2) + \tfrac{9}{10}N_0W_2 + \tfrac{4}{5}n_0(2W_1-W_2)\\
\dot{N}_1 &= \tfrac{1}{2}N_2(2W_1-W_2) - \tfrac{1}{5}N_1(4W_1+7W_2) + \tfrac{9}{10}N_{-1}W_2 - \tfrac{1}{5}n_0(W_1-5W_2)\\
\dot{N}_0 &= \tfrac{1}{2}N_2W_2 + \tfrac{2}{5}N_1(W_1-W_2) - \tfrac{9}{5}N_0W_2 + \tfrac{2}{5}N_{-1}(W_1-W_2) + \tfrac{1}{2}N_{-2}W_2\\
&\qquad + \tfrac{4}{5}n_0(2W_2-W_1) \qquad \ldots\ldots(3)
\end{aligned}$$

with two symmetrical equations for N_{-1} and N_{-2}; n_0 is the difference in population between adjacent levels when equilibrium between spin system and lattice is achieved in absence of radiofrequency power, and is given by $N\Delta/6$, where N is the total number of nuclei. The general solution of these five equations is characterized by five relaxation times. However, since the equations are symmetrical in $N_{\pm 1}$ and $N_{\pm 2}$, and since the initial conditions for both cases 1 and 2 are similarly symmetrical, we may put $N_{-1} = N_1$ and $N_{-2} = N_2$, and we have three equations whose solution is characterized now by only three relaxation times. Writing $N_p' = N_p - n_0$, these equations are

$$\begin{aligned}
\dot{N}_2' &= -\tfrac{1}{2}N_2'(4W_1+W_2) + \tfrac{2}{5}N_1'(W_1+W_2) + \tfrac{9}{10}N_0'W_2\\
\dot{N}_1' &= \tfrac{1}{2}N_2'(2W_1-W_2) - \tfrac{1}{10}N_1'(8W_1+5W_2) \qquad \ldots\ldots(4)\\
\dot{N}_0' &= N_2'W_2 + \tfrac{4}{5}N_1'(W_1-W_2) - \tfrac{9}{5}N_0'W_2.
\end{aligned}$$

The general solution of these equations is of the form

$$N_p' = \sum_{q=1,2,3} a_{pq}\exp(-\lambda_q t) \qquad \ldots\ldots(5)$$

where the three relaxation constants λ_q are the eigenvalues of the matrix of coefficients of (4), and are therefore the roots of the cubic

$$\begin{aligned}
100\lambda^3 - 280\lambda^2(W_1+W_2) + 3\lambda(40W_1^2 + 208W_1W_2 + 45W_2^2)\\
-36W_1W_2(4W_1+7W_2) = 0. \qquad \ldots\ldots(6)
\end{aligned}$$

For the particular situation in which $W_1 = W_2$ the cubic factorizes immediately to give three roots $\frac{4}{5}W_1$, $\frac{3}{2}W_1$, $\frac{33}{10}W_1$. In case 1 the initial conditions are all $N_p' = -n_0$, and it turns out that six of the nine coefficients a_{pq} are zero giving

$$N_p/n_0 = 1 - \exp(-\tfrac{4}{5}W_1t). \qquad \ldots\ldots(7)$$

The growth of the observed signal is therefore characterized by a single relaxation time $5/4W_1$. In case 2 the value of N_0' initially is again $-n_0$ if saturation of the centre line is complete, but the initial values of the other N_p' must be calculated. If P is the transition probability for transitions between $m = \pm\frac{1}{2}$ brought about by the saturating radiation, we must add PN_0 to, and subtract $2PN_0$ from, the equations for $\dot{N}_1'$ and $\dot{N}_0'$ in (4) respectively. When dynamic equilibrium is achieved under the influence of the saturating radiation, all $N_p' = 0$ and we solve (4) to find that for $P \gg W_1$ we have $N_0' = -n_0$, $N_1' = 27n_0/49$, $N_2' = -9n_0/49$. Using these values as initial conditions for case 2 we find that the growth of the central line, which is proportional to N_0, is given by

$$N_0/n_0 = 1 - 0{\cdot}06\exp(-\tfrac{4}{5}W_1t) - 0{\cdot}85\exp(-\tfrac{3}{2}W_1t) - 0{\cdot}09\exp(-\tfrac{33}{10}W_1t). \qquad \ldots\ldots(8)$$

Thus three relaxation times $5/4W_1$, $2/3W_1$ and $10/33W_1$ describe the return to equilibrium, though the much larger coefficient of the second exponential term gives the growth a rather closely exponential behaviour with relaxation time $2/3W_1$. The return to equilibrium for both cases, given by (7) and (8), is illustrated in Fig. 2. The more rapid growth in case 2 has qualitative similarities to the results of Day and Squire.

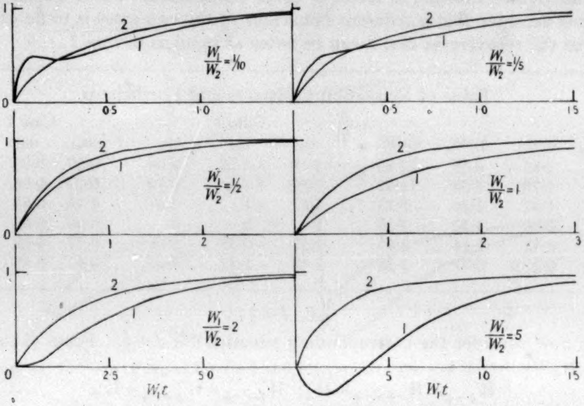

Fig. 2. Growth of N_0/n_0, to which the nuclear magnetic resonance signal is proportional, for $I=\frac{5}{2}$ and for various values of the ratio W_1/W_2. The curves labelled 1 apply when the main field is suddenly applied; the curves labelled 2 apply after saturation of the observed central line.

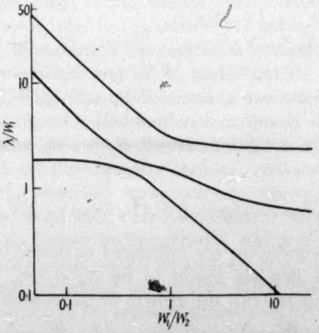

Fig. 3. The three roots λ of the cubic equation (6) as a function of W_1/W_2. The three values of $1/\lambda$ give the three relaxation times for $I=\frac{5}{2}$ with symmetrical initial conditions.

The roots of the cubic (6) have been evaluated for a range of values of the ratio W_1/W_2, and are shown in Fig. 3. The coefficients a_{pq} in (5) have been found in both cases for a range of W_1/W_2 from 0·1 to 5, and the relevant values are tabulated below. Except for case 1 with $W_1=W_2$, all the situations considered yield finite contributions from three exponential terms. The growth of N_0 is plotted in Fig. 2 for various ratios W_1/W_2. It is seen that for $W_2 < W_1$ the return to equilibrium for case 2 continues to be at least twice as fast as for case 1, whereas for $W_2 = 2W_1$ the behaviour in the two cases is less different. It would perhaps be premature without more experimental data to attempt a detailed interpretation of Day and Squire's results in terms of these calculations. Nevertheless the calculations do show that a different behaviour in the two cases is to be expected, and that the recovery in case 2 can be twice as rapid as in case 1.

Table of Relaxation Constants and Coefficients

				Case 1			Case 2		
W_1/W_2	λ_1/W_1	λ_2/W_1	λ_3/W_1	a_{01}	a_{02}	a_{03}	a_{01}	a_{02}	a_{03}
0·1	1·83	6·48	22·53	1·18	−1·07	0·89	0·87	0·02	0·11
0·2	1·78	3·38	11·62	1·50	−1·24	0·74	0·77	0·06	0·17
0·5	1·37	1·80	5·23	1·63	−1	0·37	0·14	0·67	0·19
1	0·80	1·50	3·30	1	0	0	0·06	0·85	0·09
2	0·45	1·14	2·63	1·57	−0·51	−0·06	0·77	0·18	0·05
5	0·21	0·77	2·38	2·37	−1·42	0·05	0·45	0·55	0·001

2.2. $I = \frac{3}{2}$

We now consider the corresponding situation for $I = \frac{3}{2}$. From (1) and (2) we have

$$W_{\frac{3}{2}\to\frac{1}{2}} = W_{-\frac{1}{2}\to-\frac{3}{2}} = W_1;\ W_{\frac{3}{2}\to-\frac{1}{2}} = W_{\frac{1}{2}\to-\frac{3}{2}} = W_2. \qquad \ldots\ldots(9)$$

Transitions brought about by the quadrupolar relaxation processes are shown in Fig. 1 (*b*). The equations corresponding to (4) are in this case

$$\dot{N}_1' = -2N_1'W_1;\ \dot{N}_0' = 2N_1'(W_1 - W_2) - 2N_0'W_2. \qquad \ldots\ldots(10)$$

The general solutions are

$$\begin{aligned} N_1' &= N_{1a}' \exp(-2W_1 t) \\ N_0' &= (N_{0a}' + N_{1a}') \exp(-2W_2 t) - N_{1a}' \exp(-2W_1 t), \end{aligned} \qquad \ldots\ldots(11)$$

where N_{0a}' and N_{1a}' are the values of N_0' and N_1' at time $t=0$. We note that the two relaxation times are always $1/2W_1$ and $1/2W_2$†; in particular, when $W_1 = W_2$, relaxation is simply exponential with a single relaxation time.

In case 1 the initial conditions are all $N_p' = -n_0$, and we find the growth of the central line is given by

$$\frac{N_0}{n_0} = 1 + \exp(-2W_1 t) - 2\exp(-2W_2 t). \qquad \ldots\ldots(12)$$

In case 2 the initial conditions are calculated as before, and for complete saturation of the central line are found to be $N_0' = -n_0$, $N_1' = n_0 W_2/(W_1 + W_2)$. Using these conditions in (10), the growth of the central line is given by

$$\frac{N_0}{n_0} = 1 - \left(\frac{W_2}{W_1 + W_2}\right)\exp(-2W_1 t) - \left(\frac{W_1}{W_1 + W_2}\right)\exp(-2W_2 t). \qquad \ldots\ldots(13)$$

The two equations (12) and (13) yield the same result only when $W_1 = W_2$. The form of recovery for both cases for several values of the ratio W_1/W_2 is shown in Fig. 4.

---

† In the general situation in which the initial conditions are not symmetrical in $N_{\pm 1}$, we have three equations instead of the two equations (10), and one readily finds that there are then three relaxation times $1/2W_1$, $1/2W_2$ and $1/2(W_1 + W_2)$.

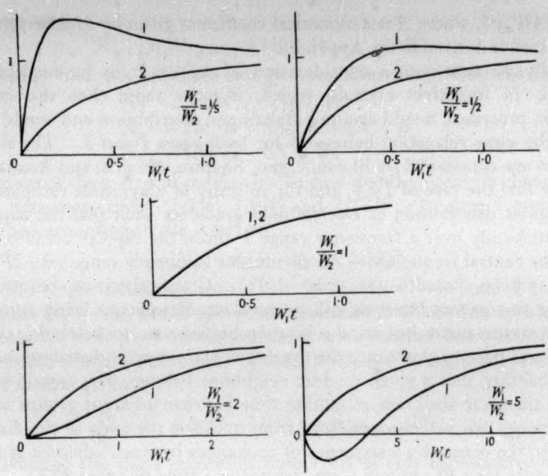

Fig. 4. Growth of N_0/n_0 for $I=\frac{3}{2}$ and for various values of the ratio W_1/W_2.

2.3. *Some General Considerations*

Other values of I may occasionally be of interest, and the calculations may be extended to cover them. The relaxation behaviour is in general described by $2I$ equations similar to (3) and the roots of the matrix of coefficients give the $2I$ relaxation times. If the initial conditions are symmetrical in $N_{\pm p}$ the number of independent equations similar to (4) and (10) is reduced to $I+\frac{1}{2}$ if $2I$ is odd and to I if $2I$ is even. The roots of the matrix of coefficients give the $I+\frac{1}{2}$ or I relaxation times, which are functions of W_1 and W_2.

Hon and Bray (1959) have found evidence in sodium iodide and to a lesser extent in potassium iodide of a preferred orientation of dislocations along the cubic axes of the crystal. As a consequence, when the applied field is directed along a cubic axis much satellite intensity coalesces at the centre, with the result that the intensity of the observed resonance line markedly increases at these particular orientations. With such a crystal in these particular orientations rapid spin-exchange would no longer be suppressed, and a Boltzmann distribution among the equally spaced levels would be attained in a time of order $T_2(\ll T_1)$. The relaxation behaviour in case 2 would then differ less from that of case 1, depending on the proportion of the satellite intensity which comes into the centre. If the whole satellite intensity coalesces at the centre within the dipolar breadth case 2 will no longer differ from case 1 and both will be described by a single exponential recovery. The same situation is found for a non-cubic crystal in particular orientations which make the first-order quadrupole splitting zero. If the second-order splittings are less than the dipolar breadth then here also cases 1 and 2 will be described by the same single exponential recovery. The relaxation behaviour of some crystals may therefore differ in certain special orientations. The single relaxation time which describes the quadrupolar relaxation process whenever a Boltzmann distribution is maintained by spin-exchange is given by

$A(W_1+4W_2)^{-1}$, where A is a numerical coefficient given by $5I(2I-1)/(2I+3)$, a result which is derived in the Appendix.

Finally we return to a consideration of the criterion for neglecting spin-exchange in imperfect crystals, which, if more rapid than the spin–lattice relaxation processes, would ensure a Boltzmann distribution and would therefore lead to the same relaxation behaviour for both cases 1 and 2. The situation is similar to one considered by Bloembergen, Shapiro, Pershan and Artman (1959). Consider first the case of $I=\frac{3}{2}$, and for an order of magnitude estimate suppose a rectangular distribution of electric field gradients such that the satellites are spread uniformly over a frequency range P times the dipolar breadth on either side of the central frequency. We divide this frequency range into $2P$ intervals each of dipolar breadth (of order $1/T_2$). Cross-relaxation between nuclei belonging to adjacent intervals will proceed rapidly, energy being conserved by dipolar rearrangement, but cross-relaxation between nuclei belonging to remoter intervals will be very slow since the overlap of their dipolar distributions is weak. The probability that a given nuclear neighbour belongs to a certain interval is P^{-1}, and therefore the cross-relaxation time between adjacent groups is of order PT_2. Energy can be communicated from nuclei at the ends of the distribution to those in the centre by a sequence of exchanges between adjacent groups, and will therefore take P^2 random steps, requiring a time of order P^3T_2. The time taken for exchange of energy between the central satellite interval and the centre line will be much faster, so that P^3T_2 is an estimate of the time taken for equilibrium to be obtained over the four levels. Since the distribution of electric field gradients is not rectangular, but has wide skirts, this estimate is likely to be too low. For $I=\frac{5}{2}$ a similar argument applies to both inner and outer satellites, though the distribution for the outer satellites is twice as wide. If therefore P^3T_2 exceeds the spin–lattice relaxation times, we are justified in neglecting spin-exchange processes. Since Day and Squire (1959) find a different relaxation behaviour for cases 1 and 2 for potassium iodide at 4·2°K, it seems that P^3T_2 must be at least comparable with the relaxation time, which requires P to be at least 100. This is slightly larger than the value one deduces from the work of Solomon (1958) for a single crystal of potassium iodide at liquid nitrogen temperature, and may suggest that we are not justified in entirely neglecting the spin-exchange processes in this crystal at 4·2°K†.

§ 3. Magnetic Relaxation

In this section we consider the relaxation behaviour of a crystal in which the spin–lattice relaxation mechanism is predominantly magnetic. This could arise if there were a high density of paramagnetic relaxation centres, or if the nuclear quadrupole moment were small, so that the quadrupole relaxation mechanism could not compete with the magnetic mechanism, and yet could be accompanied by sufficiently large electric field gradients to disperse the satellites.

Magnetic relaxation by the lattice can only cause transitions between adjacent nuclear levels. The transition probabilities may be written

$$W_{m\to m-1}=W(I+m)(I-m+1). \qquad \ldots\ldots(14)$$

---

† *Note added in proof.*—Professor Day kindly informs us that the crystal used by Day and Squire (1959) was significantly strained by quick cooling as evidenced by an asymmetrical resonance line shape. It is therefore likely that P exceeds 100 for this crystal at 4·2°K.

For $I=\frac{3}{2}$ we have

$$W_{\frac{3}{2}\to\frac{1}{2}}=W_{-\frac{1}{2}\to-\frac{3}{2}}=3W;\ W_{\frac{1}{2}\to-\frac{1}{2}}=4W, \qquad \ldots\ldots(15)$$

and we readily find that the three energy-level differences follow the equations

$$\begin{aligned} \dot{N}_1' &= -6WN_1'+4N_0'W \\ \dot{N}_0' &= 3N_1'W-8N_0'W+3N_{-1}'W \\ \dot{N}_{-1}' &= 4N_0'W-6N_{-1}'W. \end{aligned} \qquad \ldots\ldots(16)$$

From the roots of the matrix of coefficients we find that the system is characterized by three relaxation times $1/2W$, $1/6W$ and $1/12W$. In case 1 equilibrium is approached according to the equation

$$N_0=N_{\pm1}=n_0[1-\exp(-2Wt)] \qquad \ldots\ldots(17)$$

in which the single relaxation time $1/2W$ is operative. In case 2 the initial conditions are $N_0'=-n_0$ and $N_{\pm1}'=0$, since saturation of one line does not affect the difference in level populations associated with another line when magnetic relaxation is the effective mechanism (Pound 1950). The regrowth of the centre line is in this case given by

$$\frac{N_0}{n_0}=1-\tfrac{2}{5}\exp(-2Wt)-\tfrac{3}{5}\exp(-12Wt). \qquad \ldots\ldots(18)$$

A term involving the third relaxation time $1/6W$ is only encountered when N_1 and N_{-1} are initially unequal.

For $I=\frac{5}{2}$ we find a set of five equations similar to (16), the matrix of whose coefficients readily factorizes to give the five relaxation times describing the system. They are $1/2W$, $1/6W$, $1/12W$, $1/20W$, $1/30W$. In case 1 the growth of each of the five lines is described by the single relaxation time $1/2W$, a result which we expect generally (Andrew and Swanson 1960). In case 2 the first, third and fifth members of the series of relaxation times contribute to the relaxation process, the recovery being given by

$$\frac{N_0}{n_0}=1-\tfrac{9}{35}\exp(-2Wt)-\tfrac{4}{15}\exp(-12Wt)-\tfrac{10}{21}\exp(-30Wt). \qquad \ldots\ldots(19)$$

With asymmetrical initial conditions all five relaxation times enter.

It will be noticed that for the two values of I considered, namely $\frac{3}{2}$ and $\frac{5}{2}$, the $2I$ relaxation times which describe the relaxation behaviour in the general case are given by the first $2I$ members of the series $[p(p+1)W]^{-1}$, where p is an integer. We can show that this is generally true for all values of I. For general I there are $2I$ equations similar to (16) which describe the relaxation behaviour; the square matrix of their coefficients, of order $2I$, is

$$\begin{bmatrix} -4I & 2(2I-1) & 0 & 0 & — & & \\ 2I & -4(2I-1) & 3(2I-2) & 0 & — & & \\ 0 & 2(2I-1) & -6(2I-2) & 4(2I-3) & — & & \\ 0 & 0 & 3(2I-2) & -8(2I-3) & — & & \\ 0 & 0 & 0 & 4(2I-3) & — & & \\ 0 & 0 & 0 & 0 & — & 0 & 0 \\ & & & & — & 2(2I-1) & 0 \\ & & & & — & -4(2I-1) & 2I \\ & & & & — & 2(2I-1) & -4I \end{bmatrix}. \qquad \ldots\ldots(20)$$

The general diagonal element is $-2(I+m)(I-m+1)$, the elements immediately above and below are $(I+m)(I-m+1)$, and all other terms are zero. The eigenvalues of this matrix are in fact the $2I$ members of the series $p(p+1)$, where p is an integer running from unity to $2I$†, thus showing that the $2I$ relaxation times are given by $[p(p+1)W]^{-1}$.

APPENDIX

Spin–Lattice Relaxation Time for Quadrupole Relaxation in Presence of Rapid Spin Exchange

For nuclei in a cubic environment the $2I$ spacings between adjacent energy levels are all equal and rapid spin-exchanges maintain a Boltzmann distribution of population. The spacings may also be almost equal for certain orientations of crystals containing nuclei in a non-cubic environment, and if the residual inequality is less than the dipolar breadth, a Boltzmann distribution is maintained in these cases also. For $I=\frac{3}{2}$ the spin–lattice relaxation time for a quadrupolar relaxation mechanism has been calculated earlier (Andrew, Swanson and Williams 1961) and the calculation for general I, given here, follows the same lines.

Let $N_{m+\frac{1}{2}}$ be the difference in population $N_{m+1}-N_m$. If a Boltzmann distribution is maintained all $N_{m+\frac{1}{2}}$ are equal, and the time-dependence of each is identical. It therefore suffices to find the time-dependence of the total nuclear magnetization M. The total magnetic moment of the system is proportional to

$$\begin{aligned}\sum_{-I}^{I} N_m m &= \sum_{-I}^{I} \tfrac{1}{2}(I+m+1)(I-m)N_{m+\frac{1}{2}}\\ &= \tfrac{1}{3}I(I+1)(2I+1)N_0, \qquad \ldots\ldots(21)\end{aligned}$$

if all $N_{m+\frac{1}{2}}=N_0$.

The rate of change of this quantity is

$$\sum_{-I}^{I} \dot{N}_m m = \sum_{-I}^{I} \tfrac{1}{2}(I+m+1)(I-m)\dot{N}_{m+\frac{1}{2}}. \qquad \ldots\ldots(22)$$

Taking into account all the transitions that can be effected by quadrupolar relaxation, we have in the general case

$$\begin{aligned}\dot{N}_{m+\frac{1}{2}} = {} & N_{m-\frac{3}{2}}W_{m\to m-2} + N_{m-\frac{1}{2}}(W_{m\to m-1} + W_{m\to m-2} - W_{m+1\to m-1})\\ & - N_{m+\frac{1}{2}}(2W_{m+1\to m} + W_{m+2\to m} + W_{m+1\to m-1})\\ & + N_{m+\frac{3}{2}}(W_{m+2\to m+1} + W_{m+3\to m+1} - W_{m+2\to m})\\ & + N_{m+\frac{5}{2}}W_{m+3\to m+1}\\ & - n_0(W_{m\to m-1} - 2W_{m+1\to m} + W_{m+2\to m+1} + 2W_{m\to m-2}\\ & \qquad - 2W_{m+1\to m-1} - 2W_{m+2\to m} + 2W_{m+3\to m+1})\\ & + \text{spin exchange terms.} \qquad \ldots\ldots(23)\end{aligned}$$

After a time of order T_2, which is generally much less than T_1, a Boltzmann distribution is attained through the agency of the spin-exchange terms, and these terms are thereafter very small and can be omitted. Putting all $N_{m+\frac{1}{2}}=N_0$ we then have

---

† We are glad to acknowledge assistance from Professor D. E. Littlewood in confirming this point.

$$\begin{aligned}\dot{N}_{m+\frac{1}{2}} &= (N_0-n_0)(W_{m\to m-1}-2W_{m+1\to m}+W_{m+2\to m+1}+2W_{m\to m-2} \\ &\qquad -2W_{m+1\to m-1}-2W_{m+2\to m}+2W_{m+3\to m+1}) \quad \ldots\ldots(24) \\ &= (N_0-n_0)[W_1(8I^2+8I-48m^2-48m-18) \\ &\qquad -2W_2(8I^2+8I-24m^2-24m-12)]/2I(2I-1)^2, \quad \ldots\ldots(25)\end{aligned}$$

using (1) and (2). Substituting (25) in (22) and carrying out the summations we get after reduction

$$\sum \dot{N}_m m = -\frac{(N_0-n_0)(I+1)(2I+1)(2I+3)(W_1+4W_2)}{15(2I-1)}. \quad \ldots\ldots(26)$$

Combining (21) and (26) we find that the nuclear magnetization follows the equation

$$\dot{M} = -\frac{(M-M_0)(W_1+4W_2)(2I+3)}{5I(2I-1)}, \quad \ldots\ldots(27)$$

from which we deduce that the spin–lattice relaxation time is given by

$$\frac{1}{T_1} = \frac{(2I+3)}{5I(2I-1)}(W_1+4W_2). \quad \ldots\ldots(28)$$

Micro-disk Patterns on Diamond Dodecahedra

By D. C. PANDEYA and S. TOLANSKY
Department of Physics, Royal Holloway College, University of London

MS. received 25th November 1960

Abstract. An account is given of microscopic and interferometric studies on slightly raised disk formations which appear on the dodecahedral faces of several diamonds. One small diamond exhibits more than a thousand such disks on its faces. Interferometry shows that the disks are slight elevations. It is conjectured that they owe their origin to a protective action of small bubbles. Evidence is given that the crystals showing the disks have been subjected to a solution or etch mechanism in the final stages of the crystal formation. The suggested micro-bubbles adhering to the surface would locally prevent dissolution, leaving ultimately slightly raised disks on the surface. By postulating the possibility of slight movement or oscillation of the conjectured bubbles, most of the observed complex topographical features of the disks can be accounted for.

§ 1. INTRODUCTION

RECENTLY the announcement of the finding of circular disk patterns on diamond dodecahedral faces has been made, apparently independently, by several workers. The first description of these that we can find are two pencil drawings of dodecahedra faces made by J. R. Sutton (1928, Figs 38 and 40). Here Sutton sketchily describes circular ring patterns, which are undoubtedly of the kind described here. A report of some further details of such features was made by J. F. H. Custers to a conference on diamond physics held at Oxford, 1957. In 1958 at a diamond physics conference in Cambridge, S. Tolansky and D. C. Pandeya gave a detailed description of some hundreds of these features and more information is given by Pandeya (1959).

Recently a translation has been made available of a report (in Russian) published by Kvohov (1959), who mentions the earlier work of Sutton but not unnaturally is unaware of the later work mentioned above, which has in fact been given very little circulation. Kvohov describes the features on twelve U.S.S.R. diamonds. He also states that Kucharenko (1950) in a monograph on Ural diamonds discussed such features, attributing their origin to corrosion processes. It will later be shown that we are in complete agreement with this view, arriving at this same conclusion from interferometric studies of the microtopography of the disk features. Kucharenko's report, which is not available to us, refers to diamonds from the Urals, and it appears that 3–4% of this material exhibits the disk patterns. They occur exclusively on dodecahedroid faces which usually also exhibit elsewhere signs of corrosion.

§ 2. OBSERVATIONS

Although we have found these circular patterns on relatively few of the dodecahedra we have studied, the striking feature we emphasize is their profuse and liberal distribution on many of the faces of the crystals which do exhibit them. Some faces have over one hundred such disks on them, and one diamond shows more than a thousand such features.

Crystal A. A transparent dodecahedron of weight 0·8 carat established by its ultra-violet transmission as Type I is first considered. Figs 1 and 2 (Plate I) show regions on one face, illustrating the circular patterns. They also show clear evidence of the familiar etch of a dodecahedron face. Circles are of three types (*a*) simple, (*b*) multiple, touching internally, (*c*) incomplete arcs.

Figure 2 shows part of the circles and a close network which we have previously established as a characteristic of etching on dodecahedral faces.

To establish the microtopography of these circles an interferogram (Fig. 4) was taken of the group shown in Fig. 3 (Plate I). This establishes that the circular pattern is a raised disk of edge height of some half a light wave (we confirmed this with fringes of equal chromatic order in order to remove ambiguity in direction. The disk is not flat but slightly sunken at the centre.

Where disks overlap, the edges are stepped. The interferograms show that disk heights range from some 700 to 6000 Å. The small boat shapes are hillocks, of height between 1800 and 2800 Å.

The independent nature of the intersecting circles is shown by the interferogram Fig. 5 (Plate II) for a pair of crossing disks.

A variant of the disks is shown in Fig. 6 (Plate II) which shows but a few arc lines, clearly part of the disk system of radius of curvature bigger than the crystal face itself. This type of pattern has an important bearing on interpretation. We have succeeded in securing a high magnification interferogram (×1500) of good interferometric definition over part of this system and this is shown in Fig. 7 (Plate II) to a slightly smaller magnification (×900). The region is that outlined by a rectangle in Fig. 6. These fringes show that the boundary of the ring pattern is not quite sharp but is quite definitely curved.

The following has been noted concerning the density distribution of the disks on the twelve faces of the crystal.

Faces	Index of the face	Number of circles
1	(110)	182
2	$(1\bar{1}0)$	175
3	$(\bar{1}10)$	106
4	$(\bar{1}\bar{1}0)$	145
5	(101)	130
6	$(10\bar{1})$	13
7	$(\bar{1}01)$	117
8	$(\bar{1}0\bar{1})$	58
9	(011)	107
10	$(01\bar{1})$	130
11	$(0\bar{1}1)$	106
12	$(0\bar{1}\bar{1})$	80
	Total	1349

The total reaches the astonishing number of 1349 for the one crystal. What is significant is that one face $(10\bar{1})$ is largely free of disks compared with its opposite face, which is richly covered.

Crystal B. A Type II good quality rounded dodecahedron of weight some 0·4 carat. Each face exhibits striking linear networks of the kind which Emara and Tolansky (1957) have formerly established as being etch, or solution, ruts. Each face is divided clearly by a shorter diagonal and on each the disks are concentrated at the ends of this shorter diagonal.

Figure 8 (Plate II) shows how the network and disk patterns are quite independent and it is conjectured that they have been formed separately, at different times. It will be suggested later that the network pattern appears after the circles. The disk heights in Fig. 8 are a mere 600 Å but the ruts are a good deal less in depth than this, being quite shallow indeed. In the interferogram, Fig. 9 (Plate II) for the region shown in Fig. 8 the disks can clearly be identified, and in the high dispersion region at the top of the picture the very shallow depths of the rut marks are revealed. They are clearly visible in Fig. 8 only because a good phase-contrast microscope is being used.

On this crystal the disks range in number from 50 to 75 on the different faces and disk diameters vary from 0·03 to 0·4 mm.

Crystal C. We were fortunate in being able to study a very large Type I diamond of weight 19 carat. This diamond was about one inch long, as shown in Fig. 10 (Plate II) where it is matched against part of a foot rule. Despite the irregular shape, some faces are of clear dodecahedroid character. On these appear hundreds of disk patterns. Many are circular, more are elliptical, some are quite irregular. Typical areas showing an amazing variety are Fig. 11 (Plate III) and, especially noteworthy, Fig. 12 (Plate III).

No clear evidence exists for etch networks on this diamond, yet it is quite evident that these patterns are related to those already described. Mixed up with the disks are occasional incomplete features as in Fig. 13 (Plate III).

So irregular is this diamond that the securing of multiple-beam interferograms was formidably difficult. Yet comparison between Fig. 14 and its interferogram Fig. 15 (Plate III) gives clear evidence that there are also here slightly raised disks, plateaux which are slightly sunken in the centre.

§ 3. INTERPRETATION

All the features are elevated disks of height ranging from 200 to 3000 Å, but when several disks pile together the height may reach 6000 Å. That they are not pressure crack figures is certain, for several reasons. To begin with, we have adequately demonstrated in this laboratory (Tolansky 1955) that pressure crack figures on dodecahedron faces appear as strictly oriented hexagons and never as circles. Secondly, the interferometric profile of a percussion mark differs completely from that of the disks.

It might be considered whether explosion from within the crystal could lead to the observed patterns. Such an interpretation might account for (*a*) the raised disks, (*b*) the multiplicity of rings and (*c*) intersections with slight displacements at intersections. Yet such a conjecture can be rejected entirely, for by polishing off the face of one crystal to a depth of 1 μ all trace of the disks was removed. This established that the microstructure is a highly localized surface effect and excludes both percussion from outside and explosion from within as possible explanations.

Four main features require to be accounted for, namely:

(i) The circular character,
(ii) The frequent appearance of a succession of circles, usually of diminishing radius, closely anchored to one region,
(iii) The appearance of curvatures with radii which are clearly larger than the size of the crystal face,
(iv) The association of etch networks with the disks.

The following simple theory accounts for the observed facts. It is considered that towards the end history of the formation of these diamonds conditions have changed so as to favour dissolution at the surface, i.e. etching sets in. Proof of this is supplied by the etch networks. However, it is now postulated that clinging to the diamond in these final stages were numerous micro-bubbles. These might have been either gaseous or liquid. The viscosity of the surrounding molten magma region may well have enabled such bubbles to remain *in situ* for quite an appreciable time. Now such a bubble would protect the diamond surface from any etching. If, then, etching proceeded the circular region in contact with the bubble would ultimately stand up proud, as a small elevated disk, whilst the rest of the unprotected surface would slowly dissolve away. Such a mechanism produces precisely the observed shape, with lack of sharpness at the boundary.

Other features are also simply explained by this hypothesis. A bubble could move slightly to a nearby position. This would account for disk overlapping disk.

Then again a bubble could oscillate to different positions close by, and thus a multiple pattern, closely tied together, results.

The appearance of a family of diminishing disks all anchored to one point can be explained in two ways: (i) one can envisage a reduction in bubble size in spasmodic steps whilst the etching action runs continuously or, alternatively, (ii) one can envisage a continual reduction in bubble size, with the etching action taking place discontinuously. Either mechanism would fully account for such specific multiple patterns.

The appearance of curvatures of radius exceeding that of the crystal face can be simply explained by the conjecture of contact with a large bubble of diameter larger than the crystal face itself.

Strongly supporting this theory of bubbles is the fact that the Table indicates that disk concentrations are respectively large and small on one pair of opposite faces. This is what one would expect for the pair of faces accidentally lying horizontally for, if the bubbles are lighter than the magma, the high concentration will be on the lower lying face and the low concentration on the upper, but if we are involved in liquid bubbles of material heavier than the magma the situation reverses. In both cases the concentration of disks should be high on one face and low on the opposing face.

It also seems quite clear that the familiar etch network where it appears has been created *after* the disks were formed, since they overlie the disks and are a good deal shallower than any disk height. Thus after the major solution mechanism producing the disks, some time later, on some faces, the less active network etching mechanism takes place.

The reason why these disks appear only on dodecahedral faces remains to be considered. We have already experimentally established (Pandya and Tolansky 1954) that diamonds etch more easily and more rapidly on dodecahedral than on octahedral faces, yet quite a fierce etch can and does take place on octahedral faces. However, quite significant is the fact that on natural diamonds, whereas a considerable proportion of dodecahedral faces show etch markings, such etch markings are very rare on octahedra. This would all suggest that the temperature, pressure and concentration conditions which favour octahedral growth are usually such as to exclude etch on octahedra. Even if bubbles attach themselves to octahedral faces, there is not likely to be a subsequent solution process to lead to disks. Of course it is also possible that the temperature and pressure conditions needed for octahedra (presumably higher than for dodecahedra) may not encourage bubble formation.

ACKNOWLEDGMENTS

We should like to thank Professors F. C. Frank and M. H. L. Pryce, both of the University of Bristol, for helpful suggestions during discussion.

Magnetic Anisotropy and Rotational Hysteresis in Single Crystals of Magnetite below the Transition Temperature

By R. F. PEARSON and R. COOPER

Mullard Research Laboratories, Salfords, Redhill, Surrey

MS. received 23*rd November* 1960, *in revised form* 15*th December* 1960

Abstract. Torque curves have been measured at 82°K on gallium- and aluminium-substituted single crystals of magnetite. The paper consists of two parts, one dealing with the values of the constants required to describe the intrinsic anisotropy of Fe_3O_4 below the crystallographic transition and the other concerned with the irreversible nature of the torque curves observed on some of the gallium-substituted crystals. A model based on the ordering of Fe^{2+} and Fe^{3+} ions is proposed to explain this rotational hysteresis which occurs in higher fields than would be necessary for magnetic saturation.

---

§ 1. INTRODUCTION

In order to study the origin of the magnetocrystalline anisotropy in magnetite (Fe_3O_4) a systematic investigation is being made of the anisotropy constants of single crystals of magnetite containing substitutions of gallium or aluminium. Experimental values of K, the first-order anisotropy constant, deduced from torque measurements over the temperature range 120°K to 400°K, have been reported recently by Pearson (1959).

As a first stage to extending the measurements down to lower temperatures, torque curves of these samples were recorded at about 80°K (the boiling point of liquid air). It was then seen that some of the crystals showed rotational hysteresis (i.e. irreversible torque curves) in high fields, about 12000 oersteds, when one would normally have assumed the crystal to have reached magnetic saturation. Examination of the literature showed that similar effects had been observed in a natural magnetite crystal by Briukhatov (1957). The latter's explanation for this phenomenon was somewhat vague and difficult to understand though this may have been due to deficiencies in the translation of the original Russian article.

In the present paper a detailed account is given of the rotational hysteresis effects found in the series of substituted magnetite crystals, and a possible explanation of these effects in terms of electron ordering processes is put forward. It has been noticed since that Narovskyar (1958) gives a similar independent explanation, and reports further experiments on the variation of rotational hysteresis with temperature in natural single crystals of magnetite.

§ 2. EXPERIMENTAL DETAILS

Torque curves were measured on single crystal samples (shaped in the form of spheres 1·5 mm in diameter), using the recording torque magnetometer which is more fully described in a previous paper (Pearson 1959). The samples were mounted using x-ray methods, such that torque curves were recorded in a (100) crystallographic plane. All the measurements were taken at 82°K; this temperature was produced by totally immersing the specimens in liquid air.

§ 3. EXPERIMENTAL RESULTS

Torque curves were recorded at 82°K on single crystals of substituted magnetite, the chemical compositions of which (analysed for Ga, Fe and oxygen unbalance) are shown in Table 1. The probable ionic distribution was determined from magnetic moment measurements made by Dr. F. W. Harrison.

Table 1

	Chemical analysis of crystals Atomic percentage of metal ions			Probable ionic distribution A site		B site		
Sample	Ga^{3+}	Fe^{2+}	Fe^{3+}	Ga^{3+}	Fe^{3+}	Ga^{3+}	Fe^{2+}	Fe^{3+}
M		0·97	2·02		1·0		0·97	1·02
MGa1	0·08	0·96	1·95	0·05	0·95	0·03	0·96	1·00
MGa2	0·14	0·94	1·90	0·11	0·89	0·03	0·94	1·01
MGa3	0·27	0·93	1·77	0·21	0·79	0·06	0·94	0·98
MGa4	0·36	0·92	1·70	0·27	0·73	0·09	0·92	0·97
	Al^{3+}			Al^{3+}				
MA11	0·11	0·95	1·81	0·03	0·97	0·08	0·95	0·96

The effect on the torque curves when the sample is cooled down in the presence of a strong magnetic field (12 000 oersteds) directed along different directions in the (100) plane was also investigated, the results for the magnetite crystal are shown in Figs 1 and 2. The sample is said to show rotational hysteresis when the torque curve is irreversible, i.e. the curves taken in a forward and reverse direction of rotation of the magnetization do not coincide. This behaviour is shown by many of the samples at 82°K as shown by the torque curves for MGa1, MGa2, MGa3, MGa4 in Figs 3, 4, 5, 6.

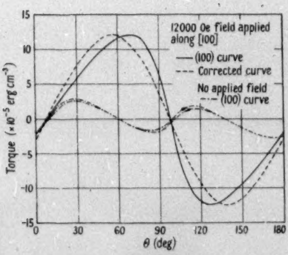

Fig. 1

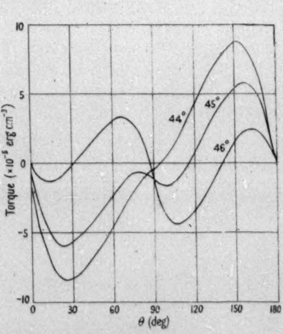

Fig. 2

Fig. 1. Experimental torque curves for magnetite cooled to 82°K.

Fig. 2. Experimental (100) torque curves for magnetite cooled to 82°K in a 12 000 Oe magnetic field at 44°, 45°, 46° to the [100] direction.

The crystals with low gallium content, MGa1 and MGa2, show similar behaviour to magnetite; the torque curve approximates to a $\sin 2\theta$ curve when cooled in the presence of a field whereas cooling in the absence of a field results mainly in a $\sin 4\theta$ component with a much smaller amplitude. Samples MGa3 and MGa4 are unaffected by cooling in a field to 80°K.

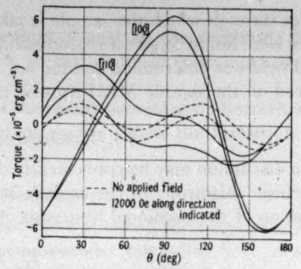

Fig. 4

Fig. 3. Experimental (100) torque curves for gallium 1 at 82°K.

Fig. 4. Experimental (100) torque curves in forward and reverse directions of rotation for gallium 2 cooled to 82°K.

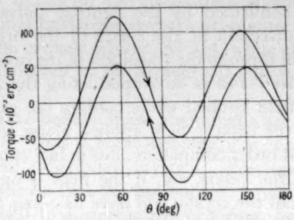

Fig. 5

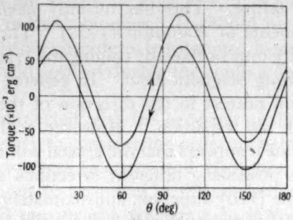

Fig. 6

Fig. 5. Experimental (100) torque curve for gallium 3 cooled to 82°K in absence of magnetic field, showing large rotational hysteresis.

Fig. 6. Experimental (100) torque curve for gallium 4 cooled to 82°K in absence of magnetic field, showing rotational hysteresis.

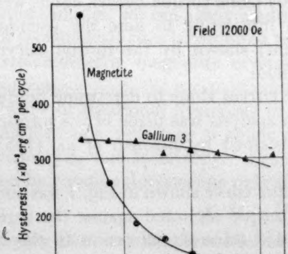

Fig. 7

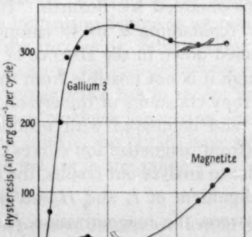

Fig. 8

Fig. 7. Rotational hysteresis at 82°K plotted against the number of torque curve cycles.

Fig. 8. Hysteresis loss at 82°K plotted against applied field.

It was found that after cooling the samples down to 82°K, the hysteresis loss depended on the number of torque curves measured on the samples and this is illustrated in Fig. 7 where the rotational hysteresis is plotted against the number of cycles through which the sample is taken for samples M1, MGa3. When the samples were found to give a reproducible torque curve, the variation of loss with applied field was determined and the results plotted in Fig. 8. The torque curve measured on the sample MAl1 showed no rotational hysteresis at 82°K.

§ 4. DISCUSSION OF RESULTS

The discussion may be conveniently divided into two parts; one dealing with the intrinsic anisotropy of the crystals at 82°K and the other part devoted to an explanation of the rotational hysteresis effects present in some of the samples.

4.1. *Anisotropy of Fe_3O_4 at* 82°K

Previous workers (Bickford 1953) have investigated the properties of magnetite below the transition point (119°K) and it seems fairly certain that the crystallographic transformation of the structure from cubic to orthorhombic at this temperature is due to the ordering of Fe^{2+} and Fe^{3+} on the octahedral sites of the lattice. This has recently been confirmed by the neutron diffraction experiments of Hamilton (1958). The direction of the *c*-axis of the ordered structure may be fixed by cooling the crystal through the transition in the presence of a strong magnetic field. In general, the *c*-axis is developed along the [100] direction nearest to the direction of the field applied while cooling the sample through the transition. However, with the cooling field applied along certain directions it appears that the crystal will not order completely, but in fact contains regions possessing different directions of the *c*-axis, e.g. if the field is applied along the [110] direction, approximately half the crystal will have its *c*-axis along the [010] and the other half along the [100] direction. Bozorth, Williams and Goertz (1953) compared theoretical expressions with experimental torque curves obtained for Fe_3O_4 at 82°K under a variety of cooling conditions. From these results he derived the principal anisotropy constants for the orthorhombic state of the crystal. The experimental results obtained on the present sample of Fe_3O_4 are shown in Figs 1 and 2 and these (100) plane torque curves agree well with the results obtained by Bozorth. It is interesting to note the pseudo-cubic symmetry (containing a $\sin 4\theta$ component) shown by the torque curve of a crystal cooled down in the absence of a field.

Although it is not possible from these curves alone to determine uniquely all the anisotropy constants of the crystal, an analysis was made of the torque curve in Fig. 1 and compared with results obtained by Bozorth *et al.* (1953) and Calhoun (from magnetization curves).

In order to analyse our results, the torque curve shown in Fig. 1 was corrected for non-alignment of I_s and H and the torque replotted against the true angle made between the magnetization I_s and a reference direction in the crystal. This curve was then separated into the different harmonic components by Fourier analysis. The final results are shown in Table 2 (details of this calculation

Table 2

Method	Torque in (100) plane calculated from anisotropy constants ($\times 10^{-5}$ erg cm^{-3})
Magnetization curve (Calhoun)	$(12{\cdot}8)\sin 2\theta-(3{\cdot}1)\sin 4\theta$
Torque measurements (Bozorth *et al.*)	$(10{\cdot}65)\sin 2\theta-(2{\cdot}7)\sin 4\theta$
Present analysis of torque curves.	$(11{\cdot}4)\sin 2\theta-(0{\cdot}7)\sin 4\theta$

are given in Appendix I). With this method of analysis the amplitude of the $\sin 2\theta$ torque curve component comes near to that deduced from magnetization measurements of Calhoun (1954).

It is suggested that a similar analysis of the results presented by Bozorth would provide the true anisotropy constants of magnetite below the transition temperature.

4.2. *Rotational Hysteresis at* 82°K

If we now go on to consider the torque curve obtained for a crystal of Fe_3O_4 which was cooled through the transition point without an applied field, as shown in Fig. 2, we notice, in contrast to the other curves on this diagram, that the torque values obtained during the forward and reverse directions of rotation of the applied field do not coincide, i.e., the sample is said to show rotational hysteresis. Curves of this type were previously reported by Briukhatov (1957). Similar curves found for the substituted crystals are shown in Figs 3, 4, 5, 6 and the rotational hysteresis is more pronounced in these samples. It should be noted that the crystals MGa3, MGa4, while showing considerable rotational hysteresis, are unaffected by the presence of a large field applied during the cooling down to 82°K.

As we believe these phenomena are connected with the ordering of the Fe^{2+} and Fe^{3+} ions in these samples, it is necessary to consider the ordering behaviour of these substituted crystals. Previous workers (Verwey and Haaijman 1941) have shown that the presence of foreign ions or vacancies in the octahedral sites will tend to suppress the ordering, both moving the transition to lower temperatures and tending to broaden the transition. Measurements of the initial permeability of the samples M, and MGa1 have shown transition temperatures of 114°K and 107°K compared with 119°K for stoichiometric Fe_3O_4, while in a crystal of composition $Al_{0\cdot1}Fe_{2\cdot9}O_4$ (most of the substituted aluminium going into the octahedral sites) the transition, if present, is below 82°K. So, in the substituted samples, we can safely assume that the ordering of the magnetic ions on the B (octahedral) sites is inhibited to an increasing degree as we move from a nearly stoichiometric magnetite crystal with increasing substitutions of non-magnetic ions.

A theory of rotational hysteresis in ferromagnetics has in recent years been produced for the simple case of single domain particles possessing either shape or magnetocrystalline anisotropy. Bean and Meiklejohn (1956) have shown that there can be rotational hysteresis only if the field is in the range

$$K/M_s < H < 2K/M_s.$$

Applying this very simple model to our present results we would expect no rotational hysteresis due to this cause if $H > 2K/M_s$.

For Fe_3O_4 below the transition $K = 1{\cdot}2 \times 10^6$ erg cm^{-3}, $M_s = 500$

$$H > \frac{2K}{M_s} = \frac{2{\cdot}4 \times 10^6}{500} = 4{\cdot}8 \times 10^3 \text{ oersteds.}$$

The present torque curves were carried out in fields of 12 000 oersteds and therefore, it seems that unless anisotropy of at least 5×10^6 erg cm^{-3} is present some other mechanism is responsible for the large hysteresis losses. Briukhatov (1957) plotted the variation of hysteresis loss against applied field for samples cooled below the transition with and without an applied field. Whereas samples cooled in a field showed no losses above fields of 5000 oersteds, samples cooled in the absence of a field possessed increasing rotational hysteresis at 10 000 oersteds. It was hoped the present results would reveal the variation in losses at higher fields, but owing to the difficulty of accurately measuring the loss (given by the difference in area between the two curves taken in different directions of rotation) it is difficult to say whether the losses are increasing or remaining constant in fields of 14 000 oersteds.

It is suggested that the losses are due to the phenomenon known as 'axis switching' which has previously been reported in Fe_3O_4 below the transition by Bickford (1953). In these cases a crystal in which the *c*-axis has been established along the [010] direction, if then placed in a magnetic field parallel to the [001] direction will reduce its energy considerably if the [001] direction becomes the new easy direction of magnetization. This *c*-axis transfer or axis switch requires an electron exchange from Fe^{2+} to Fe^{3+} ions in the octahedral sites and Calhoun (1954) has described experiments in which the external field required to cause the 'switch' was determined as a function of temperature below the transition. If a sample, consisting of different regions each with the *c*-axis along a different cube edge direction, is more easily capable of axis switching than a sample wholly ordered along a particular *c*-axis, then this would explain why a magnetite sample cooled through the field transition in a demagnetized state shows more rotational hysteresis than a sample cooled down in an applied field. Although axis switching in a wholly ordered crystal reduced the anisotropy energy, it would probably require a large change in the elastic energy of the sample. Nearer the transition point axis switching becomes easier and, therefore, one would expect higher losses due to this effect at 82°K in samples where the proportion of substituted foreign cations in Fe_3O_4 is increased as these crystals would possess transition temperatures closer to 82°K. Measurements of Bickford (1953) showed that (for a sample magnetized in a (100) plane) axis switching occurred when the applied field H reached an angle of 50° with the [001] direction. On reversing the direction of rotation of the field, switching recurred at an angle of 40° to the [001] direction. The torque curve given by such a simple model is shown in Fig. 9, assuming that all the sample is switched. The absence of any discontinuity in the experimental torque curves indicates that the switching is probably taking place at slightly differing points on the curve and not all the sample can change the direction of the *c*-axis, i.e. only a proportion of the sample is switched. Similarly the presence of unstable regions in the crystal would account for the decrease in hysteresis with number of torque cycles as shown in Fig. 7.

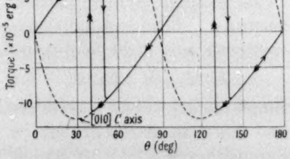

Fig. 9. Theoretical torque curve showing rotational hysteresis.

A more conclusive test of this mechanism would be to measure torque curves in much higher fields, say up to 50 000 oersteds. In such high fields the model would predict at least an increase in the rotational hysteresis whereas if the loss were due to the presence of a large anisotropy, it would tend to disappear. The graph in Fig. 8 of rotational hysteresis against applied field seems, at the moment, to support the proposed model. It is hoped that further experiments at even lower temperatures (<82°K) will also tend to show whether the model is valid, as it is expected for magnetite crystal (M_1) the loss should decrease as the temperature is lowered, as we go further away from the transition temperature; whereas with a sample MGa4 initial lowering of the temperature will increase the losses as the ordering increases and then the losses will decrease as the ordering is completed. Preliminary experiments at 20°K (obtained by immersing the crystals in liquid hydrogen) have confirmed this model. The magnetite crystal M_1 showed no rotational hysteresis at 20°K when cooled in the absence of a field, whereas the crystal MGa7 ($Ga_{0.63}Fe_{2.36}O_4$) showed large hysteresis at 20°K in contrast to the negligible hysteresis exhibited at 82°K. Measurements are now being extended down to liquid helium temperatures, the results of which should enable a more quantitative theory of the effect to be given.

§ 5. CONCLUSION

Torque curves have been measured at 82°K on a series of gallium- and aluminium-substituted magnetite crystals. Many of these crystals show rotational hysteresis in high fields, a fact first noted by Briukhatov (1957) for magnetite only. This hysteresis is shown to be related to the ordering of the ferrous (Fe^{2+}) and ferric (Fe^{3+}) ions which takes place on the octahedral sites at low temperatures.

APPENDIX

EXPRESSIONS FOR TORQUE IN (100) PLANE

Using Bozorth's notation where θ_a, θ_b, θ_c are the angles between the magnetization and the orthorhombic axes *a*, *b*, *c* respectively,

$$E = K_a \sin^2 \theta_a + K_b \sin^2 \theta_b + K_c \sin^2 \theta_c + K_a{}^1 \sin^4 \theta_a + K_b{}^1 \sin^4 \theta_b + K_c{}^1 \sin^4 \theta_c$$

if cooled in a field parallel to [001] in (100). The torque is then given by

$$L_{100} = \tfrac{1}{4}(2K_a + 2K_b - 4K_c + 3K_a{}^1 + 3K_b{}^1 - 4K_c{}^1) \sin 2\theta + \tfrac{1}{8}(K_a{}^1 + K_b{}^1 + 4K_c{}^1) \sin 4\theta.$$

Using Calhoun's notation where α_1, α_2 are the direction cosines of the magnetization with respect to the orthorhombic axes

$$E = K_1\alpha_1{}^2 + K_2\alpha_2{}^2 + K_{11}\alpha_1{}^4 + K_{12}\alpha_1{}^2\alpha_2{}^2 + K_{22}\alpha_2{}^4.$$

The torque is then given by

$$L_{100} = \tfrac{1}{4}(2K_1 + 2K_2 + K_{11} + K_{12} + K_{22}) \sin 2\theta - \tfrac{1}{8}(K_{11} + K_{12} + K_{22}) \sin 4\theta.$$

Magnetic Anisotropy in Single-crystal Nickel Films

By J. C. ANDERSON†

Royal Holloway College, Englefield Green, Surrey

MS. received 12th October 1960, in revised form 18th January 1961

Abstract. Single-crystal thin films of nickel, in the thickness range 50–500 Å have been prepared, by epitaxial growth on rock-salt, and their magnetic anisotropy measured.

All films show a uniaxial anisotropy superposed on the normal cubic anisotropy. In the discontinuous films, annealing in vacuum reduces the uniaxial component whilst in continuous films annealing increases it. Films grown in a vacuum of 10^{-7} mm are found to have few imperfections visible in the electron microscope and give more consistent results. The uniaxial component of anisotropy is shown to be a function of thickness, and is affected by the degree of vacuum achieved during deposition. It is suggested that the mechanism of directional ordering of oxygen atoms in the metal lattice, as proposed by Heidenreich, Nesbit and Burbank in 1959 would account for the results.

§ 1. Introduction

THE technique of preparing single-crystal metallic films by epitaxial growth has been reviewed by Pashley (1956). This method has been used in the present work to produce single-crystal nickel films for the purpose of measuring their magnetic anisotropy.

It has been found that the films prepared, all having a thickness of under 550 Å, generally displayed cubic anisotropy together with a superposed uniaxial component. The value obtained, from the best films, for the cubic anisotropy constant K_1 is identical with the value for bulk nickel at room temperature quoted by Bozorth (1952) of $-4{\cdot}6 \times 10^4$ erg cm^{-3}.

The uniaxial component of anisotropy is considered to arise by the magnetic annealing mechanism, well known in polycrystalline materials (see, for instance, Bozorth 1956). As soon as the growing film reaches a ferromagnetic state, the normal cubic anisotropy energy may be regarded as an internal magnetic field directed along one of the easy directions of magnetization. In nickel the anisotropy field is approximately 100 oersted and subsequent deposition of metal may be regarded as taking place in this field. Mechanisms which produce uniaxial anisotropy in films evaporated in a magnetic field should, therefore, be operative in the present case. It has been found that the value of uniaxial anisotropy constant is dependent upon the thickness of the film, the conditions under which it is prepared and its treatment subsequent to evaporation.

§ 2. Preparation of Specimens

The techniques described by Heavens, Miller, Moss and Anderson (1961) were used to prepare continuous, single-crystal nickel films of thicknesses down to approximately 100 Å. This involves the evaporation of approximately 1000 Å of copper on to a single-crystal rock-salt substrate held at approximately 450°c.

---

† Now at Department of Electrical Engineering, Imperial College, London, S.W.7.

The desired amount of nickel is then evaporated on to the copper, the composite film is floated off the rock-salt and the copper is dissolved away in saline solution. The films were circular, of $\frac{3}{8}$ in. diameter, and were mounted on quartz cover slips. For insertion in the magnetometer a circular section carrying the film was cut out of the cover-slip by ultrasonic trepanning. All the films used in the present experiments had a (100) face, and electron diffraction in a Metropolitan-Vickers EM3 microscope was used to examine their orientation.

Films prepared in a standard Edwards plant, having a best vacuum of 10^{-5} mm during evaporation, showed a considerable density of imperfections. Fig. 1 (Plate) is a typical micrograph of such a film, having a thickness of 159 Å. Various features may be distinguished in this photograph. In the area A the broad white lines have a $\langle 110 \rangle$ orientation and are considered to be twins. The features, of which that at B is typical, are very similar in appearance to stacking faults observed by Pashley (1959) in gold films, and are therefore assumed to be stacking faults. The loop features, such as that at C, are similar in appearance to dislocation loops shown by Pashley in the same paper. As he showed that a (100) film is suitable for observing dislocations this is what these loops are considered to be. In view of the fact that films of this type exhibited uniaxial anisotropy in a $\langle 110 \rangle$ direction, the large number of fine white lines, observed in the micrograph, were considered significant. These may be expected to arise if there is an ordering of impurities, such as oxygen, as suggested by Heidenreich, Nesbit and Burbank (1959). In the case of nickel Heidenreich detected oxygen ordering in $\langle 111 \rangle$ directions, but for a thin film having a (100) face the preferred direction for oxygen ordering could be expected to be $\langle 110 \rangle$.

In view of the high density of imperfections in the continuous films obtained in the standard evaporation plant, it was decided to improve the vacuum during evaporation. A bakeable, stainless-steel plant employing a mercury diffusion pump with two cold-traps was used. After pumping down, the vacuum was improved by gettering, first with aluminium and then with titanium. It was found possible to obtain pressures of 10^{-7} mm during evaporation regularly; the best achieved was 5×10^{-8} mm. The pressure was measured with an Alpert gauge having an accuracy to approximately $\pm 10\%$. Evaporation of both the copper and the nickel had to be done from tungsten filaments as the geometry of the high-vacuum plant did not permit the use of electron bombardment evaporation.

A typical film, of thickness 290 Å and evaporated at a pressure of 10^{-7} mm, is shown in Fig 2 (Plate). Large areas of this film were virtually featureless under the electron microscope. The photograph represents the worst area found and will be seen to contain relatively few dislocations. The straight-line features have a $\langle 110 \rangle$ orientation and are not easy to interpret; if they are stacking faults the differences in their widths are surprising, but this seems the most likely interpretation. The contour fringes over the whole surface are attributed to sagging of the film on the microscope grid.

§ 3. THEORY

The anisotropy energy density is assumed to be adequately expressed by

$$E = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2) + K_2(\alpha_1^2\alpha_2^2\alpha_3^2) + K_u \sin^2\theta.$$

There α is a direction cosine of the magnetization M_s with respect to the cubic axes and θ is the angle between M_s and the 'easy' direction of magnetization.

In a single-crystal thin film having a (100) face, the magnetization must lie in the plane of the film. We may take the easy direction in this plane as making a fixed angle ϕ with, say, the y axis where the (100) face is the yz plane. Then

$$\alpha_1 = 0, \quad \alpha_2 = \cos(\theta+\phi), \quad \alpha_3 = \sin(\theta+\phi)$$

and

$$\begin{aligned} E &= K_1[\sin^2(\theta+\phi)\cos^2(\theta+\phi)] + K_u \sin^2\theta \\ &= K_1[\sin^2(\theta+\phi) - \sin^4(\theta+\phi)] + K_u \sin^2\theta. \end{aligned}$$

The torque maintaining M_s at an angle θ to the easy direction is given by

$$L = \frac{\partial E}{\partial \theta} = -\tfrac{1}{2}K_1 \sin 4(\theta+\phi) + 2K_u \sin 2\theta.$$

Thus it is seen that, in a curve of torque against θ, the cubic anisotropy has a 4θ dependence whilst the uniaxial term has a 2θ dependence. 12-ordinate Fourier analysis is used to extract the coefficients $\tfrac{1}{2}K_1$ and $2K_u$.

Since the crystallographic directions in the film are not precisely known, the coefficients of the 4θ and 2θ components are evaluated using, as the origin for analysis, the origin of the curve. The origin for analysis is then moved by 5° and the components are again evaluated, this being repeated over a range of positions of the origin. By plotting the value of coefficient against position of origin the maximum value of the coefficient is found, together with the direction in which it occurs.

In bulk nickel the easy directions are cube diagonals of the type $\langle 111 \rangle$. Since the present films have a (100) face, there is no $\langle 111 \rangle$ direction in the plane of the film; the easy direction becomes $\langle 110 \rangle$, since, to take a $\langle 111 \rangle$ direction, the magnetization would have to be directed out of the plane of the film, and this is prevented by the large demagnetization coefficient.

§ 4. EXPERIMENTAL RESULTS

4.1. *Films Grown by Evaporation of Nickel directly on to Rock-salt*

The magnetic anisotropy of films having a granular structure, due to growth directly on rock-salt, was measured in a torque magnetometer. As the absolute value of torque was in all cases low the magnetometer was of high sensitivity. The film, on its circular quartz disk, was stuck on the end of a light quartz rod and suspended by a 50 cm length of phosphor-bronze strip (0·05 mm thick by 0·5 mm wide) between the poles of an electromagnet. A fiduciary mark was made on the film, which was viewed from above, via a 90° prism through a telescope with a calibrated, rotatable cross-wire. The film was set at a given angle to the axis of the field, with the magnet switched off, by rotating the suspension until the fiduciary mark coincided with the cross-wires. The field (10 000 gauss) was then switched on and the suspension rotated to bring the film back to its original position. Torque was measured by rotation of the suspension.

All the granular films, in the unannealed state, gave a strong uniaxial component of anisotropy in a $\langle 110 \rangle$ direction in the plane of the film, coinciding with one of the cubic 'easy' directions. The value of the cubic anisotropy constant varied between approximately -2×10^4 and -5×10^4 erg cm^{-3}. For films of the same order of thickness (typically in the region of 500 Å) the values of the anisotropy constants were found to vary over a wide range in spite of considerable effort being made to keep the production technique uniform.

The influence of annealing in vacuum upon the uniaxial anisotropy was studied and again it was found difficult to obtain reproducible results. In the majority of cases annealing in vacuum at a pressure of 10^{-5} mm was found to reduce the uniaxial anisotropy, and a one-hour anneal at 750°c eliminated it altogether. Some typical results are given in Table 1.

Table 1

Thickness (Å)	K_u/K_1 unannealed	K_u/K_1 annealed	Annealing treatment	Remarks
530	1·2	0·46	½ hr at 650°c	
430	1·5	0·06	½ hr at 750°c	
480	1·47	0·34	½ hr at 820°c	Oxidation visible
367	1·9	0	1 hr at 750°c	

An electron micrograph of a film annealed at 750°c for one hour was published in the paper by Anderson *et al.* (1961) and showed that the film broke up into discrete globules, the interstices being filled with what was assumed to be nickel oxide. The torque curve was taken and the uniaxial component found to be negligibly small. The film thickness was 367 Å.

4.2. *Low Vacuum Films Grown on Copper*

A study was made of the influence of annealing upon continuous nickel films grown on a copper substrate. Two groups of films, the first having thicknesses in the region of 170–190 Å and the second in the region of 50–70 Å were studied. The results for films in which the value of the cubic anisotropy constant was within ± 10% of bulk value are given in Table 2, from which it will be seen that annealing for half an hour at 650°c reduces the ratio K_u/K_1, but that raising the annealing temperature causes the ratio to increase. This increase in ratio is not linear with temperature and is most marked when the temperature goes from 650°c to 700°c. Annealing at temperatures above 750°c left the film visibly oxidized, and was therefore rejected. Temperatures below 600°c were found to have little effect.

Table 2

Thickness (Å)	K_u/K_1	Annealing treatment
171	1·31	—
192	1·03	½ hr at 650°c
186	1·42	½ hr at 750°c
187	1·58	1 hr at 750°c
62	1·66	—
56	1·27	½ hr at 650°c
72	2·46	½ hr at 700°c
38	2·8	½ hr at 750°c

4.3. *High Vacuum Films Grown on Copper*

In view of the results quoted in the preceding paragraph the films prepared in the high-vacuum plant were not annealed. Magnetic anisotropy was measured

Table 3

Thickness (Å)	K_1 ($\times 10^4$ erg cm^{-3})	Remarks
99	$-4\cdot64$	
148	$-4\cdot60$	
154	$-4\cdot62$	
182	$-4\cdot14$	
200	$-4\cdot50$	
211	$-1\cdot19$	rejected
210	$-4\cdot19$	
241	$-3\cdot54$	rejected
250	$-4\cdot61$	
264	$-4\cdot60$	
298	$-3\cdot30$	rejected
315	$-4\cdot54$	
334	$-2\cdot09$	rejected

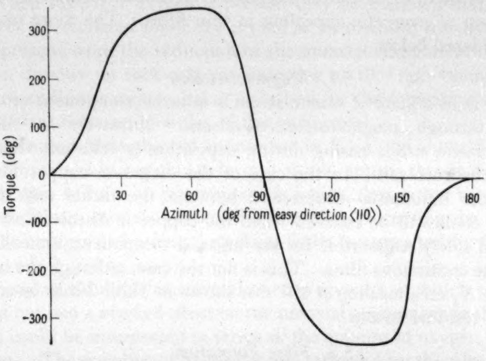

Fig. 3. Graph of torque against orientation for 99 Å nickel, single-crystal film grown on copper. $K_1 = -4\cdot64\times10^4$ erg cm^{-3}; $K = +5\cdot4\times10^4$ erg cm^{-3}.

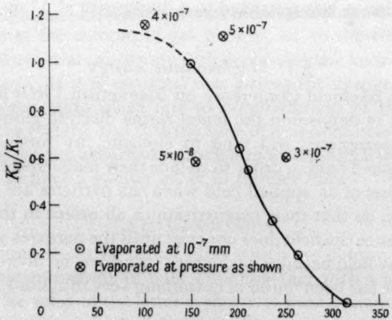

Fig. 4. Graph of the ratio K_u/K_1 against thickness for nickel films grown on copper in ultra-high vacuum.

for each of these films and the results were only used if the value of the cubic anisotropy constant was within ±10% of bulk value. This criterion led to the rejection of far fewer films than was the case with the films prepared at 10^{-5} mm, and frequently the value measured for K_1 was precisely $-4{\cdot}6 \times 10^4$ erg cm^{-3}. Table 2 gives the actual values obtained in 13 films. A typical torque curve, for one of these films, is shown in Fig. 3.

Figure 4 shows the ratio of K_u/K_1 plotted as a function of thickness. Films obtained in a vacuum of 10^{-7} mm show ratios which lie on a smooth curve, the ratio increasing with decreasing thickness. A slight increase in pressure to 4×10^{-7} mm causes the ratio to increase, whilst a reduction to 5×10^{-8} mm causes it to decrease.

§ 5. DISCUSSION

A number of theories have been suggested by various workers to account for the phenomenon of magnetic annealing in thin films. The more important of these are considered below.

5.1. *Magnetostriction*

If the film is in a state of elastic strain a uniaxial component of anisotropy would arise through magnetostrictive effects. However, in the present experiments, elastic strain arising during deposition is relieved when the film is floated off the rock-salt. In the case of the nickel-on-copper films, strain arising from the differential contraction between the nickel and the copper when the film cools will be relieved when the copper is dissolved away.

Were strain solely responsible for the uniaxial component, annealing should remove it in the continuous films. This is not the case, although the initial drop in the ratio K_u/K_1 on annealing at 650°C as shown in Table 2 may be attributable to the relief of residual strains.

5.2. *Fibre Formation*

Knorr and Hoffman (1959) have shown that there can be a contribution to uniaxial anisotropy through the beam from the evaporating metal striking the substrate at an angle. In the present experiments the geometry of the apparatus was such that the beam was restricted to a divergence of 5° on either side of the normal to the substrate.

5.3. *Magnetostatic Energy*

Wohlfarth (see Sheffield Conference on Magnetism 1960) has suggested that in the early stages of deposition the metal forms discrete globules which, when they become ferromagnetic, will tend to elongate, by further growth, in the direction of the applied field in order to reduce their magnetostatic energy. This assumes the presence of an applied field when the particles are still in the superparamagnetic stage, so that their magnetizations all orient in the same direction. In the present instance the field does not exist until the particles are ferromagnetic, when the anisotropy field becomes operative. Further, no micrographic evidence to support this view has been found in examining very thin films grown on copper.

5.4. *Directional Order*

In alloy films both Néel (1954, 1959) and Taniguchi (1955) have suggested that uniaxial anisotropy may be induced if the coupling coefficients between the spins on different atom pairs are different. At the annealing temperature it is assumed that the solute atom pairs diffuse into an arrangement of minimum energy along the direction of the field. This, however, depends on the presence of atoms of two different kinds. In the pure material this would not apply, but there remains the possibility of non-magnetic inclusions or lattice vacancies behaving in a similar manner.

5.5. *Oxygen Ordering*

Heidenreich, Nesbit and Burbank (1959) have shown that magnetic annealing requires the presence of oxygen during the evaporation of the film. They have further demonstrated that absorbed oxygen tends to diffuse into a preferred orientation along a ⟨111⟩ direction in a face-centred cubic crystal. In the case of the (100) specimens used, the preferred direction may be expected to become ⟨110⟩. When sufficient oxygen is present they have shown that a metal monoxide may be precipitated *inside* the crystal as an oriented sub-lattice.

In the present work the reduction of the uniaxial component obtained in the films grown directly on rock-salt, on annealing at 10^{-5} mm vacuum, is thought to be due to sufficient oxygen being absorbed for the formation of an isotropic oxide sub-lattice between globules of the pure metal.

The continuous films showed an increase in K_u/K_1 on annealing at 10^{-5} mm. Since the film is not in a globular form it would appear that it does not absorb sufficient oxygen to form an isotropic oxide lattice, but rather that the oxygen it does absorb diffuses into the preferred orientation, increasing the uniaxial anisotropy. The existence of oriented stacking faults is supported by the micrograph of Fig. 1.

In the case of the high-vacuum films, the pressure at which the evaporation was carried out had a marked effect on the uniaxial component as shown in Fig. 4. This again could be interpreted in terms of the amount of oxygen present during evaporation. The number of oxygen atoms collected by the film during evaporation will be proportional to the product of the pressure and the duration of the evaporation. In this case, of nickel evaporating from a tungsten filament, there was little difference in the time taken to evaporate all the nickel for the films between 50 Å and 300 Å. Thus the amount of oxygen collected may be expected to be proportional to the amount of gas present, i.e. to the vacuum pressure.

The increase of uniaxial anisotropy with decreasing thickness may be accounted for in a similar way. If it is assumed that during the evaporation of the nickel absorption of oxygen takes place due to bombardment of the film by oxygen atoms present in the system, and that the time of evaporation is virtually constant, then the amount of oxygen absorbed by each film will be much the same. It would then be expected to have a greater effect in thinner films.

§ 6. CONCLUSION

It has been found that thin nickel films which are continuous, parallel-sided flat slabs give cubic anisotropy of bulk value together with a uniaxial component of anisotropy. The value of the latter is shown to bear a relation to film thickness and evaporation pressure.

The experimental results tend to support the oxygen-ordering mechanism of induced uniaxial anisotropy proposed by Heidenreich, Nesbit and Burbank

(1959). There is some evidence of a contribution to uniaxial anisotropy from strain effects.

ACKNOWLEDGMENTS

This research was supported by the Department of Scientific and Industrial Research. The author has had useful discussions with Dr. P. Wohlfarth; Mr. R. F. Miller has provided much assistance in the experimental work, and Mrs. M. Brown carried out all the micro-chemical thickness determinations and drew the diagrams.

The Preparation of Continuous Single-Crystal Thin Films of Nickel and Nickel–Iron Alloys

By O. S. HEAVENS, R. F. MILLER,
G. L. MOSS and J. C. ANDERSON
Royal Holloway College, University of London

MS. received 3rd *November* 1960, *in revised form* 19th *December* 1960

Abstract. Thin films of nickel and some face-centred cubic nickel–iron alloys have been grown epitaxially from the vapour phase on to the principal planes of rock-salt and copper, and their structure and orientation investigated by transmission electron microscopy. Conditions have been determined for the production of continuous films of thickness down to 100 Å. The mass and composition were determined microchemically; thicknesses given are on the assumption of bulk density.

§ 1. Introduction

THE phenomenon of epitaxy offers the possibility of obtaining films which are monocrystalline. This process generally requires that the materials be deposited on a heated monocrystalline substrate. Previous work (Bassett and Pashley 1958–9) on gold films deposited on cleaved rock-salt and mica has shown that such films are generally aggregated. It is clear that the properties of such aggregates will differ markedly from those of a parallel-sided continuous film. This applies particularly to the structure-sensitive magnetic properties, electrical properties and optical constants. The feasibility of producing films which are both monocrystalline and continuous, in thicknesses down to tens of ångströms, has been examined for films of nickel and certain nickel–iron alloys.

The films were grown by condensation from the vapour phase, the choice of substrate being governed by the following factors: (*a*) Epitaxial growth of the condensed material must occur to produce a single-crystal film; (*b*) the film must approximate as closely as possible to the ideal parallel-sided thin sheet over the area of the specimen required for subsequent investigation; (*c*) at the optimum temperature for epitaxial growth the vapour pressure of the substrate should be sufficiently low not to interfere with the formation of the film under the evaporation conditions used; (*d*) the films must be removable from the substrate for examination by electron microscopy and so that stresses set up during cooling may be relieved.

Reference to the work of Collins and Heavens (1957) suggested the use of rock-salt. Optically smooth (100), (110) and (111) faces were obtained by a suitable polishing technique, the Beilby layer being removed by thermal etching at 350°c for one hour *in vacuo*. Since the mode of growth of metals on ionic substrates is known to differ considerably from that on metallic substrates, copper was also investigated as a substrate. The copper was condensed from the vapour on to polished faces of rock-salt to produce monocrystalline films.

§ 2. METHOD OF PREPARATION

For work on the cube face of rock-salt, cleavage faces were used: (110) and (111) faces were prepared by string cutting using water. The faces were then polished on wet filter paper supported on glass. This procedure removes gross features due to either cleavage steps or cutting marks. Polishing is then continued on a wax lap (Strong *et al.* 1938) using a suspension of tin oxide in brine. Dry polishing on Selvyt cloth produces the final finished surface. In order to remove any traces of wax a final stage of polishing using isopropyl alcohol on Selvyt is applied.

The nickel and nickel–iron alloys were evaporated by electron bombardment of a pendant drop (Heavens 1959 a) at a pressure of 2×10^{-5} mm Hg. This possessed the advantage that there was no possibility of contamination by supporting material. In addition, the temperature of the vapour source, and hence the rate of evaporation, could be critically controlled.

The composition of alloy films deposited in this way was found to differ essentially from that of the source material. The change in composition as a function of the life of the molten drop is shown in Fig. 1. On a substrate at 7 cm distance from the source, the rate of deposition was approximately 100 Å per minute.

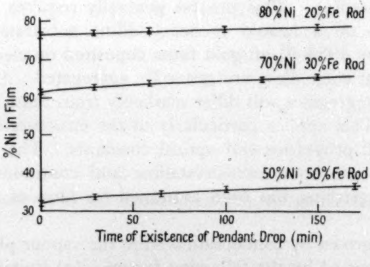

Fig. 1. Composition of alloy films as a function of time of existence of molten drop, and composition of the original rod.

The masses of the films were determined by colorimetric microchemistry (Heavens 1959 b) using Nioxime (Johnson and Simmons 1946) as reagent for nickel, and Tiron (Hopkins and Williams 1956) for iron. When estimating nickel in the presence of iron, the pH of the solution must be brought to 7 in order to prevent oxidation of the Nioxime by ferric iron. The light transmission measurements were made using a Pulfrich photometer.

Direct measurements of the thicknesses of some films were also made using multiple-beam interferometry. The thicknesses obtained agreed with those deduced from the measured areas and masses on the assumption that the density of the films is the same as that of the bulk. In view of the continuous nature of the films as revealed by electron microscopy, this result is to be expected. Similar behaviour has also been reported for pure iron films (Heavens 1959 b).

For films of thickness about 100 Å, the accuracy of thickness measurement is estimated to be to ± 3%.

§ 3. FILM STRUCTURES OBSERVED

Complete orientation was observed for substrate temperatures of 330°C, somewhat lower than is reported in earlier work. The films were removed by solution of the substrate in water, care being taken not to deform them in the process.

3.1. *Films Grown on Cleaved* (100) *NaCl Faces*

Examination of these films by optical and electron microscopy revealed considerable discontinuities and gross features due to cleavage structures on the rock-salt surface (Fig. 2, Plate I). Cleavage faces on rock-salt invariably show cleavage steps on the surface, the density varying from specimen to specimen. In favourable cases, regions many hundreds of microns across may contain only a few features such as are shown in Fig. 2. In the initial stages of growth the films consisted of isolated nuclei. As the thickness increased these nuclei grew and combined to form a continuous film at about 800–900 Å. There was, however, still considerable variation in thickness from place to place. Electron diffraction showed parallel orientation in all cases, additional spots indicating twinning on {111} type planes. Micrographs showed diffraction contrast features probably due to twins and stacking faults.

3.2. *Films Grown on Polished* (100), (110) *and* (111) *NaCl Faces*

Films grown on these substrates were free from gross imperfections and showed excellent orientation. The twin spots in the diffraction patterns were far less prominent than in the case of films grown on cleaved (100) faces, (Figs. 3 (*a*) (*b*), Plate I). In the case of (110) films extra diffraction spots were also observed indicating twinning on {111} planes. This was supported by micrographs in which twins and stacking fault fringes were seen by diffraction contrast to lie along ⟨211⟩ type directions. Dislocation loops were also observed. An aggregated (100) nickel film of about 500 Å thickness was removed from the substrate and annealed for 2 hours at 1000°C at 2×10^{-5} mm Hg pressure. On re-examination, the film was found to have coalesced further into larger aggregates (Fig. 4, Plate I) and to have become considerably disorientated. It is not clear why the film shown in Fig. 4 holds together. Electron diffraction of the regions between the large aggregates shows very faint, diffuse rings, possibly arising from a film of cracked hydrocarbon which will have formed during the first examination of the film, before annealing. We note that, as the melting point of nickel is 1452°C, the atoms of the film must possess very considerable mobility, even some four hundred degrees below the melting point.

In the work of Bassett and Pashley (1958–9), it was found that films grown on monocrystalline metal substrates showed greater continuity than those directly on rock-salt. In order that such epitaxially grown films be useful for study, it is essential that no diffusion of the underlying metal takes place at the temperature necessary for epitaxial growth. Measurements by Belser (1960) on films deposited on copper show no diffusion at temperatures below 400°c. Copper, which was known to grow epitaxially on rock-salt, was therefore selected as a suitable substrate metal for the growth of nickel and the nickel–iron alloys.

3.3. *Epitaxial Growth on* (100), (110) *and* (111) *Faces of Cu*

Copper was evaporated from a tungsten filament on to the polished faces of rock-salt, maintained at 330°c *in vacuo*, to produce continuous single crystal films of about 1500 Å thickness whose orientation was parallel to the substrate. The rate of deposition was approximately 1000 Å min^{-1}. The nickel and nickel–iron alloys were found to grow epitaxially on the copper at a deposition temperature of 330°c. In view of the need to remove the films for subsequent measurements on the superimposed nickel or nickel–iron layer, electron diffraction patterns of copper films were taken after they had been removed from the rock-salt and picked up on copper grids. Clear Kikuchi patterns were obtained in transmission (Fig. 5, Plate II) showing that the removal need not introduce serious distortion in the film. After mechanical deformation, (110) copper films showed twinning and stacking faults along ⟨211⟩ directions together with gross distortions shown by the extinction contours in Fig. 5 (*b*). The composite films were floated off the rock-salt and the copper dissolved in sodium chloride solution leaving the ferromagnetic film behind.

When examined in the electron microscope (Metropolitan Vickers EM3) the nickel and nickel–iron films showed good orientation parallel to the respective rock-salt faces. The mode of growth differed from that on rock-salt in that the initial nucleation was rapidly followed by a 'lacework' structure, the holes of which filled in to form a continuous film at about 100 Å thickness. Figs 6 (*a*) and 6 (*b*) (Plate II) compare the structure of Ni films of thickness of about 100 Å (*a*) deposited directly on rock-salt, (*b*) deposited on thick continuous copper films. In the latter case, the broad dark bands are extinction contours. In view of the way in which the fine lines in the pattern move with tilt of specimen, it is highly probable that these too are extinction contours. These films grown on copper showed considerably less twinning than the films grown directly on rock-salt. Many of these imperfections appear to be associated with the pressure in the system during deposition. Evaporation at low pressures favours the formation of films containing a smaller number of dislocations and other features than are obtained from evaporations at higher pressures. Annealing experiments showed that the faults are very stable, remaining even after four hours at 700°c *in vacuo*.

In view of the difficulties of interpretation of the properties of aggregated, polycrystalline films such as are formed on amorphous substrates, the successful production of continuous monocrystalline films by the method described above would appear to offer great advantages for thin film study. The magnetic anisotropy of films grown in this way is described in another paper (Anderson 1961).

ACKNOWLEDGMENT

Thanks are due to Mrs. M. Brown for her assistance with the thickness measurements.

Reflection and Polarization of Elastic Waves in a LiF Crystal: Mode Conversion from Longitudinal to Transverse

BY N. JOEL

Centro de Investigaciones de Cristalograafía, Instituto de Física y Matemáticas,
Universidad de Chile, Casilla 2777, Santiago, Chile

MS. received 20*th December* 1960

Abstract. An experiment is described in which a longitudinal wave of ultrasonic frequency travelling in a crystal of LiF (anisotropic medium) is incident on a crystal–air boundary and is reflected as a transverse wave. Such a mode conversion, or complete change in the state of polarization, of an elastic wave had previously been observed only in isotropic media. The corresponding calculations are also given; they agree with the experimental results.

---

§ 1. INTRODUCTION

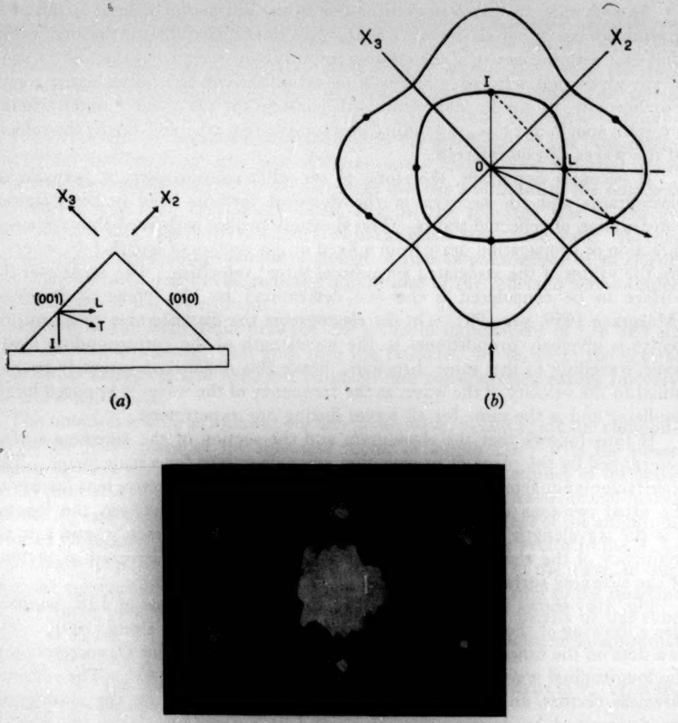
WHEN an elastic wave, whatever its state of polarization, is incident on a boundary between two crystals (anisotropic media), there are in general three reflected waves and three refracted waves: one quasi-longitudinal and two quasi-transverse waves in each set. A comprehensive review on the propagation of elastic waves in crystals has been given by Musgrave (1959). The relative amplitudes of the reflected and refracted waves depend on the presence of symmetry elements in one or both crystals, on special orientations of the boundary and direction of incidence relative to the principal axes of the crystals, and on the particular values of the elastic constants. As a consequence of this, there are special cases where one or more of the reflected or refracted waves may vanish altogether.

In this paper a particular case of a longitudinal wave of ultrasonic frequency propagating in a cubic crystal and incident on a crystal–air boundary is examined. It is found that in LiF, under the conditions described below, it is possible, on reflection, to convert a truly longitudinal wave completely into a quasi-transverse wave.

An interesting example of the visualization of such a mode conversion in fused quartz (isotropic) has been given by Hammond and Carter (1958). In the present work, however, the visualization of the elastic waves is achieved by means of Bergmann–Schaefer diffraction elastograms (Bergmann 1954). One of the advantages of this technique, apart from other ones to be explained below, is that the elastograms are, except for a scale factor, the sections of the 'slowness surface' required for the graphical construction of the reflected slowness vectors which, in turn, determine the directions of the wave normals and the rays.

§ 2. RESULTS

While setting up some experiments for a redetermination of the elastic constants of ammonium dihydrogen phosphate by means of diffraction elastograms (Joel and Wooster 1960), it became of interest to study the reflection of



(*a*) (*b*)

(*c*)

Fig. 1. (*a*) Shape and orientation of the specimen of LiF used in this work. (*b*) Section of slowness surface in the orientation corresponding to the specimen used. The heavy dots correspond to the incident wave and to the reflected waves that are expected geometrically; they are also the spots to be expected on the elastogram. (*c*) Actual diffraction elastogram of specimen shown in (*a*); the patch at the centre is the heavily over-exposed incident beam of light. Compare with (*b*) and notice the absence of diffraction spots right and left of the centre. ($\lambda = 5780$ Å, $f = 132$ cm, $\nu = 8143$ kc/s.)

elastic waves at a crystal–air boundary. Among other specimens, one of LiF was tried under the following conditions: its shape is that of a triangular prism (Fig. 1(*a*)); the two parallel optically polished faces are (100), the two small side faces are (010) and (001), and the large side face, in contact with the driving quartz plate, is (011). Thus, the longitudinal waves emitted by the X-cut quartz plate travel in the LiF specimen along [011] and are incident on (010) and (001) at an angle of 45°. Instead of the complete elastogram, diffraction patterns such as the one shown in Fig. 1(*c*) were obtained.

As each spot on the elastogram is due to the diffraction of light at the phase grating set up by an elastic wave with wave normal parallel to the line joining that spot with the centre of the elastogram, it becomes apparent that the presence of any given spot is in fact a means of detecting the corresponding elastic wave†. Furthermore, by simple inspection of the elastogram it is possible to tell whether a certain spot is due to a longitudinal or a transverse wave; and finally the velocity of the waves can be inferred.

It becomes important, therefore, to see what relation there is between the elastograms and the sections of the slowness surfaces used in the graphical construction of reflected waves. The slowness surface is defined thus: for each direction of propagation draw from a fixed origin vectors of length $1/V$, where V are the values of the associated (in general three) velocities. The section of this surface to be considered is the one determined by the plane of incidence (Musgrave 1959, page 90). On the elastograms the distance of a spot from the centre is inversely proportional to the wavelength of the corresponding elastic wave, travelling in that same direction; hence this distance is inversely proportional to the velocity of the wave, as the frequency of the waves is imposed by the oscillator and is the same for all waves during one experiment.

It thus follows that the elastogram and the section of the slowness surface determined by the plane of propagation coincide except for a scale factor. This scale factor is equal to $f\lambda\nu$, where f is the focal length of the objective lens (assuming the usual two-lens diffraction set-up with parallel light between the lenses), λ is the wavelength of the light used in observing the diffraction and ν is the frequency of the elastic waves. The elastograms can thus be used as sections of the slowness surfaces.

Fig. 1(*b*) shows the (100) section of the slowness surface of LiF, which is also a drawing of the complete elastogram for LiF observed along [100]‡. The two dots on the inner curve, above and below the central point O, correspond to the longitudinal waves incident on the two faces inclined at 45°. The reflected slowness vectors, and hence also the corresponding points on the elastogram, are determined by drawing through point I lines perpendicular to the axes X_2 and X_3. This is shown in detail in Fig. 1(*b*) for the waves reflected on the face parallel to X_2: the perpendicular to X_2 through point I intersects the slowness surface at points L and T. OL is the direction of the reflected longitudinal slowness vector (and wave normal) and OT is the direction of the transverse one. These are also shown in Fig. 1(*a*). The inclined face parallel to X_3 gives rise to reflected waves symmetrical with the ones mentioned above relative to the line OI. Furthermore, for each elastic wave two spots appear on the elastogram, symmetrical relative to the central point O. So that the diffraction pattern to be expected consists of the eight spots marked in Fig. 1 (*b*).

---

† The converse is not necessarily true, for the absence of a given spot is not a sure indication of the absence of the corresponding elastic wave. This is so because the brightness of a spot depends not only on the amplitude of the elastic wave but also on the elasto-optical constants of the crystal.

‡ This section of the slowness surface also includes a circle, as can easily be seen from Eqn (1). However, this circle has been omitted in Fig. 1 (*b*) for the reason that the reflected wave associated with it has amplitude zero ($A_{T'}=0$, see results below) and because, as a consequence of this, that circle does not appear on the elastogram. This apparent exception is due to the special symmetry conditions of the particular example under discussion.

Comparison of Figs 1(*b*) and (*c*) shows a striking difference: the absence in Fig. 1(*c*) (the experimental diffraction pattern) of the two dots left and right of the centre, corresponding to the reflected longitudinal waves. Only the dots corresponding to the incident waves and to the reflected quasi-transverse waves appear. It soon became obvious that this effect could not be attributed to unfavourable elasto–optical constants because, due to the symmetry of LiF, the directions of the incident beam and that of the expected longitudinal reflected beam are in this case equivalent. So, it became clear that the amplitude of the reflected longitudinal wave was vanishingly small, that is, the reflected flux of energy was totally (or very nearly so) concentrated in the quasi-transverse wave. As this would afford an interesting example of change of state of polarization of an elastic wave, the next step was to calculate the amplitudes of the reflected waves under the conditions of the experiment.

Because of the large ratio between the acoustic impedances of LiF and air (about 30 000), the energy that goes into the refracted waves, from the crystal to the air, is negligible and need not be taken into consideration except for very accurate calculations.

The notation will be as follows: for any given wave, y_2 and y_3 are the components in the (100) plane of the slowness vector of length $1/V$; V is the phase velocity or wave normal velocity; q_2 and q_3 are the direction cosines of the wave normal (and also of the slowness vector); α is the angle the wave normal makes with the X_2 axis ($\cos\alpha = q_2$); p_1, p_2 and p_3 are the direction cosines of the amplitude vector or vibration direction; β is the angle that an amplitude vector in the X_2X_3 plane makes with the axis X_2 ($\cos\beta = p_2$); A is the amplitude of the wave, so that $A\mathbf{p}$ is the corresponding amplitude vector. Parameters referring to the incident and the three possible reflected waves will be indicated by means of the subindices I, L, T, T′, respectively. The amplitude of the incident longitudinal wave is taken $A_\mathrm{I} = 1$.

For LiF the elastic constants are: $c_{11} = 113{\cdot}5 \times 10^{10}\,\mathrm{dyn\,cm^{-2}}$, $c_{12} = 48$, $c_{44} = 63{\cdot}5$, $\rho = 2{\cdot}64\,\mathrm{g\,cm^{-3}}$ (Spangenberg and Haussühl 1957).

The calculation of the slowness vectors and other related quantities follows easily from the equation of the trace of the slowness surface in the plane Y_2Y_3:

$$\begin{vmatrix} c_{44}(y_2^2+y_3^2)-\rho & 0 & 0 \\ 0 & c_{11}y_2^2+c_{44}y_3^2-\rho & (c_{12}+c_{44})y_2y_3 \\ 0 & (c_{12}+c_{44})y_2y_3 & c_{44}y_2^2+c_{11}y_3^2-\rho \end{vmatrix} = 0 \qquad \ldots\ldots(1)$$

and from the known boundary conditions (see Musgrave 1959, pp. 88–90), which in this case imply that all four waves have the same slowness component y_2.

The direction cosines of the amplitude vectors follow from:

$$\left.\begin{aligned} [c_{44}(q_2^2+q_3^2)-\rho V^2]p_1 &= 0 \\ (c_{11}q_2^2+c_{44}q_3^2-\rho V^2)p_2+(c_{12}+c_{44})q_2q_3p_3 &= 0 \\ (c_{12}+c_{44})q_2q_3p_2+(c_{44}q_2^2+c_{11}q_3^2-\rho V^2)p_3 &= 0 \\ p_1^2+p_2^2+p_3^2 &= 1 \end{aligned}\right\} . \qquad \ldots\ldots(2)$$

The expressions for the displacement of each of the waves now have the form

$$\mathbf{u} = A\mathbf{p}\sin 2\pi\nu\left[t-\frac{\mathbf{q}\,.\,\mathbf{x}}{V}\right] = A\mathbf{p}\sin 2\pi\nu(t-\mathbf{y}\,.\,\mathbf{x}) \qquad \ldots\ldots(3)$$

and the strains are as usual

$$\epsilon_{ij}=\tfrac{1}{2}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right). \qquad \ldots\ldots(4)$$

The equations from which the values of A are obtained follow in this case from the condition that at the free surface the normal and shear stresses should vanish, and they take in this particular example the form

$$\left.\begin{aligned}\sum\frac{A}{V}(c_{11}p_3q_3+c_{12}p_2q_2)&=0\\ \sum\frac{A}{V}(p_2q_3+p_3q_2)&=0\\ \sum\frac{A}{V}p_1q_3&=0\end{aligned}\right\} \qquad \ldots\ldots(5)$$

where the summations are to be carried out over the four waves I, L, T, T′. The results are summarized in Table 1.

Table 1

	I	L	T	T′
y_2^2 (km sec^{-1})$^{-2}$	0·00915	0·00915	0·00915	0·00915
y_3^2 (km sec^{-1})$^{-2}$	0·00915	0·00915	0·04999	0·03242
$1/V$ (km sec^{-1})$^{-1}$	0·135	0·135	0·243	0·204
V (km sec^{-1})	7·39	7·39	4·11	4·90
q_2	0·707	0·707	0·393	0·469
q_3	−0·707	0·707	0·919	0·883
α (deg)	315	45	66·8	62
p_1	0·000	0·000	0·000	1·000
p_2	−0·707	0·707	−0·835	0·000
p_3	0·707	0·707	0·551	0·000
β (deg)	135	45	146·6	—
A	1·0000	0·0323	1·042	0·0000

The absence of coupling between the first two and the last of Eqns (5) has as a consequence that $A_{\mathrm{T}'}=0$. This can be predicted by means of symmetry considerations, and the column headed T′ corresponding to the pure-transverse wave vibrating along [100] could have been omitted altogether†. It is given here only for the sake of generality.

The result is that $A_{\mathrm{T}}=1{\cdot}042$ and $A_{\mathrm{L}}=0{\cdot}0323$, that is, A_{L} is only about 3% of A_{T}. But of more interest is a comparison between the energy fluxes associated with these two reflected waves.

The direction of this flux, i.e. that of the ray, is the direction of the normal to the slowness surface at the end of the corresponding slowness vector. This flux **F** is given, in direction and magnitude, by its components (Synge 1956)

$$F_i=2\pi^2\nu^2\sum_{jkl}\frac{1}{V}A^2c_{ijkl}p_jp_lq_k. \qquad \ldots\ldots(6)$$

The direction cosines n_i of the ray (normal to the slowness surface) are thus

$$n_i=F_i/(F_1^2+F_2^2+F_3^2)^{1/2} \qquad \ldots\ldots(7)$$

and as the rays are in this example also in the plane of the wave normals, that is, in the plane (100), their angle γ with the axis X_2 is given by $\sin\gamma=n_3$.

---

† This is the wave associated with the circle that was omitted in Fig. 1 (*b*).

This angle γ is important as it affects the cross section of the reflected beams and hence also the total flux associated with each of the waves. Taking as unity the area of the boundary excited by the incident beam, the total flux for each of these beams is $|\mathbf{F}|n_3$ and the balance of energy requires that

$$\sum |\mathbf{F}|n_3 = 0 \qquad \ldots\ldots (8)$$

where the summation is carried out over the three waves I, L and T.

Table 2 summarizes the results (the factor $2\pi^2\nu^2$ and a power of ten have been omitted throughout).

Table 2

	I	L	T
F_1	0·000	0·000	0·000
F_2	1·380	0·0014	−0·223
F_3	−1·380	0·0014	1·379
$\lvert\mathbf{F}\rvert$	1·951	0·002	1·396
n_2	+0·707	+0·707	−0·1597
n_3	−0·707	+0·707	+0·9872
γ (deg)	315	45	99·2
$\lvert\mathbf{F}\rvert n_3$	−1·380	+0·0014	+1·379

From the last line of Table 2 it can be seen that of the incident energy, only 0·1% is to be found in the reflected longitudinal wave L and 99·9% of it is carried by the reflected quasi-transverse wave T. (The fact that the sum of the two reflected total fluxes is equal to the incident one is a check on the correctness of the calculations.) It is also interesting to notice that the amplitude vector of the quasi-transverse wave is in the plane of incidence at an angle of 80° to its wave normal, that is, 10° away from pure transversality, and that the ray forms an angle of 32° with this wave normal.

Alternatively, the energy flux can also be calculated thus: First, the direction cosines n_i of the normal **N** to the slowness surface are calculated by normalizing

$$N_i = \frac{\partial \Delta}{\partial y_i} \qquad \ldots\ldots (9)$$

where Δ is the determinant (1). Now, the energy density is proportional to ρA^2; the ray velocity, that is, the actual rate of propagation of the energy along the ray is $V/\Sigma n_i q_i$ where the denominator is the cosine of the angle between the ray and the corresponding wave normal; finally the cross section of the beam introduces as before the factor n_3. So that the total fluxes are, for each wave (omitting the same constant factors as before):

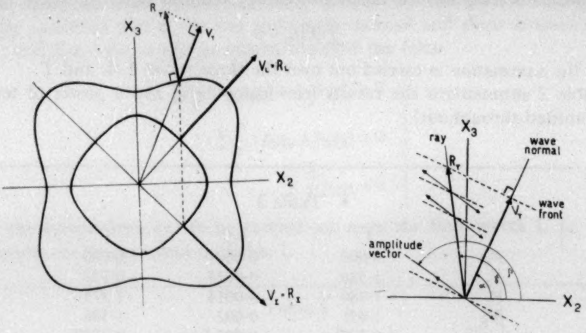
$$\rho A^2 V n_3 / \sum n_i q_i \qquad \ldots\ldots (10)$$

which in this particular case can also be written

$$\rho A^2 V \sin\gamma / \cos(\gamma - \alpha). \qquad \ldots\ldots (11)$$

In this way the same numerical results are obtained.

Figure 2 illustrates some of the relations between the parameters involved in this problem, particularly for the quasi-transverse wave.



(*a*) (*b*)

Fig. 2. (*a*) Wave normals and rays for the incident and the two reflected waves. The length of the vectors indicates the phase velocity or wave normal velocity V and the ray velocity R. (*b*) Angular relations between wave front, wave normal, ray and amplitude vector for the quasi-transverse wave; also the ray velocity and wave normal velocity are indicated. $\alpha = 66^\circ{\cdot}8$; $\beta = 146^\circ{\cdot}6$; $\gamma = 99^\circ{\cdot}2$.

§ 3. CONCLUSIONS

The calculations confirm the fact first observed experimentally that a longitudinal wave travelling in LiF along [011] and reflected by a crystal–air boundary parallel to either (010) or (001) gives rise to a quasi-transverse wave only. To be more precise, 99·9% of the incident energy is carried by the reflected transverse wave and 0·1% is carried by the reflected longitudinal wave. Calculations were made in order to find the angle of incidence that gives total mode conversion; angles of incidence of 40°, 41°, 42°,... 50° were tried and the answer was 47°.

With modern computing facilities it becomes feasible to investigate numerically in a systematic way the general problem of reflection and refraction at a plane boundary between two anisotropic media and to search for other examples of change in the state of polarization of elastic waves similar to the one described in this paper. Musgrave (1960) recently calculated the amplitudes and energy fluxes of elastic waves reflected at an internal crystal–air plane boundary in hexagonal crystals (beryl, zinc, ice) for various orientations and directions of incidence. His graphs show that cases of total mode conversion from longitudinal to transverse can also be found in zinc and beryl for some special orientations and directions of incidence.

ACKNOWLEDGMENTS

I am grateful to Mr. G. Gifford for his assistance in part of the calculations and to Mr. M. J. P. Musgrave for showing me the unpublished results of his calculations and for making helpful suggestions regarding the presentation of this paper.

Horizontal Refraction in a Three-dimensional Medium of Variable Stratification

By D. E. WESTON

Admiralty Research Laboratory, Teddington, Middlesex

M.S. received 12*th December* 1960

Abstract. In the sea the repeated horizontal deflection of a sound ray due to reflection at a sloping bottom produces a curvature of the horizontal path. The reflection angles in three dimensions are calculated for a sloping bottom or sound velocity interface. Even if the stratification varies in both horizontal directions there is for slow variations a simple relation between the changes in vertical and horizontal ray angle. It is then shown that the horizontal curvature may be predicted by associating a refractive index or phase velocity with each horizontal position. A formula for intensity and some illustrative problems are presented. For example it is shown that on reflection from a coastline the vertical ray angle at closest approach is equal to half the total horizontal angle through which the ray is turned.

---

§ 1. Introduction

In a previous paper (Weston 1959, to be referred to as I) the problem of rays in a two-dimensional stratified medium (or centrally symmetrical three-dimensional medium) was considered, only slow changes in structure and depth being allowed. For a ray in a given locality a characteristic time T was defined by

$$T = \int_0^H \frac{\sin \phi dh}{c} \qquad \ldots\ldots(1)$$

where H is the depth (of water), h the measurement depth, ϕ the (vertical) angle the ray makes with the boundaries, and c the local sound velocity. T was shown to be constant for the ray, independent of locality.

These ideas are extended here to the three-dimensional medium where the structure and depth are allowed to vary slowly in both horizontal directions, a subject only touched on qualitatively in the previous paper. The theory is general and holds for both elastic and electromagnetic waves, but the major application in mind is to low-frequency underwater sound propagation. Thus each time a sound ray is reflected at a sloping bottom it is deflected horizontally, producing a curvature of the horizontal path (Fig. 1). It is shown that this curvature may be conveniently predicted by associating a refractive index or phase velocity with each horizontal position, hence the term 'horizontal refraction' in the title. No experimental results are given but a few detailed applications are considered. No relevant published work is known to the author apart from Weston (1959), though the idea of a horizontal deflection at a sloping bottom is not new.

§ 2. REFLECTION IN THREE DIMENSIONS AT A SLOPING BOTTOM

Reflection at a sloping bottom is difficult to visualize, but detailed visualization is perhaps unimportant since the calculation is straightforward if direction cosines are used. Set up an x, y, z orthogonal coordinate system with x and y horizontal and z vertical, x being measured along the contours, and y in the direction of greatest downward bottom slope α (see Fig. 1). Let the horizontal projection of the incident ray make an angle θ with the x axis. Direction cosines for the incident ray are

$$\cos\phi\cos\theta, \qquad \cos\phi\sin\theta, \qquad \sin\phi.$$

For a tilted coordinate system x, y', z' with y' lying in the bottom the direction cosines are

$$\cos\phi\cos\theta, \qquad \cos\phi\sin\theta\cos\alpha+\sin\phi\sin\alpha, \qquad \sin\phi\cos\alpha-\cos\phi\sin\theta\sin\alpha$$

After reflection they become

$$\cos\phi\cos\theta, \qquad \cos\phi\sin\theta\cos\alpha+\sin\phi\sin\alpha, \qquad -\sin\phi\cos\alpha+\cos\phi\sin\theta\sin\alpha.$$

Changing back to the xyz system and simplifying they become

$$\cos\phi\cos\theta, \qquad \cos\phi\sin\theta\cos 2\alpha+\sin\phi\sin 2\alpha, \qquad \cos\phi\sin\theta\sin 2\alpha-\sin\phi\cos 2\alpha.$$

Consider first the vertical ray angle, the third direction cosine above becoming for α very small equal to $-\sin(\phi-2\alpha\sin\theta)$. Thus the change in vertical ray angle is controlled by the parallel component of slope $\alpha\sin\theta$, and the orthogonal component has only a second-order effect. The vertical ray angles will depend only on the profiles along the ray track, and it was under these conditions that it was shown in I that there is a unique characteristic time T (Eqn (1)) independent of locality for a given ray.

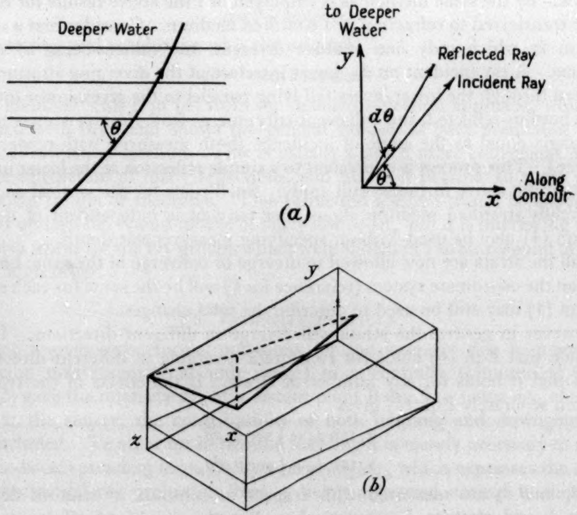

Fig. 1. (*a*) Plan views of ray geometry; (*b*) isometric view of ray geometry.

Secondly consider the horizontal angle, and twist to a coordinate system x'', y'', z with x'' along the horizontal projection of the incident ray. The first two direction cosines become

$$\cos\phi\sin^2\theta\cos 2\alpha+\sin\phi\sin\theta\sin 2\alpha+\cos\phi\cos^2\theta,$$
$$\cos\phi\sin\theta\cos\theta\,(\cos 2\alpha-1)+\sin\phi\cos\theta\sin 2\alpha.$$

The tangent of the horizontal deflection angle is given by the somewhat unwieldy ratio of the second to first direction cosine. However, for α small it simplifies to $+2\alpha\cos\theta\tan\phi$, or $2\tan\phi$ times the orthogonal component of slope (also quoted in I). The positive sign shows that deflection is towards the deeper water. In practice in the sea both α and ϕ are commonly small, and the horizontal deflection may sometimes be neglected. On other occasions it may be quite appreciable or even large, especially if there are several reflections.

Summarizing for α very small

$$d\phi=-2\alpha\sin\theta \qquad \ldots\ldots(2)$$

$$d\theta=+2\alpha\cos\theta\tan\phi \qquad \ldots\ldots(3)$$

whence

$$\tan\theta\,d\theta=-\tan\phi\,d\phi. \qquad \ldots\ldots(4)$$

These three equations are the most important result of this section.

§ 3. EXTENSION TO A MEDIUM OF VARIABLE STRATIFICATION

Although bottom slope is the most important cause of horizontal deflections, horizontal changes in water structure may also contribute. It will be shown that Eqn (4) applies whatever the changes in velocity structure, provided they are slow. By the same method as is employed in I the above results for reflection will be transferred to refraction in a stratified medium. Consider first a stratified medium in which only one stratum diverges, the others being of constant thickness. A ray incident on the lower interface of the diverging stratum will be refracted through the lower layers (all lying parallel to the given lower interface), will be bottom-reflected, and will eventually emerge from the given lower interface at an angle equal to the angle of incidence (both measured with respect to the interface). This process is equivalent to a simple reflection at the lower interface, so that all the above formulae still apply. Snell's law for the vertical angles in a horizontally stratified medium shows that $\tan\phi\,d\phi$ is independent of depth, so that Eqn (4) may be used without specifying measurement depth.

If all the strata are now allowed to diverge or converge in the same horizontal direction the coordinate system (reference for θ) will be the same for each stratum, and Eqn (4) may still be used to describe the total changes.

However in general the strata will diverge in different directions. If it can be shown that Eqn (4) holds for two strata diverging in different directions, it follows that it holds for any number of strata. If the effects of the two strata are taken separately Eqn (3) gives

$$\alpha_1\tan\phi_1=\tfrac{1}{2}\sec\theta_1\,d\theta_1 \qquad \ldots\ldots(5)$$

$$\alpha_2\tan\phi_2=\tfrac{1}{2}\sec\theta_2\,d\theta_2. \qquad \ldots\ldots(6)$$

Here θ_1 and θ_2 are measured with respect to contours of stratum depth for stratum 1 and stratum 2 respectively. For the combined effect some new coordinate or contour system must be chosen. It is necessary to choose so that there are no changes in horizontal angle (i.e. $d\theta$ is zero) on moving normal to the contours, and θ will lie between θ_1 and θ_2

$$\alpha_1 \tan\phi_1 \sin(\theta-\theta_1) = \alpha_2 \tan\phi_2 \sin(\theta_2-\theta). \qquad \ldots\ldots(7)$$

This is also the condition for $\tan\phi\, d\phi$ to be zero (or $c\sec\phi$ to be constant) when moving along the contours. Substituting Eqns (5) and (6) into (7) and rearranging

$$\tan\theta(d\theta_1+d\theta_2) = \tan\theta_1\, d\theta + \tan\theta_2\, d\theta_2$$
$$= -\tan\phi_1\, d\phi_1 - \tan\phi_2\, d\phi_2. \qquad \ldots\ldots(8)$$

Thus the complete generality of Eqn (4) is established for slow changes, θ being measured with respect to the contours of $c\sec\phi$ and $\tan\phi\, d\phi$ being measured in any stratum ($d\theta$ and $d\phi$ are now the total changes in angle due to divergence of all the strata).

§ 4. HORIZONTAL REFRACTION

Consider now the horizontal projection of the ray path, which consists of a series of lines connecting the bottom bounces. Actually each line is also slightly curved or kinked due to ray passage through the sloping interfaces. If all the slopes are small these lines will approximate to a continuous curve.

Associated with each ray group there is a horizontal velocity $c\sec\phi$, which corresponds to the mode phase velocity (see I). Snell's law for vertical refraction shows that at a given position $c\sec\phi$ is independent of depth. For low-order *modes* the horizontal path can of course be predicted from the horizontal variations in refractive index or phase velocity. Take therefore Snell's law for *horizontal* refraction of modes having the phase velocity $c\sec\phi$ (see Fig. 1)

$$\cos\theta = kc\sec\phi. \qquad \ldots\ldots(9)$$

Differentiating and combining with the original

$$d\theta = -\cot\theta\tan\phi\, d\phi. \qquad \ldots\ldots(10)$$

This is identical with Eqn (4) from the detailed reflection approach, which was concerned with *rays*, and shows the general validity of path prediction by the horizontal refraction method. This is usually a much more convenient method than the calculation of many reflections, and makes it possible to apply several well-known results or theorems. This refraction method would be expected to work for underwater sound modes of fairly low order, and it is interesting to note that it also works for the ray groups which were shown in I to correspond to modes of very high order.

§ 5. INTENSITY FORMULA

Paper I gives some formal equations for the intensity due to a source A (producing unit intensity at unit range) in a centrally symmetrical region. Eqn (42) gave the intensity dI_B at a distant point B due to a range $d\phi_A$ of vertical angles at the source, the contributions of both upgoing and downgoing rays being included. To allow for horizontal focusing it is merely necessary to replace the cylindrical spreading term $1/r$ by a term $d\theta_A/dq_B$ which expresses the density of the horizontal ray projection lines, q being measured normal to these lines

$$dI_B = \frac{2\cos\phi_A\, d\phi_A\, d\phi_B}{c_B\, dT}\,\frac{d\theta_A}{dq_B}. \qquad \ldots\ldots(11)$$

This effect of horizontal refraction on intensity is usually small, but not always so for a limited range of vertical angles. However, at a given position any horizontal focusing will occur for only one group of vertical angles—and since to get the total intensity Eqn (11) must be integrated over all the allowed vertical angles the overall effect is still usually small.

It is possible to devise situations in which there is some reinforcement over a wide range of angles, for example a long and relatively narrow channel or trough in the ocean or a long lake or sea-loch. The sound rays incident on the sloping walls will be turned back into the centre of the channel, and eventually bounce along between the two walls. There is a close analogy with the vertical sound channels in the sea, and the result is trapping in both the vertical and the horizontal dimension with formally no further spreading loss. Similarly in an ocean basin or enclosed lake of smooth profile, rays of suitable angle might travel round and round without ever escaping, nor ever hitting the bottom at a high angle.

It must be remembered that there are various limitations to the above formula (11), in addition to the condition of slowness of change. The most important is that losses on bottom reflection and other causes of attenuation are not included. These effects may sometimes be very small, for example with low-frequency sound which is refracted in the water at the bottom of its path rather than bottom-reflected. However, in general for comparison with experiment or for realistic prediction allowances must be made for these losses, for example in shallow water the important reflection losses are the controlling feature. One concept which is sometimes useful and sometimes meaningful is the Rayleigh critical angle or angle for total internal reflection; on simple theory there is no loss below this angle but a large loss above it. This idea is used in the next section, but it must be borne in mind that in practice the critical angle may be blurred and that even for angles below it there will always be residual losses.

§ 6. Reflection from a Coastline

6.1. *Arbitrary Smooth Bottom Profile*

To illustrate the above ideas a series of linked problems will be discussed. Consider first the reflection from a coastline or underwater bank. There are two extreme cases, either of which may produce a good reflection: a rough steep coastline with underwater precipices which can throw back the sound directly, or a smoothly and gently sloping coastline. An idealized form of the latter will be discussed, with contour lines of phase-velocity (corresponding roughly to depth contours) running parallel to the coast. For a given ray group the horizontal ray path will be of the type shown in Fig. 2 (which illustrates the special case treated later), and several points may be noted.

There will always be a bearing error, and even for the same ray group a destination downslope may be reached either by setting off downslope *or* by setting off upslope and curving round. The angles in this horizontal projection may be found from Snell's law, and the symmetrical form of Eqn (9) is

$$\cos\phi\cos\theta = kc. \qquad \ldots\ldots(12)$$

Therefore

$$\phi(\theta=0) \simeq \theta(\phi=0) \qquad \ldots\ldots(13)$$

and this is exact if c is constant. Thus whatever the shape of the underwater profile normal to the coast, the vertical ray angle ϕ_0 at closest approach is approximately equal to the horizontal angle θ_0 between the ray path when distant (deep water) and the coastline. The errors are negligible when ϕ_0 exceeds about 20°, so that the rays are little affected by the local velocity structure. This means that all the ray groups arriving from the θ_0 direction will have a similar vertical angle at their closest approach, and will undergo a similar number of bottom reflections in the process of turning round. This happens because the shallower the angle of the ray when distant the further inshore it penetrates, and the more sharply it turns round. The total loss in turning may depend strongly on whether or not ϕ_0 exceeds the critical angle. It will also of course depend on the mean bottom slope, since the greater the slope the fewer bottom reflections there will be in turning round. Both these criteria affect all ray groups similarly, so that similar turning round losses may be expected.

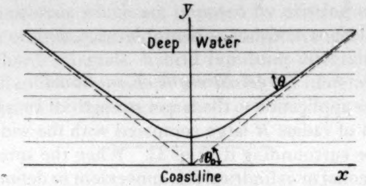

Fig. 2. Plan view of reflection from a coastline.

6.2. *Linear Bottom Profile*

It is instructive to treat the special case of the above when the bottom slope α is constant and the water is isovelocity. Eqn (13) is now exact and applies to all ray groups, and the geometry is such that an increase in vertical ray angle at a given point is equivalent to an increase in the general scale (ratio as $\sin\phi$ ratio). The horizontal path shape may be found directly from Eqn (12), substituting for $\cos\phi$ using Eqn (1)

$$\cos\theta\left\{1-\left(\frac{cT}{\alpha y}\right)^2\right\}^{1/2}=kc. \qquad \ldots\ldots(14)$$

This is one form of the equation of a hyperbola (as shown in Fig. 2), or rather a double set of hyperbolae. The arrival or asymptote angle θ_0 depends on the k and c, and the closest approach then depends on the slope α plus the T value or vertical angle group. The apparent turning round point of the ray is where the asymptote crosses the coast, at the origin of the coordinate system, and is the same for all ray groups arriving on θ_0. This means that for a distant source and distant receiver in the present model there is no dispersion in apparent bearing.

For this simple model the results expressed in Eqns (12) and (13) may also be reached rapidly from first principles. None of the reflections can affect the value of the first direction cosine, i.e. the component of ray velocity parallel to the x axis is a constant for the ray. The angle between the ray and the x direction must also be constant, so that the product $\cos\phi\cos\theta$ is constant as shown in (12).

Another useful concept is that of the images of the source, multiply reflected between the two surfaces. All the images will lie on a circle in the yz plane, centred on the x axis and passing through the source. A simple optical analogue may be constructed with two mirrors, when it is possible to see the complete circle of images. This still works for moderately large wedge angles, and is the principle of the kaleidoscope. There is a possibility of further optical analogue experiments, using vertical soap films which are thicker towards their lower edge.

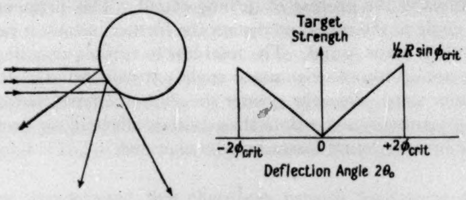

Fig. 3. Reflection from a circular island.

6.3. *Target Strength of an Island*

Consider lastly the application to the target strength of an island, assuming the island is circular and of radius R large compared with the width of the region of (gentle) bottom slope surrounding it (Fig. 3). When the spreading of sound is basically two-dimensional or cylindrical it is convenient to define target strength as

$$\frac{\text{intensity at unit distance of cylindrically spreading scattered wave}}{\text{intensity of incident parallel beam}} . \qquad \dots\dots(15)$$

From Fig. 3 the power intercepted by an elementary circumferential length ds is proportional to $\sin\theta\, ds$, and at unit range this same power in the reflected wave is spread over a wave front $2\,ds/R$. The quotient gives the target strength for a perfect reflector of local radius of curvature R (not restricted to full circle):

$$\text{Target strength} = \tfrac{1}{2}R\sin\theta. \qquad \dots\dots(16)$$

A first approximation to what might really happen is to assume perfect reflection up to the critical angle ϕ_{crit} and zero thereafter, and the result is shown in Fig. 3. This suggests that the best reflection may occur for deflection angles of the order of $\pm 30°$, unless the coast is rough or steep-to.

§ 7. CONCLUSIONS

Some results have been established for propagation in a three-dimensional stratified medium in which there are slow random variations of the stratification with horizontal position. The changes in vertical and horizontal ray angle on reflection at a sloping bottom or interface are given in Eqns (2) and (3), and it is shown that the simple relation between the two (Eqn (4)) still holds for the total changes due to all strata. The chief result of the paper is that the horizontal ray path refraction may be calculated by associating a phase velocity $c\sec\phi$ with each horizontal position. This has many applications in underwater sound propagation, some of which have been discussed.

Evaluation of Molecular Integrals by a Numerical Method

By E. A. MAGNUSSON[†] and C. ZAULI[‡]
Department of Chemistry, University College London

Communicated by D. P. Craig; MS. received 14*th November* 1960, *in revised form* 22*nd December* 1960

Abstract. Numerical integration in elliptical coordinates is proposed as a convenient method for the computation of most types of two-electron molecular integrals including some types of three- and four-centre integrals, and in some cases, of one-electron two- and three-centre integrals. This method removes a great deal of the burden of analysis and in addition lifts many of the restrictions on the form of the orbitals which are imposed by existing methods.

For Slater-type orbitals general formulae are given to facilitate the calculation of two-centre Coulomb integrals, hybrid repulsion integrals and certain three-centre integrals. Explicit expressions are listed for integrals involving orbitals of the first, second and third quantum shell.

§ 1

SEVERAL general methods (Barnett and Coulson 1951, Kotani *et al.* 1955, Roothaan 1951, Rudenberg 1951, Rudenberg *et al.* 1956) are available for the computation of one- and two-electron two-centre molecular integrals involving Slater-type orbitals

$$\phi(nlm)=(2k)^{n+1/2}[(2n)!]^{-1/2}r^{n-1}\mathrm{e}^{-kr}Y_{lm}(\theta,\phi) \qquad \ldots\ldots(1)$$

where $n>l\geqslant m$ are integers and $Y_{lm}(\theta,\phi)$ spherical harmonics.

One-electron integrals are usually obtained in terms of auxiliary functions or given as explicit expressions containing the relevant parameters, but two-electron integrals present difficulties of another order.

Although numerous tables of auxiliary functions exist (Kotani *et al.* 1955, Kopinek 1950, 1951, 1952, Miller *et al.* 1959, Roothaan 1955), in terms of which it is possible to express most two-electron two-centre integrals over Slater orbitals (for principal quantum number $n\leqslant 2$), it is often a difficult procedure to reduce a particular integral to the required form. With some methods the amount of analysis is lessened by performing the final integration numerically (over a single variable) but this poses the problem of additional computation.

When orbitals beyond the second quantum shell or orbitals of unusual form are being considered these difficulties become very serious. In these cases the present method is particularly appropriate but its advantages apply also to the simpler situations. The method is based on numerical quadrature in two dimensions (in the case of multi-centre integrals, sometimes three dimensions) and requires no new mathematical formulation.

[†] Now at the Science Department, A.M. College, Cooranboug, N.S.W., Australia.

[‡] Now at the Istituto di Chimica Industriale dell'Università, 4 Viale Risorgimento, Bologna, Italy.

The accuracy of the method is limited by the sensitivity of the numerical method of integration to variation in the integrand. It thus depends on the number of points in space at which the integrand is evaluated. This is not a serious problem when digital computing facilities are available and the demands on time are in most cases reasonable even for computation by desk machines, especially when two- or three-place accuracy is adequate.

§ 2. ONE-ELECTRON INTEGRALS

2.1. *Two-centre Integrals*

Assuming a system of elliptical coordinates with the two centres A and B as foci, then, as long as the normalized wave functions belong to the class (2)†,

$$\phi_i = [C_i/2\pi]^{1/2} f_i(\mu, \nu) \exp(im_i\phi) \qquad \ldots\ldots(2)$$

where C_i is a normalizing constant, the formulation of the integrand for a two-dimensional numerical integration is trivial. When the operator involved is a function of the coordinates, e.g. $M_\gamma(\theta, \phi) \exp(im_\gamma\phi)$, then the integral may be expressed as

$$(\phi_\alpha|M_\gamma|\phi_\beta) = \frac{R^3}{8}[C_\alpha C_\beta]^{1/2}\delta(m_\alpha - m_\beta + m_\gamma)\int_1^\infty\int_{-1}^1 f_\alpha{}^* f_\beta M_\gamma(\mu^2 - \nu^2)\, d\nu\, d\mu \qquad \ldots\ldots(3)$$

while in the case of the kinetic energy operator it is

$$(\phi_\alpha| -\tfrac{1}{2}\Delta|\phi_\beta) = \frac{R}{4}[C_\alpha C_\beta]^{1/2}\delta(m_\alpha - m_\beta)\int_1^\infty\int_{-1}^1 \Big[(\mu^2-1) f_{\alpha\mu}{}^* f_{\beta\mu} + (1-\nu^2) f_{\alpha\nu}{}^* f_{\beta\nu} - m^2\Big\{\frac{1}{(\mu^2-1)} + \frac{1}{(1-\nu^2)}\Big\} f_\alpha{}^* f_\beta\Big]\, d\nu\, d\mu \qquad \ldots\ldots(4)$$

where R is the internuclear distance and $f_{i\omega} = \partial f_i/\partial\omega$.

The choice of wave function permitted by Eqn (2) is wide enough to make the method useful when ordinary analytical procedures become impracticable, e.g., when the θ-dependence of an orbital function is subjected to a variational treatment; when n is non-integral; in cases where 'bond orbitals' are used; when analytical approximations to Hartree–Fock orbitals are being considered; and finally, in the case of Hartree–Fock atomic orbitals in numerical form.

2.2. *One-electron Three-centre Integrals*

The type of one-electron three-centre integral which usually occurs in molecular calculations is

$$(\phi_\alpha|r_C{}^{-1}|\phi_\beta) = \int \phi_\alpha{}^*(1)\phi_\beta(1)\frac{1}{r_C}\, d\tau_1. \qquad \ldots\ldots(5)$$

Centre C is taken to have coordinates x_C, y_C and z_C in $R/2$ units with respect to a Cartesian system with origin in the midpoint of AB and with its z-axis coincident with AB (see for instance Eyring, Walter and Kimball 1944). Here the orbital quantization along the z-axis loses its meaning and real functions are most conveniently employed: the ϕ-dependent part of the orbitals will here be indicated as Φ_i. If $1/r_{\mathrm{C}}$ is expressed in elliptical coordinates Eqn (5) becomes

---

† The form of these functions is subjected to the obvious limitations that the molecular integrals must converge.

$$(\phi_\alpha|r_{\mathrm{C}}^{-1}|\phi_\beta)=\frac{R^2}{4}[C_\alpha C_\beta]^{1/2}\int_1^\infty\int_{-1}^1 f_\alpha f_\beta(\mu^2-\nu^2)$$
$$\times\int_0^{2\pi}\Phi_\alpha\Phi_\beta[\mu^2+\nu^2-2\mu\nu z_{\mathrm{C}}+R_{\mathrm{C}}^2-1-2(\mu^2-1)^{1/2}$$
$$\times(1-\nu^2)^{1/2}(x_{\mathrm{C}}\cos\phi+y_{\mathrm{C}}\sin\phi)]^{-1/2}\,d\phi\,d\nu\,d\mu \qquad \ldots\ldots(6)$$

with $R_{\mathrm{C}}^2=x_{\mathrm{C}}^2+y_{\mathrm{C}}^2+z_{\mathrm{C}}^2$. In a few cases the integration over ϕ may be carried out analytically, but this is not generally feasible: for the trivial case $x_{\mathrm{C}}=y_{\mathrm{C}}=0$ (i.e. A, B and C collinear) in which the z-axis quantization is retained Eqn (6) is written

$$(\phi_\alpha|r_{\mathrm{C}}^{-1}|\phi_\beta)=\frac{R^2}{4}[C_\alpha C_\beta]^{1/2}\delta(m_\alpha-m_\beta)$$
$$\times\int_1^\infty\int_{-1}^1 f_\alpha^* f_\beta[\mu^2+\nu^2-2\mu\nu z_{\mathrm{C}}+z_{\mathrm{C}}^2-1]^{-1/2}(\mu^2-\nu^2)\,d\nu\,d\mu$$
$$\ldots\ldots(6\,a)$$

and may thus be computed by two-dimensional numerical integration. The more general case (6) is best dealt with by three-dimensional numerical integration if a cumbersome expansion of $1/r_{\mathrm{C}}$ is to be avoided. Examples are given in §4.

§ 3. Two-electron Integrals

3.1. *Two-centre Integrals*

In the elliptical system of reference with foci A and B, all types of two-centre integrals (i.e. Coulomb, exchange and hybrid integrals) may be dealt with in the same notation:

$$(\phi_\alpha\phi_\beta|r_{12}^{-1}|\phi_\gamma\phi_\delta)=\int\phi_\alpha^*(1)\phi_\beta(1)U_{\gamma\delta}\,d\tau_1 \qquad \ldots\ldots(7)$$

with

$$U_{\gamma\delta}=\int\phi_\gamma^*(2)\phi_\delta(2)r_{12}^{-1}\,d\tau_2. \qquad \ldots\ldots(8)$$

The potential $U_{\gamma\delta}$ in elliptical coordinates may be written as

$$U_{\gamma\delta}=\frac{R^2}{2}[C_\gamma C_\delta]^{1/2}u_{\gamma\delta}(\mu,\nu)\exp(iM\phi) \qquad \ldots\ldots(8\,a)$$

and Eqn (7) thus becomes

$$(\phi_\alpha\phi_\beta|r_{12}^{-1}|\phi_\gamma\phi_\delta)=\frac{R^5}{16}[C_\alpha C_\beta C_\gamma C_\delta]^{1/2}\delta[M+M']$$
$$\times\int_1^\infty\int_{-1}^1 f_\alpha^* f_\beta u_{\gamma\delta}(\mu^2-\nu^2)\,d\nu\,d\mu \qquad \ldots\ldots(9)$$

with $M'=m_\alpha-m_\beta$ and $M=m_\gamma-m_\delta$.

To perform numerical integration after Eqn (9) explicit expressions for $u_{\gamma\delta}$ are needed. In general the potential $U_{\gamma\delta}$ may be obtained (Wang 1939) by solving the corresponding Poisson equation

$$\nabla^2U_{\gamma\delta}=-4\pi\phi_\gamma^*\phi_\delta \qquad \ldots\ldots(10)$$

so that $u_{\gamma\delta}$ is a solution of Eqn (10 *a*)

$$\frac{\partial}{\partial\mu}\left[(\mu^2-1)\frac{\partial u_{\gamma\delta}}{\partial\mu}\right]+\frac{\partial}{\partial\nu}\left[(1-\nu^2)\frac{\partial u_{\gamma\delta}}{\partial\nu}\right]-M^2u_{\gamma\delta}\left[\frac{1}{(\mu^2-1)}+\frac{1}{(1-\nu^2)}\right]=-(\mu^2-\nu^2)f_\gamma{}^*f_\delta. \qquad \ldots\ldots(10\,a)$$

How best to solve this equation depends on the form of the functions $f_i(\mu, r)$. In some cases this presents analytical difficulties. If it is convenient to expand the product $f_\gamma{}^*f_\delta$ in terms of associated Legendre functions of the first kind (Tauber 1959)

$$f_\gamma{}^*f_\delta=\frac{1}{(\mu^2-\nu^2)}\sum_{n=M}^{\infty}U_n{}^M(\mu)\mathrm{P}_n{}^M(\nu) \qquad \ldots\ldots(11)$$

then the general form for $u_{\gamma\delta}$ is

$$u_{\gamma\delta}=\sum_{n=M}^{\infty}\frac{\mathrm{P}_n{}^M(\nu)}{C_n{}^M}\left[\mathrm{P}_n{}^M(\mu)\int_\mu^\infty U_n{}^M(\mu)\mathrm{Q}_n{}^M(\mu)\,d\mu+\mathrm{Q}_n{}^M(\mu)\int_1^\mu U_n{}^M(\mu)\mathrm{P}_n{}^M(\mu)\,d\mu\right] \qquad \ldots\ldots(12)$$

where (Hobson 1931)

$$C_n{}^M=2^{2M}\frac{\Gamma(1+\frac{1}{2}M+\frac{1}{2}n)\Gamma(\frac{1}{2}+\frac{1}{2}M+\frac{1}{2}n)}{\Gamma(1-\frac{1}{2}M+\frac{1}{2}n)\Gamma(\frac{1}{2}-\frac{1}{2}M+\frac{1}{2}n)} \qquad \ldots\ldots(12\,a)$$

and $\mathrm{Q}_n{}^M$ are associated Legendre functions of the second kind. It is often possible to perform the integration over the independent variable ν analytically (Tauber 1959). In general, the use of Eqn (12) will be practical when the sum (11) consists of a finite number of terms.

In what follows discussion is restricted to the situation in which ϕ_γ and ϕ_δ are defined by a polar system of coordinates centred on the same nucleus, say A; two-centre exchange integrals, which measure the interaction between charge distributions both of which are bi-centric, are thus excluded.

If the charge distribution $f_\gamma{}^*f_\delta$ is spherically symmetrical, the corresponding Poisson equation reduces (Hartree 1957) to

$$d^2[u_{\gamma\delta}r]/dr^2=-2r^{-1}f_\gamma{}^*f_\delta \qquad \ldots\ldots(13)$$

where $u_{\gamma\delta}$ is now related to the potential in the following way

$$U_{\gamma\delta}=[C_\gamma C_\delta]^{1/2}u_{\gamma\delta}. \qquad \ldots\ldots(13\,a)$$

Eqn (13) may be readily integrated even when the charge distribution is given in tabular numerical form; this suggests that the numerical data obtained from Hartree–Fock calculations on atomic configurations can be used to obtain accurate potentials which should represent a considerable improvement on core potentials obtained with conventional Slater orbitals. Such types of potentials have been found to be well represented by analytical expressions consisting of a very few exponential terms, so that Coulomb and hybrid integrals involving spherically symmetrical configurations of Hartree–Fock orbitals may be readily computed.

When the distribution of charge $f_\gamma{}^*f_\delta$ is not spherically symmetrical, more convenient methods than the direct solution of Eqn (10) may be used.

A list of potentials for real orbitals with $n \leqslant 2$ is given in the paper of Barnett and Coulson (1951) and of Roothaan (1951). A more complete list appears in Table 1 for potentials arising from products of complex orbitals† with $l_\gamma + l_\delta \leqslant 4$

---

† Integrals involving real orbitals may always be expressed in terms of those involving complex orbitals.

for any integral value of n. These are expressed in terms of auxiliary functions defined in the Appendix. Table 2 lists these functions explicitly for products of orbitals with $n \leqslant 3$.

These tables make it possible to compute any hybrid and Coulomb repulsion integral which has one of its charge distributions centred on A and represented by a product of orbitals of type (1). No restriction need be applied to the analytical form of the other charge distribution.

3.2. *Many-centre Two-electron Integrals*

If A and B are the foci of the elliptical system of coordinates to which ϕ_γ and ϕ_δ are referred, the general type of many-centre two-electron integral is written

$$(\phi_\alpha\phi_\beta|r_{12}^{-1}|\phi_\gamma\phi_\delta) = \int \phi_\alpha(\mu'\nu'\phi'|1)\phi_\beta(\mu'\nu'\phi'|1)U_{\gamma\delta}(\mu,\nu)\,d\tau_1. \qquad \ldots\ldots(14)$$

where the primed coordinates are those of the elliptical system which specify ϕ_α and ϕ_β. The problem is to express these coordinates in terms of μ, ν and ϕ of the reference system.

Supposing ϕ_α and ϕ_β to be functions of coordinates with centres C and D as foci, then the simplest type of four-centre integral occurs when $\phi' = \phi$, i.e. all four centres lie in a straight line.

Integral (14) is thus written

$$(\phi_\alpha\phi_\beta|r_{12}^{-1}|\phi_\gamma\phi_\delta) = \frac{R^5}{16}[C_\alpha C_\beta C_\gamma C_\delta]^{1/2}\delta(M+M')\int_1^\infty\int_{-1}^1 f_\alpha^*(\mu',\nu')f_\beta(\mu',\nu')u_{\gamma\delta} \times (\mu^2-\nu^2)\,d\nu d\mu \qquad \ldots\ldots(15)$$

where μ', ν' are related to μ and ν in the following way

$$\left.\begin{matrix}\mu'\\ \nu'\end{matrix}\right\} = \frac{R}{R_{\mathrm{cd}}}[(\mu^2+\nu^2-2\mu\nu z_{\mathrm{c}}-1+z_{\mathrm{c}}^2)^{1/2} \pm (\mu^2+\nu^2-2\mu\nu z_{\mathrm{d}}-1+z_{\mathrm{d}}^2)^{1/2}]. \qquad \ldots\ldots(15\,a)$$

R_{cd} is here the distance between centres C and D, and z_{c}, z_{d} are the z-coordinates of these points referred to the Cartesian system with origin at the midpoint of AB (Eyring *et al.* 1944).

When centres C and D do not lie on the z-axis real functions for the ϕ-dependent part of the orbitals are more conveniently used [cf. Eqn (6)]†.

In the case where ϕ_α and ϕ_β possess no ϕ-dependence we have, indicating with $\Phi_{\gamma\delta}$ the ϕ-dependent part of the potential‡,

$$(\phi_\alpha\phi_\beta|r_{12}^{-1}|\phi_\gamma\phi_\delta) = \frac{R^5}{32\pi}[C_\alpha C_\beta C_\gamma C_\delta]^{1/2}\int_1^\infty\int_{-1}^1\int_0^{2\pi} f_\alpha(\mu',\nu')f_\beta(\mu',\nu')u_{\gamma\delta}(\mu^2-\nu^2) \times \Phi_{\gamma\delta}\,d\phi\,d\nu\,d\mu \qquad \ldots\ldots(16)$$

---

† For the particular situation where the centres are coplanar and the axis of quantization of the third or fourth centre is parallel to that of the first and second centres we have

$$\tan\phi' = \tan\phi - \frac{y_{\mathrm{c}}}{(\mu^2-1)^{1/2}(1-\nu^2)^{1/2}\cos\phi}.$$

For other arrangements of centres the expression may be more complicated.

‡ Potentials $U_{\gamma\delta}$ for real functions may always be obtained as linear combinations of potentials generated by complex orbitals.

Table 1†. Potentials generated by Products $\phi_\gamma{}^*(nlm)\phi_\delta(n'l'm')$ of Complex Slater Orbitals centred on Nucleus A

$$U_{nlm,\,n'l'm'} = (2l+1)^{1/2}(2l'+1)^{1/2}k_{\mathrm{a}}\rho_{\mathrm{a}}{}^{N+1}\,\frac{(1+\tau_{\mathrm{a}})^{n+\frac{1}{2}}(1-\tau_{\mathrm{a}})^{n'-\frac{1}{2}}}{[(2n)!(2n')!]^{1/2}}\,u_{nlm,\,n'l'm'}\,\mathrm{e}^{iM\phi}$$

where $\rho_{\mathrm{a}} = 2k_{\mathrm{a}}r_{\mathrm{a}} = k_{\mathrm{a}}R(\mu+\nu)$; $k_{\mathrm{a}} = (k_\gamma + k_\delta)/2$; $N = n+n'-1$; $M = m'-m$.
The functions $u_{nlm,\,n'l'm'}$ are here listed.

† For convenience the $A_{\alpha 0}^{\gamma 00}$'s are written as A_α^γ.

---

while the relations between μ', ν' and μ, ν are

$$\left.\begin{matrix}\mu' \\ \nu'\end{matrix}\right\} = \frac{R}{R_{cd}}\, [\{\mu^2+\nu^2-2\mu\nu z_c+R_c{}^2-1-2(\mu^2-1)^{1/2}(1-\nu^2)^{1/2}(x_c\cos\phi+y_c\sin\phi)\}^{1/2}$$
$$\pm\{\mu^2+\nu^2-2\mu\nu z_d+R_d{}^2-1-2(\mu^2-1)^{1/2}(1-\nu^2)^{1/2}$$
$$\times(x_d\cos\phi+y_d\sin\phi)\}^{1/2}]. \qquad \ldots\ldots\ldots(17)$$

The variables are not easily separated and three-dimensional integration is again necessary. Examples are given in the next section.

§ 4. NUMERICAL INTEGRATION

Methods of quadrature involving constant increments of the variable (such as Simpson's or Weddle's rule) are usually the most suitable for computation on a desk machine, but for automatic machine computation the Gaussian method of quadrature is by far the most efficient (see Table 3).

Normally the integrand is found to vary rather rapidly for low values of μ. It is advisable to split the range of integration over this variable, choosing a finer net for the lower range. The values of S and T in the two ranges $1 \leqslant \mu \leqslant S$ and $S \leqslant \mu \leqslant T$ need to be chosen with due regard for the type of wave function and the internuclear distance but, in general, S may be taken between 1·5 and 2, and T will rarely need to be assigned a value greater than 10. In practice the upper limit T is determined by finding the value of μ which makes the integrand negligible in respect of the last accurate figure desired for the value of the integral. For instance, if five decimal figure accuracy is wanted T will be chosen equal to the value of μ which makes the integrand less than 10^{-6}–10^{-7}. For many types of two-centre integrals it has been found that a good choice of S is $1+0{\cdot}1T$. As far as three-centre integrals of the type $(\phi_a|r_c^{-1}|\phi_b)$ are concerned a convenient value of S is the coordinate μ of the third centre C; the problems arising from the discontinuity of the integrand when r_c is zero are thus avoided. The same choice of S has been found convenient also for two-electron integrals of the type $(\phi_a\phi_a|r_{12}^{-1}|\phi_b\phi_c)$.

For Gaussian integration no transformation of the range of integration over the variable ν is required, while for the variable μ in the range $A \leqslant \mu \leqslant B$ a transformation of the following type is needed

$$\mu = \tfrac{1}{2}(B-A)\mu' + \tfrac{1}{2}(B+A)$$

but with simplified coding systems now so widely used, programming requires very little time. Using a Ferranti MERCURY computer and a net of 512 points we have been able to obtain at least six significant figure accuracy for two-centre Coulomb and hybrid integrals which are found in the literature, and for integrals involving 3*d*-orbitals, which were computed by a conventional method (Barnett and Coulson 1951). For two-dimensional integration on the Ferranti MERCURY computer the computing time is generally about 15 seconds for each value. Two or three significant figure accuracy should usually be attainable for such cases by Weddle's rule integration on a desk machine over a net of 200–300 points.

An example of the calculation of a two-centre repulsion integral

$$(\phi_\alpha\phi_\alpha|r_{12}^{-1}|\phi_\beta\phi_\beta)$$

Table 3. Numerical Integration of a Two-centre Coulomb Repulsion Integral (see text). Internuclear Distance $R = 3$ A.U.

is given in Table 3. Here ϕ_α is a non-conventional type of orbital,

$$\phi_\alpha=\left\{\frac{A}{r}\left[e^{-kr}-e^{-k'r}\right]+B\,e^{-k''r}\right\}\cos\theta$$

and ϕ_β is a Slater $3d_{z^2}$ with exponent $k_{3d}=2/3$. Different methods of quadrature and nets of various sizes are compared.

Some calculations were also performed on three-centre integrals such as $(2p\pi_a|r_c^{-1}|2p\pi_b)$ and $(2p\pi_a2p\pi_a|r_{12}^{-1}|2p\pi_b2p\pi_c)$ which arise in the calculation of the benzene molecule. Three-dimensional numerical integration was carried out with lattices of various sizes: the results showed that an 8192 point lattice (16 points for both variables ν and ϕ, 32 for μ) gives for the above cases a five significant figure accuracy, which is not greatly improved using 12 288 or 16 384 points. A transformation of the range of integration identical with that described for μ is required for ϕ: the choice of the limits of integration of the latter variable depends on the symmetry of the integral, but it is recommended to begin the integration at a value of ϕ which, as for S, corresponds to the coordinate ϕ of the centre C. Since in the Gaussian method the points are more closely spaced at either end than they are in the middle of the integration range, this choice of limits produces the further advantage that the points are closest in those regions of space where the integrand is largest.

APPENDIX

The potentials listed in Table 1 have been obtained by a modification of the Roothaan and Rudenberg scheme (Roothaan 1951, Rudenberg 1951, Rudenberg *et al.* 1952–3, 1956). By transforming the product of Legendre functions $\theta_{lm}\theta_{l'm'}$ to give a sum, the product $\phi(nlm)\phi(n'l'm')$ is written as a linear combination of basic charge distributions $[NLM]$. The potential of such a distribution is given by

$$U_{NLM} = [2/(2L+1)]^{1/2}[b/NLO_{\mathrm{a}}]_{\rho_{\mathrm{a}}\to\sigma}\theta_{LM}(\theta)\,\mathrm{e}^{iM\phi} \qquad \ldots\ldots(18)$$

where $\sigma = (k_\gamma + k_\delta)r_{\mathrm{a}}$ and

$$[b/NLO_{\mathrm{a}}] = \int [NLO_{\mathrm{a}}]\, r_{\mathrm{b}}^{-1}\, d\tau. \qquad \ldots\ldots(18\,a)$$

Integrals (18 *a*) are obtained as follows. Let us define a function

$$\begin{aligned} A_{\alpha\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) = {} & (-1)^{\beta+\delta+\epsilon}\, 2^{-\alpha-\beta-\gamma-\delta-2\epsilon-1} \\ & \times \int_1^\infty \int_{-1}^1 \exp[-\tfrac{1}{2}\rho_{\mathrm{a}}(\mu+\nu)](\mu+\nu)^\alpha(\mu-\nu)^\beta(1+\mu\nu)^\gamma(1-\mu\nu)^\delta(\mu^2-1)^\epsilon \\ & \times (1-\nu^2)^\epsilon\, d\nu\, d\mu \end{aligned} \qquad \ldots\ldots(19)$$

simply related to the more general function (Roothaan 1951, Rudenberg 1951, Rudenberg *et al.* 1952–3, 1956)

$$A_{\alpha\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) = \lim_{\rho_{\mathrm{b}}\to 0} \rho_{\mathrm{b}}^{-\alpha-\beta-\gamma-\delta-2\epsilon-1} C_{\alpha\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}, \rho_{\mathrm{b}}). \qquad \ldots\ldots(19\,a)$$

Integrals (18 *a*) are linear combinations of functions (19) with $\beta = \delta = \epsilon = 0$, determined by the Legendre functions associated with $[NLO]$ and may thus be obtained by the symbolic substitution of $A_{N-n,\,0}^{n00}(\rho_{\mathrm{a}})$ for $\cos^n\theta$ in the Legendre function

$$[b/NLO_{\mathrm{a}}] = 2\rho_{\mathrm{a}}^{N+1} C\theta_{L0}[A_{N-n,\,0}^{n00} \to \cos^n\theta] \qquad \ldots\ldots(20)$$

where

$$C = k_{\mathrm{a}}(1+\tau_{\mathrm{a}})^{n+1/2}(1-\tau_{\mathrm{a}})^{n'+1/2}/[(2n)!(2n')!]^{-1/2}$$

and

$$k_{\mathrm{a}} = \tfrac{1}{2}(k_\gamma + k_\delta) \qquad \tau_{\mathrm{a}} = (k_\gamma - k_\delta)/(k_\gamma + k_\delta).$$

Thus since

$$\theta_{20} = (\sqrt{5}/2\sqrt{2})(3\cos^2\theta - 1),$$

we have

$$[b/N2O_{\mathrm{a}}] = \rho_{\mathrm{a}}^{N+1} C \frac{\sqrt{5}}{\sqrt{2}} [3A_{N-2,\,0}^{200} - A_{N0}^{000}].$$

Explicit expressions for $A_{\alpha\beta}^{\gamma\delta\epsilon}$ may be obtained through Eqn (19 *a*). However, this method is not always satisfactory since the existing list of $C_{\alpha\beta}^{\gamma\delta\epsilon}$ is not complete. The use of formulae for varying the indices of $A_{\alpha\beta}^{\gamma\delta\epsilon}$-functions has been found to be more satisfactory.

Some of these formulae are analogous to those given by Rudenberg *et al.* (1952–3) for the $C_{\alpha\beta}^{\gamma\delta\epsilon}$-functions.

Index α

$$\frac{\partial}{\partial\rho_{\mathrm{a}}} A_{\alpha\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) = -A_{\alpha+1,\,\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) \qquad \ldots\ldots(21)$$

$$A_{\alpha\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) = \int_{\rho_{\mathrm{a}}}^\infty A_{\alpha+1,\,\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}})\, d\rho_{\mathrm{a}} \qquad \ldots\ldots(21\,a)$$

Index γ

$$2A_{\alpha\beta}^{\gamma+1,\delta\epsilon}(\rho_{\mathrm{a}}) = A_{\alpha\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) + A_{\alpha+2,\,\beta}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) - A_{\alpha,\,\beta+2}^{\gamma\delta\epsilon}(\rho_{\mathrm{a}}) \qquad \ldots\ldots(22)$$

$$A_{0\beta}^{000}(\rho_{\mathrm{a}}) = 2\rho_{\mathrm{a}}^{-2}[\tfrac{1}{2}\beta(\beta-1)A_{0,\,\beta-2}^{000}(\rho_{\mathrm{a}}) + (-1)^\beta]. \qquad \ldots\ldots(22\,a)$$

The procedure to obtain a particular $A^{\gamma 00}_{\alpha 0}$ is thus:

$$\begin{tikzcd}
& A^{000}_{0\beta} \arrow[dr, "(21)", "(21a)"'] & & \\
A^{000}_{00} \arrow[ur, "(22a)"] \arrow[dr, "(21)", "(21a)"'] & & A^{000}_{\alpha\beta} \arrow[r, "(22)"] & A^{\gamma 00}_{\alpha 0} \\
& A^{000}_{\alpha 0} \arrow[ur, "(22)", "(22a)"'] & &
\end{tikzcd}$$

ACKNOWLEDGMENTS

We are indebted to Professors C. A. Coulson and D. P. Craig for their valuable comments and criticism.

The calculations were carried out with the help of tape-editing equipment purchased by means of a grant from the London University Central Research Fund. The research was in part supported under contract with the Air Research and Development Command of the U.S. Air Force (C.Z.); and one of us (E.A.M.) was supported by the Royal Society. Support by these bodies is gratefully acknowledged.

The g_J Value of the 6^3P_1 Level in Mercury

By J. N. DODD
Department of Physics, University of Otago, Dunedin, New Zealand

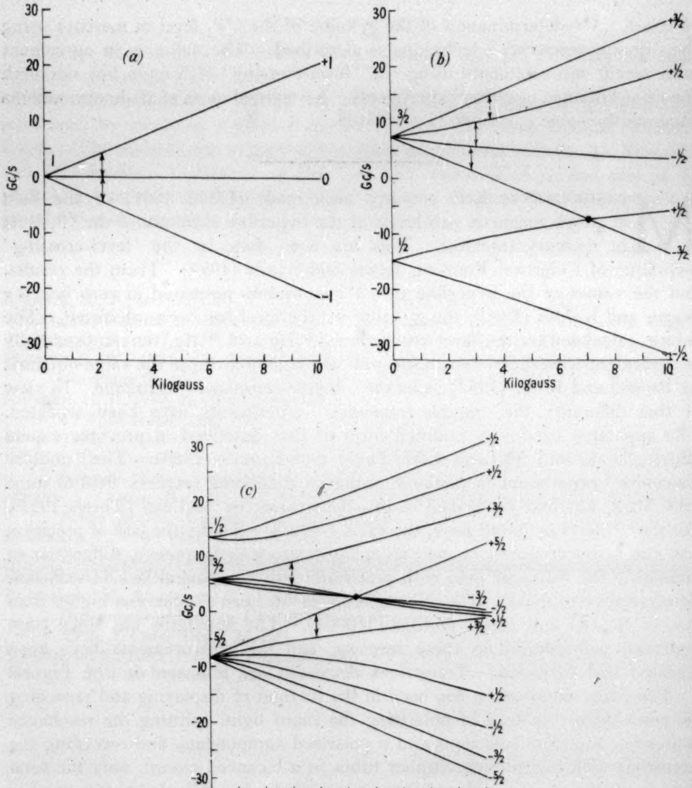
MS. received 21*st December* 1960

Abstract. A redetermination of the g_J value of the 6^3P_1 level in mercury using the 'double-resonance' technique is described. The value is in agreement with recent measurements using the 'level-crossing' technique but not with the value obtained in earlier experiments. A weighted mean of all determinations suggests the value $g_J = 1{\cdot}486\,31 \pm 0{\cdot}000\,08$.

MEASUREMENTS have recently been made (Dodd 1961) of the field at which magnetic sub-levels of the hyperfine structure of the $^3P_1$ level in mercury intersect. This has been done by the 'level-crossing' technique of Colgrove, Franken, Lewis and Sands (1959). From the results, and the values of the hyperfine coupling constants measured in zero field by Stager and Kohler (1960), the g_J value for the level has been calculated. The values, calculated for the level crossings in ^{199}Hg and ^{201}Hg, were substantially in agreement with each other, but significantly different from the value obtained by Brossel and Bitter (1952) using the 'double-resonance' technique. In view of this difference the 'double-resonance' experiments have been repeated. The apparatus used is a modified form of that described in previous papers (Bogle, Dodd and McLean 1957, Dodd and Kinnear 1960). The 'double-resonance' experiment in mercury, using an oscillating magnetic field of some 4300 Mc/s, was first performed in this department by McLean (Thesis 1957). For the $^3P_1$ level he found for g_J the value $1{\cdot}486(8) \pm 0{\cdot}006$; the lack of precision was due to uncertainties in measuring the microwave frequency, difficulties in measuring the magnetic field with precision, and to a general lack of sufficient signal relative to noise. It is to be noted that McLean's value was higher than that of Brossel and Bitter ($1{\cdot}4838 \pm 0{\cdot}0004$). The apparatus has since been improved considerably in these respects, and the measurements have been repeated and extended. Transitions discussed are indicated in the Figure.

The main modification has been in the method of displaying and recording the resonances. Instead of polarizing the input light, splitting the resonance fluorescent radiation into its π and σ polarized components, and recording the intensities with two photomultiplier tubes in a balanced circuit, only the total intensity of the resonance fluorescence is recorded using a single photomultiplier tube. The variation of this intensity with field arises from a superposition of the intensities of the π and σ polarized components. The variation with other parameters may be calculated from the unmodulated term in the complete expression for the intensity of resonance fluorescence (Dodd and Series 1961).

The 'steady' magnetic field was modulated at 9 c/s with a sweep amplitude of about 5 gauss. The reduction in intensity of fluorescent radiation as the magnetic field passed through resonance was displayed by a cathode-ray tube whose sweep was synchronized to the field modulation. It has been found possible to achieve a signal-to-noise ratio approaching 100 for the 'double-resonance' effect in the even isotopes. The field at which the resonance signal occurred was measured by a proton magnetometer using the substitution method described in an earlier paper (Dodd 1961). The field at which the maximum of the resonance signal occurred could be established to within about 0·1 gauss.



The Zeeman sub-levels of the 6^3P_1 level of mercury: (*a*) even isotopes, $I=0$; (*b*) ^{199}Hg, $I=\frac{1}{2}$; (*c*) ^{201}Hg, $I=\frac{3}{2}$. The levels are labelled by the quantum numbers F at zero field and m_F at high field. The arrows indicate the positions of 'double-resonance' signals for a frequency of 4344 Mc/s. The spots indicate the positions of 'level crossings'.

The amplitude of the oscillating magnetic field B_1 could be varied continuously by altering the power fed from the klystron to the microwave cavity. The amplitude could be made sufficient to cause the double-peaked effect discussed by Brossel and Bitter, and to broaden considerably the resonance curve. No detailed measurements were made, but it was confirmed that the peak separation agreed with the estimated value of B_1. In carrying out the determination of the steady field at the maximum of the resonance curve, the microwave power was lowered to about one-quarter of that available; under these conditions the resonance was single-peaked with a width little greater than that expected from the natural life of the $^3P_1$ level.

Extensive measurements established the resonant field to be that appropriate to a proton precessional frequency $f_P = 8{\cdot}8913 \pm 0{\cdot}0005$ Mc/s ($2088{\cdot}3 \pm 0{\cdot}1$ gauss). In contrast, however, to the 'level-crossing' experiments, where the accuracy was limited only by the field measurement, the 'double-resonance' experiment requires also a knowledge of the frequency of the oscillating field causing the transition in the excited level. This was measured by the use of a coaxial wavemeter, with a vernier scale calibrated to 0·001 cm. With careful use the random errors could be reduced below this figure. The wavelength was then corrected to vacuum wavelength, account being taken of the pressure, temperature, and humidity of the air. There remains the systematic error in the instrument. Comparison against good quality measuring instruments suggested that this was not greater than one vernier division. The error in measuring the wavelength, and hence the microwave frequency, was on this basis estimated at 2 parts in 10^4. The measured frequency, $f = 4344{\cdot}38 \pm 0{\cdot}90$ Mc/s, appeared to remain constant from day to day, and to be independent of the power levels used in exciting the cavity. Errors in the value of g_J, as quoted below, are estimated on the basis of this uncertainty in f.

For the 'double resonance' in the even isotopes the value of g_J may be calculated using the relation $g_J = g_P f/f_P$, in which g_P is the proton g-value given by Liebes and Franken (1959) to be $g_P = (328{\cdot}731)^{-1}$. Therefore,

$$g_J \text{ (even isotopes)} = 1{\cdot}486\,35 \pm 0{\cdot}000\,30.$$

Since the mercury resonance cell contained a natural isotopic mixture of mercury atoms, it was possible also to observe 'double-resonance' signals in the odd isotopes, ^{199}Hg and ^{201}Hg. The strongest of these comes from the transition $|`\tfrac{3}{2}', -\tfrac{1}{2}\rangle \longleftrightarrow |\tfrac{3}{2}, -\tfrac{3}{2}\rangle$† in ^{199}Hg. This was observed, with a signal-to-noise ratio of 5, at a field appropriate to a proton precessional frequency $f_P = 12{\cdot}3277 \pm 0{\cdot}0010$ Mc/s ($2895{\cdot}3 \pm 0{\cdot}2$ gauss). The value of g_J may be calculated from

$$g_J = g_P \frac{f}{f_P} \frac{3a+2f}{2a+2f} \left\{1 + \frac{\alpha}{2}\left(\frac{a}{a+f}\right)^2\right\}$$

where α is the ratio g_I/g_J, and a is the magnetic dipole coupling constant. If we assume $\alpha = 365 \times 10^{-6}$ and $a = 14\,752{\cdot}37$ Mc/s (Stager and Kohler 1960), substitution of the values of f and f_P obtained above yields

$$g_J(199) = 1{\cdot}486\,26 \pm 0{\cdot}000\,30.$$

---

† The notation is $|F, m_F\rangle$; the quotation marks indicate that F is not a good quantum number in the presence of a magnetic field.

In a search for other ‘double-resonance’ signals two smaller ones were observed and measured. One, which was observed with a signal-to-noise ratio of about 2, corresponds to the transition $|\tfrac{5}{2}, \tfrac{5}{2}\rangle \longleftrightarrow |\text{‘}\tfrac{5}{2}\text{’}, \tfrac{3}{2}\rangle$ in ^{201}Hg and gives $g_J(201) = 1{\cdot}486\,22 \pm 0{\cdot}000\,30$. A faint signal, with signal-to-noise ratio less than unity, appears to correspond to the $|\text{‘}\tfrac{3}{2}\text{’}, \tfrac{1}{2}\rangle \longleftrightarrow |\text{‘}\tfrac{3}{2}\text{’}, -\tfrac{1}{2}\rangle$ transition in ^{199}Hg. On the basis of this assignment, $g_J(199) = 1{\cdot}486\,15 \pm 0{\cdot}000\,50$. Calculation predicts that the signal due to the $|\tfrac{3}{2}, \tfrac{3}{2}\rangle \longleftrightarrow |\text{‘}\tfrac{3}{2}\text{’}, \tfrac{1}{2}\rangle$ transition in ^{199}Hg should be about $2\tfrac{1}{2}$ times that due to the transition last mentioned and should occur at a field of 3570 gauss. No resonance was observed, nor was the resonance due to the $|\text{‘}\tfrac{3}{2}\text{’}, \tfrac{3}{2}\rangle \longleftrightarrow |\text{‘}\tfrac{3}{2}\text{’}, \tfrac{1}{2}\rangle$ transition in ^{201}Hg expected at 2979 gauss.

These experiments were carried out with the cell at the centre of a heavy copper resonant cavity. Since the ‘level-crossing’ experiments were performed using the same cell encased in light copper or aluminium sheaths which, it had been confirmed, had zero or negligible magnetic effects, it was felt desirable to repeat the ‘level-crossing’ experiments with the cell mounted in the heavy cavity. A small shift of 1 part in 10^4 was observed. This is less than the uncertainty in the ‘double-resonance’ experiments, but about three times that in the ‘level-crossing’ experiments. It has been assumed that some small magnetic property of the cavity was responsible for the effect, and the results in this paper have been corrected.

Four measurements of ‘double-resonance’ phenomena in different isotopes of mercury have substantiated the higher value for g_J obtained in the ‘level-crossing’ experiments. The Table gives a summary of all results obtained by the two methods.

Isotope	Method	States of ^{3}P$_1$	g_J
even	double resonance	$|1, 1\rangle\ |1, 0\rangle\ |1, -1\rangle$	$1{\cdot}48635 \pm 0{\cdot}00030$
199	level crossing	$|\tfrac{3}{2}, -\tfrac{3}{2}\rangle\ |\text{‘}\tfrac{1}{2}\text{’}, \tfrac{1}{2}\rangle$	$1{\cdot}48634 \pm 0{\cdot}00005$
	double resonance	$|\text{‘}\tfrac{3}{2}\text{’}, -\tfrac{1}{2}\rangle\ |\tfrac{3}{2}, -\tfrac{3}{2}\rangle$	$1{\cdot}48626 \pm 0{\cdot}00030$
	double resonance	$|\text{‘}\tfrac{3}{2}\text{’}, \tfrac{1}{2}\rangle\ |\text{‘}\tfrac{3}{2}\text{’}, -\tfrac{1}{2}\rangle$	$1{\cdot}48615 \pm 0{\cdot}00050$
201	level crossing	$|\tfrac{5}{2}, \tfrac{5}{2}\rangle\ |\text{‘}\tfrac{3}{2}\text{’}, \tfrac{1}{2}\rangle$	$1{\cdot}48606 \pm 0{\cdot}00008$
	double resonance	$|\tfrac{5}{2}, \tfrac{5}{2}\rangle\ |\text{‘}\tfrac{5}{2}\text{’}, \tfrac{3}{2}\rangle$	$1{\cdot}48622 \pm 0{\cdot}00030$

It should be noted that the ‘level crossing’ in ^{201}Hg has been analysed on the assumption that the signal is due to coherence between $|\tfrac{5}{2}, \tfrac{5}{2}\rangle$ and $|\text{‘}\tfrac{3}{2}\text{’}, \tfrac{1}{2}\rangle$ levels at the appropriate field. However, the levels $|\text{‘}\tfrac{3}{2}\text{’}, -\tfrac{1}{2}\rangle$ and $|\text{‘}\tfrac{3}{2}\text{’}, -\tfrac{3}{2}\rangle$ also cross these at approximately the same field value (the four levels all cross at the same field in neglect of the smaller perturbations due to the nuclear quadrupole moment and the direct interaction of the applied field with the nuclear magnetic moment). Since this multitude of level crossings may involve other coherences under the appropriate conditions, the value of g_J quoted may be in error by more than the figure given; this may in fact be the source of disagreement between the results of the two ‘level crossing’ measurements.

A weighted mean of all results gives for g_J the value $1{\cdot}48631 \pm 0{\cdot}000\,08$.

ACKNOWLEDGMENTS

The author wishes to record his indebtedness to Mr. A. E. Adam for his technical assistance and to Mr. R. P. Harris for the help he has given with the computations. The work has been supported by a grant from the New Zealand Research Committee.

Line Shapes in the Method of Intersecting Energy Levels

By B. P. KIBBLE and G. W. SERIES
Clarendon Laboratory, Oxford

MS. received 22nd February 1961

Abstract. The first part of this work is a study of the changes of intensity of the resonance fluorescence from mercury vapour as a small magnetic field H is applied either parallel or anti-parallel to the direction of the incident light. The changes follow either a Lorentzian or a dispersion-type function of the Zeeman splitting of the excited state, according to the orientations of polarizer and analyser in the beams of light.

In an experiment with an additional oscillatory field at a frequency ω_0, similar curves are observed in the region $H=H_0/2$. (H_0 is the field for which ω_0 is the Larmor frequency.)

The observations are relevant to a recently developed technique in which intensity changes of this sort are used to make precision measurements in spectroscopy. The Lorentzian line shape is usually observed. The possibility of obtaining line profiles of other shapes was pointed out by Franken.

§ 1. INTRODUCTION

We wish to report some observations concerning the shape of the resonance curves which are found in the spectroscopic technique known as 'level-crossing', or, alternatively, as "the method of intersecting energy levels" (Colegrove, Franken, Lewis and Sands 1959, Hirsch 1960, Hirsch and Stager 1960, Thaddeus and Novick 1960, Dodd 1961). The method has been applied by the above authors to the precise determination of g-values and hyperfine structure intervals and can be used also for the measurement of lifetimes of excited states, so that a study of the resonance line-shape is of practical, as well as of academic interest. The basis of the method is the change in intensity of the resonance radiation, observed either in transmission or in fluorescence, in circumstances in which a pair of excited levels intersect. Thus, suppose that the energies of the states $|b\rangle$ and $|c\rangle$ are functions of an applied magnetic field H (Fig. 1). At either side of the intersection the intensity I of the resonant fluorescent light is the sum of the intensities I_{ab} and I_{ac}. In the region of the intersection there is an additional contribution to I which arises from interference between the time-dependent wave-functions of the degenerate states.

A particular case of intersecting levels is realized in the coalescence at $H=0$ of a set of Zeeman levels. The polarization of the fluorescent light in a case of this sort (Hg, λ2537 Å, 6^3P_1–6^1S_0) was studied in detail by Hanle (1924, 1925). Since the Zeeman structure of the line 2537 Å is normal, the changes of intensity, as well as the changes of polarization, are easily understood in terms of the classical theory of scattering. When there is no applied field, the spatial distribution of the fluorescent light corresponds to radiation from a dipole which oscillates parallel to the electric vector of the incident light. In the presence of a strong magnetic field the radiation pattern is that of a precessing, oscillating dipole. In the transitional region between weak and strong fields the radiation pattern is governed by the angle through which the dipole precesses during the lifetime of the excited atoms.

Quantum-mechanical analysis of experiments of this type predicts that, for the geometrical arrangements which are normally used, and for single scattering processes, the intensity should be a Lorentzian function of the interval E_{bc} with half-intensity width 2Γ, where the states $|b\rangle$ and $|c\rangle$ are taken to have the same decay constant Γ. This type of curve was observed in the work referred to above, and is seen in Figs 3 (*a*) and (*c*). However, it was pointed out by Franken (1961), that, for certain geometrical arrangements the intensity should follow a dispersion type of curve.

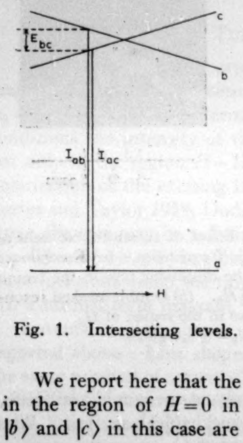

Fig. 1. Intersecting levels.

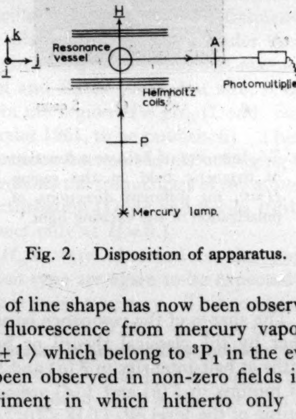

Fig. 2. Disposition of apparatus.

We report here that the dispersion type of line shape has now been observed in the region of $H=0$ in the resonance fluorescence from mercury vapour. $|b\rangle$ and $|c\rangle$ in this case are the states $|m=\pm 1\rangle$ which belong to $^3P_1$ in the even isotopes. The dispersion shape has also been observed in non-zero fields in a more complicated radio-frequency experiment in which hitherto only the Lorentzian shape had been observed.

§ 2. THE BASIC EXPERIMENT

The disposition of apparatus is indicated in Fig. 2. The analyser A passes fluorescent light whose electric vector is in the direction **i** (normal to the paper; right-handed axes are used). The magnetic field **H**, applied by Helmholz coils in the direction $\pm$**k** alternates sinusoidally at 30 c/s a few gauss on either side of zero. The changes of light intensity, measured photoelectrically, are displayed as functions of the magnetic field on an oscilloscope. The four traces shown in Figs 3 (*a*), (*b*), (*c*) and (*d*) correspond to orientations of the polarizer in the directions **i**, **j** − **i**, **j**, **j** + **i**, respectively. No changes in the fluorescent light are observed when the analyser is in the direction **k**. When the analyser is removed, traces are obtained similar to those in Figs 3 (*a*), (*b*), (*c*) and (*d*).

The changes of intensity illustrated in Fig. 3 correspond to about 50% of the fluorescent light when the field is 'strong'. In the ideal case one would expect changes of 100% in 3 (*a*) and 3 (*c*), but in practice this figure is reduced by the effects of multiple scattering in the mercury vapour, by the presence of foreign gas, and of isotopes with nuclear spin, and by small departures from the ideal geometrical conditions.

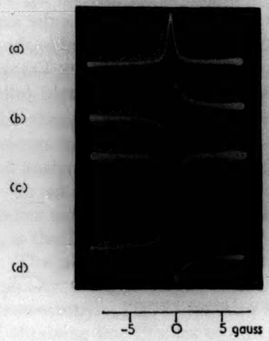

Fig. 3. Intensity of light as a function of magnetic field in the region $H=0$, for different directions of polarization of the exciting light.

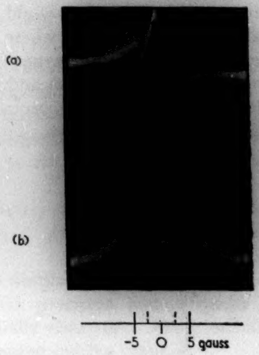

Fig. 4. Effect of an additional field at radio frequencies. (*a*) Resonances of the dispersion type in the region of $\frac{1}{2}H_0$. (*b*) Double-peaked resonances in the region of H_0.
$H_0 = \pm 5{\cdot}0$ gauss.

The shapes of the resonance curves are qualitatively as one would anticipate, either by the classical theory or by the quantum-mechanical analysis. The widths at half-intensity in 3 (*a*) and 3 (*c*), and the distances between the maxima and minima in 3 (*b*) and 3 (*d*) are approximately in agreement with the known lifetime of the level $^3P_1$ ($1{\cdot}18 \times 10^{-7}$ sec). No attempt was made to distinguish between the true lifetime and the coherence time (Barrat 1959), but simply to investigate whether dispersion-type curves did in fact appear under the postulated circumstances. The analytical condition for obtaining curves of the dispersion type is that the product $f_{ba}g_{ab}f_{ac}g_{ca}$ be pure imaginary, where f and g are the matrix elements of the interaction energy for the processes of absorption and emission of light, respectively.

A certain difficulty in applying the theory arises when the intersection takes place at $H=0$, since, owing to the presence of stray fields, the actual field does not remain in the direction $\pm\mathbf{k}$ when the applied field is small, so that it would appear that the states should be defined with respect to a rotated axis of quantization. However, the positive direction of the applied field may at all times be used as axis, notwithstanding the stray fields, provided that $\gamma H_{\text{stray}} \ll \Gamma$ (γ is the gyromagnetic ratio). The essence of the proof lies in showing that the expression $(f_{ab}g_{ba}+f_{ac}g_{ca})$ is invariant to the axis of quantization, where the states are eigenstates of J_z with respect to the particular z axis chosen. If, in the group which comprises $|b\rangle$ and $|c\rangle$, there are other eigenstates of J_z, then $f_{am}g_{ma}$ must be summed over all the eigenstates $|m\rangle$. It is assumed that there are no eigenstates of J_z other than $|a\rangle$ in the group to which $|a\rangle$ belongs.

It is easy to appreciate classically that small, stray fields are immaterial, since a field which produces only a small angle of precession during the lifetime of the atoms has a correspondingly small effect on the fluorescent light. The direction of such a small field, is, therefore, of no significance.

The energy of the state $|m_J\rangle$ in the field $\mathbf{H}$ is $g_J\beta m_J|H|$. When the direction of the field is reversed, but the axis of quantization left unchanged, the states $|m_J\rangle$ are still eigenstates of the Hamiltonian, but the energies are $-g_J\beta m_J|H|$. Hence levels of different m_J cross in zero field just as indicated in Fig. 1.

§ 3. THE RADIO-FREQUENCY EXPERIMENT

The radio-frequency experiment to which we referred above represents a more subtle case of intersecting levels. An oscillatory magnetic field at frequency ω_0 is applied to the scattering vapour in the plane normal to $\mathbf{H}$. Under these conditions the intensity of the fluorescent light changes in a resonant manner, not only in the region $H=H_0=\omega_0/\gamma$ (Brossel and Bitter 1952), but also, if the polarization of the exciting light is suitable, in the region $H=\frac{1}{2}H_0$ (Dodd, Fox, Series and Taylor 1959, Dodd, Series and Taylor 1961, to be published). These latter changes may be associated with intersections between levels belonging to $|m=0\rangle$ and $|m=\pm 1\rangle$ in a diagram which represents the frequencies of the atomic wave functions under the time-dependent perturbation (Dodd and Series 1961). (In a normal term diagram, the levels intersect only at $H=0$.)

Lorentzian line shapes in the region $H_0/2$ were observed in the work reported above. Line shapes of the dispersion type are again to be expected if the same product of matrix elements as before is pure imaginary. This condition is fulfilled for matrix elements which connect the ground state with the excited states $|0\rangle$, $|1\rangle$ and $|0\rangle$, $|-1\rangle$ when the apparatus is arranged as follows: the incident and scattered light beams in the directions $\mathbf{k}$ and $\mathbf{j}$, as in Fig 2; the field $\mathbf{H}$ in the direction $(\mathbf{k}-\mathbf{j})$, and the radio-frequency field in the direction $\mathbf{i}$; the incident light plane polarized in the direction $(\mathbf{i}-\sqrt{2}\mathbf{j})$ and the scattered light analysed in the direction $(\mathbf{i}+\sqrt{2}\mathbf{k})$.

Fig. 4 (*a*) shows an oscilloscope trace observed under these conditions. Lines of the expected shape are seen in the region of magnetic fields $\pm 2{\cdot}5$ gauss, together with a similar, more prominent line in the region of $H=0$ as before. Fig. 4 (*b*), for comparison, shows the double-peaked resonances in the region $H=H_0=\pm 5{\cdot}0$ gauss, as observed by Brossel and Bitter. The amplitude of $\mathbf{H}$, and of the oscillatory field at 10·5 Mc/s, were unchanged between Figs 4 (*a*) and 4 (*b*), but $\mathbf{H}$ was applied to the direction $\mathbf{j}$ in 4 (*b*), the polarizer was set parallel to $\mathbf{i}$ and the analyser to $\mathbf{k}$. Under these conditions, resonances at $H_0/2$ are not to be expected.

In the light of these observations, it is clear that care must be taken with the disposition and alignment of apparatus when the method of intersecting levels is applied to precision measurements.

Some Properties of Resonance Line-shape Functions

By D. G. HUGHES and D. K. C. MacDONALD
Division of Pure Physics, National Research Council, Ottawa, Canada

MS. received 27th January 1961

Abstract. Some relationships involving line-width and second moment of broadened resonance lines are investigated.

It is of particular interest to determine how the properties such as line-shape of a multiply-broadened line depend on the properties of the individual lines. In certain cases the shape of the broadened line is the same as that of the individual lines, and particular attention is paid to this class of 'self-folding' functions.

---

§ 1. Introduction

The study of resonance line-shapes and line-widths is of great importance in many branches of spectroscopy.

In this discussion we have in mind systems which are being excited by an electromagnetic field of constant amplitude and we measure the power absorption as a function of frequency (or equivalently, in the case of magnetic resonance, as a function of magnetic field). Such conditions are particularly met in nuclear magnetic resonance and electron spin resonance experiments.

A resonance line is never ideally narrow and may be broadened by a number of causes. A well-known example is that of damping or decay due to a simple relaxation mechanism. For a lightly damped resonant system a simple relaxation mechanism produces (to a good approximation) a so-called Lorentz line-shape of the form $1/[1+(\nu-\nu_0)^2]$ centred about the resonance frequency ν_0. Naturally the stronger the damping, the broader will be the resonance line.

In gaseous spectroscopy, on the other hand, a Gaussian line-shape of the form $\exp[-(\nu-\nu_0)^2]$, centred about the resonance frequency ν_0, can be expected on theoretical grounds if Doppler effects predominate. More generally, a Gaussian line-shape is found empirically to be a good approximation for many nuclear magnetic resonance absorption lines, in particular where nuclear dipole–dipole interactions in the solid state determine the line-shape.

Three problems arise when more than one source of broadening is present, whether these sources are similar or otherwise. First, we should like to define line-width in such a way that we can readily compare the widths of resonance lines of different shapes. Secondly, we wish to know how the *resultant* width of a resonance line is related to the widths of the resonance lines that would be caused by each broadening mechanism *separately*—these we call the individual resonance lines. Thirdly, we are concerned with the dependence of the shape of the overall resonance line on the shapes of the individual resonance lines.

In this note we derive an elementary, but general, theorem which relates the 'moments' of a line, which has been broadened by more than one independent mechanism, to the 'moments' of the individual lines. Thereafter, we consider a situation which we have found of interest, namely where the shape of the compound line is identical in form with each of the individual lines. It transpires that both Lorentz and Gaussian line shapes belong to the class of functions which satisfy this requirement. However, *only* the Gaussian line-shape from this class appears to be both integrable and to have a finite and non-vanishing second moment.

Let us note finally that it may perhaps be tempting to assume generally that, when several independent sources of broadening are present, the width of the compound line is given simply by the sum of the widths of the individual lines. However, this is strictly true only when each individual source of broadening is itself an ideal relaxation mechanism, or in other words, where all the individual line-shapes (and hence the resultant line-shape also) are of Lorentz form.

§ 2. LINE-WIDTH CONSIDERATIONS

Let us assume that the resonance line is determined by some function $\phi(x)$. The coordinate x will usually be measured from the central point of the resonance either in units of frequency or, when we are dealing with magnetic resonance, in units of magnetic field. (For convenience we shall assume that the resonance line is symmetrical about $x=0$ with a single maximum there, although this is not entirely mandatory.)

We shall be concerned with:

(i) the area under the resonance line : $\phi_0 \equiv \int_{-\infty}^{+\infty} \phi(x)\,dx$ (i.e. the 'zeroth moment' of $\phi(x)$),

(ii) the 'second moment' of $\phi(x)$: $\phi_2 \equiv \int_{-\infty}^{+\infty} x^2\phi(x)\,dx$ and

(iii) $\phi(0)$, i.e. the height of the absorption line at its centre.

Let us now define

$$M \equiv \frac{\{\phi(0)\}^2\,\phi_2}{\phi_0^{\,3}}. \qquad \ldots\ldots(1)$$

It then follows that M is a pure number dependent only on the type of function involved but not on the particular choice of scale for either the ordinate or abscissa. Thus for:

a rectangular function $M=\frac{1}{12}\,(0{\cdot}083)$,

a triangular function $M=\frac{1}{6}\,(0{\cdot}167)$,

for a Gaussian function $M=\frac{1}{2\pi}\,(0{\cdot}159)$,

for $\phi(x)\sim 1/(1+x^4)$ $M=\frac{2}{\pi^2}\,(0{\cdot}202)$.

Thus for most reasonably shaped, smooth, symmetrical functions, which would approximate a broadened resonance, we might reasonably expect to find M somewhere around 0·2, and this is confirmed numerically on many ***experimental*** resonance lines. In marked contrast, however, the slow convergence of the Lorentz function as $x\rightarrow\infty$ leads to an infinite ϕ_2, and consequently also an infinite value for M in this particular case.

It will now be more convenient to deal throughout with a 'normalized' line-shape function, say $f(x)=\phi(x)\bigg/\int_{-\infty}^{+\infty}\phi(x)\,dx$. Obviously then $f_0\equiv\int_{-\infty}^{+\infty}f(x)\,dx=1$, and hence also

$$M=\{f(0)\}^2 f_2. \qquad \text{......(2)}$$

Several parameters have been used in spectroscopy as a measure of resonance line-width. In particular, $1/f(0)$ has often been used, especially in nuclear magnetic resonance if x is measured in frequency units. $1/f(0)$ is then denoted by $1/2T_2$ (where T_2 is called the 'spin–spin relaxation time'). It thus follows that we can also use Eqn (2) to relate line-width, as measured by $1/f(0)$, to the second moment of the line.

The second moment of the resonance line is of direct theoretical significance; it is particularly important in the case of nuclear magnetic resonance since Van Vleck (1948) has derived a theoretical expression for the second moment due to dipole–dipole interactions in terms of the internuclear spacings of the material concerned.

§ 3. MOMENTS OF A 'FOLDED' FUNCTION

If an ideally narrow line is broadened by two mechanisms which separately yield line-shapes represented by functions $f(x)$ and $g(x)$, then the overall or resultant line-shape function $F(x)$ resulting from the presence of both mechanisms together may be written as

$$F(x)=\int_{-\infty}^{+\infty}g(z)f(x-z)\,dz \qquad \text{......(3)}$$

if both mechanisms are 'independent'. Indeed, Eqn (3) may be taken as a definition of what we mean when we say that the two mechanisms are independent. The integration in Eqn (3) is often called the 'folding' of the function $f(x)$ over the function $g(x)$, or equivalently the 'folding' of $g(x)$ over $f(x)$. If both $f(x)$ and $g(x)$ are normalized then so also is $F(x)$.

Andrew and Finch (1957) have shown that the second moment of the folded function $F(x)$ is the sum of the second moments of the individual functions $f(x)$ and $g(x)$ where these functions are symmetrical. It occasionally occurs in practice that the functions $f(x)$ and $g(x)$ are not both symmetrical; e.g. in nuclear magnetic resonance, asymmetric line-shapes are produced in poly-crystalline samples by both second-order quadrupole interactions (Cohen and Reif 1957), and asymmetric Knight shift (Knight 1956). We therefore now obtain an expression for the nth moment of a 'doubly-broadened' resonance line where no restriction is placed on the symmetry of either component. The generalization to a multiply-broadened line is trivial.

Denoting, as before, the nth moment of $F(x)$ by F_n, we have:

$$F_n=\int_{-\infty}^{+\infty}x^n\,dx\int_{-\infty}^{+\infty}f(x-z)g(z)\,dz$$

or reversing the order of integration:

$$F_n=\int_{-\infty}^{+\infty}g(z)\,dz\int_{-\infty}^{+\infty}(y+z)^n f(y)\,dy,$$

and hence

$$F_n=f_n+nf_{n-1}g_1+\frac{n(n-1)f_{n-2}g_2}{2!}+\ldots+g_n, \qquad \text{......(4)}$$

where f_n is the nth moment of $f(x)$, and g_n the nth moment of $g(x)$. Eqn (4) expresses the nth moment of the resultant function $F(x)$ in terms of the moments (1st up to the nth) of the individual broadening functions $f(x)$ and $g(x)$. In particular,

$$F_1 = f_1 + g_1,$$
$$F_2 = f_2 + 2f_1 g_1 + g_2,$$
$$F_3 = f_3 + 3f_2 g_1 + 3f_1 g_2 + g_3,$$

and
$$F_4 = f_4 + 4f_3 g_1 + 6f_2 g_2 + 4f_1 g_3 + g_4.$$

These expressions are quite general and are independent of the choice of origin. If we select the origin so that $f_1 = 0$, i.e. such that the first moment or centre of gravity of $f(x)$ about the origin is zero, then our expressions reduce to those obtained by Flynn and Seymour (1960) using a Taylor expansion method (Flynn and Seymour 1960, Eqn 11, p. 343).

We see that in the general case the first moments f_1 and g_1 enter into the expression for the second moment F_2. However for two functions symmetrical about the origin, both f_1 and g_1 are zero; thus

$$F_2 = f_2 + g_2, \qquad \ldots\ldots (5)$$

the particular result obtained by Andrew and Finch (1957). This result concerning the direct addition of second moments is most important theoretically, particularly when we recall Van Vleck's work (cf. §2). Eqn (5) evidently also holds for asymmetric functions (line-shapes) if we select the origin to be at the 'centre of gravity' of *either* of the initial functions.

Let M_1 and M_2 be the 'form-factors' of $f(x)$ and $g(x)$ as defined by Eqn (2). Therefore, $f_2 = M_1 a^2$ and $g_2 = M_2 b^2$ where a is the line-width of $f(x)$, and b is the line-width of $g(x)$, as defined previously.

Now let us suppose that the two independent broadening mechanisms are *similar*, i.e. that the functions are of the form $\alpha^{-1} f(x/\alpha)$ and $\beta^{-1} f(x/\beta)$, where α and β are 'scaling factors'. In this form the 'scaled' functions remain normalized if $f(x)$ is normalized. Moreover let us suppose that the 'folded' function is also similar to the initial function, i.e. $F(x) = \gamma^{-1} f(x/\gamma)$. Then $M_1 = M_2 = M_3$ and from Eqn (5)

$$M_1 a^2 + M_1 b^2 = M_1 c^2,$$

where c is the line-width of the 'folded' function. If the form factor M_1 is neither zero nor infinite, then

$$a^2 + b^2 = c^2, \qquad \ldots\ldots (6a)$$

and, from our definition of line-width

$$\alpha^2 + \beta^2 = \gamma^2. \qquad \ldots\ldots (6b)$$

Thus for a function that 'reproduces' itself, i.e. that satisfies the equation:

$$\frac{1}{\gamma} f\left(\frac{x}{\gamma}\right) = \frac{1}{\alpha\beta} \int_{-\infty}^{+\infty} f\left(\frac{z}{\alpha}\right) f\left(\frac{x-z}{\beta}\right) dz \qquad \ldots\ldots (7)$$

and moreover has a finite and non-zero second moment, squares of line-widths are added in accordance with Eqn (6*a*).

In §4, we consider the class of functions that are 'self-folding' (i.e. that satisfy Eqn (7)); meanwhile we consider specifically the Gaussian and Lorentz functions which are both 'self-folding'.

3.1. *The Gaussian Function*

If we set $f(x)=\pi^{-1/2}\exp(-x^2)$, (which is thus normalized),

then
$$\frac{1}{\alpha\beta}\int_{-\infty}^{+\infty} f\left(\frac{z}{\alpha}\right) f\left(\frac{x-z}{\beta}\right) dz = \frac{1}{\gamma} f\left(\frac{x}{\gamma}\right)$$
where
$$\gamma^2=\alpha^2+\beta^2 \text{ (cf. } (6b)).$$
Now from our definition of line-width it is obvious that if the line-widths of these three Gaussian functions are denoted by a, b and c respectively, then $a=\pi^{1/2}\alpha$, etc. (and in general a is directly proportional to α). Consequently $c^2=a^2+b^2$ for the Gaussian function in specific agreement with Eqn (6a), deduced generally from consideration of second moments.

3.2. *The Lorentz Function*

In contrast to the Gaussian function, the 'form-factor' M of the Lorentz function is infinite, as we have seen, and consequently Eqns (6a) and (6b) do *not* follow from Eqn (5). Specifically,

if
$$f(x)=\frac{1}{\pi(1+x^2)}, \quad \text{then} \quad \frac{1}{\alpha\beta}\int_{-\infty}^{+\infty} f\left(\frac{z}{\alpha}\right) f\left(\frac{x-z}{\beta}\right) dz$$
is readily evaluated by contour integration and equals $\gamma^{-1}f(x/\gamma)$ where now $\gamma=\alpha+\beta$. Again the 'scaling' factors α, β and γ are directly proportional to the line-widths a, b and c ($a=\pi\alpha$, etc.) and therefore in this case
$$c=a+b. \qquad \text{......(8)}$$
Thus, if a resonance is broadened by two independent Lorentz mechanisms, the overall line-width is equal to the linear sum of the individual line-widths. This corresponds precisely to the well-known rule of adding inverse relaxation times. Let us emphasize however that this is only correct for ideal relaxation mechanisms in which case all the line-shape functions are Lorentzian.

In general, Eqn (5) is equivalent to $M_1a^2+M_2b^2=M_3c^2$, where the form-factors M_1, M_2 and M_3 are all different, and no simple and exact rule relating line-widths can be given. However, as we have mentioned earlier, for most experimental resonance lines (excluding those produced by pure relaxation phenomena) the form-factors M_1, M_2 and M_3 are found to be roughly the same (about 0·2). It therefore appears that, unless we have specific evidence that we are dealing throughout with pure relaxation phenomena, it would probably be safer to assume that the square of the line-width of a 'multiply-broadened' resonance line is approximately the sum of the squares of the individual line-widths, rather than to assume as a general rule that line-widths may be added linearly.

§ 4. FUNCTIONS THAT SATISFY EQUATION (7)

$$\frac{1}{\gamma} f\left(\frac{x}{\gamma}\right)=\frac{1}{\alpha\beta}\int_{-\infty}^{+\infty} f\left(\frac{z}{\alpha}\right) f\left(\frac{x-z}{\beta}\right) dz. \qquad \text{......(7)}$$
(We assume α, β, γ real and each greater than 0.)

We are grateful to Professor V. Linis, Mathematics Department, Ottawa University, for pointing out that the general problem of finding functions that satisfy this equation may be approached as follows.

Writing the Fourier transform of $f(x)$ as
$$\psi(t)=\frac{1}{(2\pi)^{1/2}}\int_{-\infty}^{+\infty} f(x)\exp(ixt)\,dx,$$

we have

$$\frac{1}{\alpha\beta}\int_{-\infty}^{+\infty} f\left(\frac{z}{\alpha}\right) f\left(\frac{x-z}{\beta}\right) dz = \int_{-\infty}^{+\infty} \psi(\alpha t)\psi(\beta t)\exp(-ixt)\,dt.$$

Thus to satisfy Eqn (7) we require

$$\int_{-\infty}^{+\infty} \psi(\alpha t)\psi(\beta t)\exp(-ixt)\,dt = \frac{1}{(2\pi)^{1/2}}\int_{-\infty}^{+\infty} \psi(\gamma t)\exp(-ixt)\,dt. \qquad \ldots\ldots(9)$$

Eqn (9) is to be true for all values of x, and hence

$$\psi(\alpha t)\psi(\beta t) = \frac{1}{(2\pi)^{1/2}}\psi(\gamma t). \qquad \ldots\ldots(10)$$

Eqn (10) is satisfied by

$$\psi(\alpha t) = \frac{1}{(2\pi)^{1/2}}\exp(-\lambda\alpha^K|t|^K) \qquad \ldots\ldots(11\,a)$$

subject to the condition

$$\alpha^K+\beta^K=\gamma^K. \qquad \ldots\ldots(11\,b)$$

We take $\lambda>0$ and $K>0$ to ensure proper behaviour of $\psi(t)$ at $t=0$ and $t\to\infty$. We shall now for convenience, and with no real loss of generality, put $\lambda=1$. Thus

$$\frac{1}{\alpha}f\left(\frac{x}{\alpha}\right) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \exp(-\alpha^K|t|^K)\exp(-ixt)\,dt.$$

For $K=1$, $f(x)=\pi^{-1}(1+x^2)^{-1}$, i.e. a Lorentz function, and $\alpha+\beta=\gamma$ from Eqn (11 *b*), as deduced earlier (§ 3).

For $K=2$, $f(x)=\frac{1}{2}\pi^{-1/2}\exp(-\frac{1}{4}x^2)$, i.e. a Gaussian function, and now $\alpha^2+\beta^2=\gamma^2$ from Eqn (11 *b*).

We have already shown in § 3 that any integrable 'self-reproducing' function, whose second moment is finite and non-vanishing, must satisfy

$$\alpha^2+\beta^2=\gamma^2 \quad \text{(cf. Eqn } (6\,b)).$$

We have also seen that the Lorentz function, although 'self-reproducing', has an infinite second moment and is thus excluded from this requirement. It is therefore satisfying that Professor Linis kindly points out to us that for all functions of this 'self-reproducing' class where $0<K<2$, the second moment is infinite, and where $K>2$, at least for all cases where K is an even integer, $f(x)$ oscillates and the second moment vanishes identically. It would appear therefore that the Gaussian function occupies a unique position amongst the class of 'self-reproducing' functions.

A Study of the (^{3}He, d) Reactions Leading to ^{11}C and ^{12}C

By S. HINDS and R. MIDDLETON
Atomic Weapons Research Establishment, Aldermaston, Berks.

Communicated by K. W. Allen; *MS. received* 16*th January* 1961

Abstract. The reactions ^{10}B(^{3}He, d)^{11}C and ^{11}B(^{3}He, d)^{12}C have been studied, using magnetic analysis, at a bombarding energy of 9·84 Mev. A new level in ^{11}C at 6·345 ± 0·010 Mev excitation was observed. Deuteron angular distributions leading to the ground and first five excited states of ^{11}C were measured, and an attempt has been made to fit these with stripping curves. Absolute proton reduced widths for the ^{11}C levels have been extracted.

Using the ^{11}B(^{3}He, d) reaction, the energy levels of ^{12}C between 9 and 15 Mev have been studied. Natural widths of levels at 10·84, 11·82 and 13·38 Mev were measured to be 320, 300 and 700 kev respectively. Stripping analyses of the deuteron angular distributions yielded l-values of 2, 0, 0 and 1 respectively for the states of ^{12}C at 9·63, 10·84, 11·82 and 12·70 Mev. Absolute proton reduced widths and also α-particle reduced widths, from the measured total widths, have been extracted for some levels of ^{12}C.

§ 1. INTRODUCTION

The (^{3}He, d) reaction is of particular importance since it is the charged particle equivalent of the (d, n) stripping reaction. Thus, nuclei which were previously best studied by means of the (d, n) reaction can now be re-investigated with improved energy resolution using the (^{3}He, d) reaction. Also, since stripping is now established to be the predominant reaction mechanism for the (^{3}He, d) reaction at the higher bombarding energies, parities, possible spin values and reduced widths can be determined by measuring the angular distributions of the emitted deuterons. In this communication are presented the results of a magnetic analysis study of the ^{10}B(^{3}He, d)^{11}C and the ^{11}B(^{3}He, d)^{12}C reactions at an incident energy of 9·84 Mev.

If a mirror nucleus comparison is made of ^{11}B and ^{11}C, using the existing data (Ajzenberg-Selove and Lauritsen 1959), it is evident that a level is missing in ^{11}C at about 6·5 Mev excitation energy. By employing magnetic analysis to study the ^{10}B(^{3}He, d)^{11}C reaction we have readily obtained improved energy resolution and have succeeded in observing a new level in ^{11}C at 6·345 ± 0·010 Mev.

The angular distributions of the deuterons from the ^{10}B(^{3}He, d)^{11}C reaction are of particular interest because of the possibility of 'spin-flip' or exchange stripping occurring in the transition to the first excited state. This phenomenon has previously been observed in deuteron stripping reactions with ^{10}B and has been extensively discussed by Wilkinson (1957), Evans and French (1958) and Hensel and Parkinson (1958).

Little is known about the states of ^{12}C between 9 and 15 Mev excitation energy. Above 16 Mev much information has been gained from resonance scattering experiments and below 9 Mev from the ^{12}B β^- decay and also the ^{10}B(d, n)^{11}C reaction. The latter reaction has also been used to study the intermediate states, but due to their relatively high density and inherent difficulties of measuring neutron energies the available data are doubtful. The present magnetic analysis study of the ^{11}B(^{3}He, d)^{12}C reaction has therefore been primarily directed at this intermediate region of excitation of ^{12}C.

Previous studies of the ^{10}B(^{3}He, d)^{11}C and the ^{11}B(^{3}He, d)^{12}C reactions have been made at incident energies of about 5 Mev. Forsyth *et al.* (1960) have measured deuteron angular distributions from the former reaction leading to the ground and first excited states. Holmgren, Wolicki and Johnston (1959) have also measured the angular distributions of the ground and first excited state deuteron groups from the ^{11}B(^{3}He, d)^{12}C reaction. In addition they also measured yield curves for the ground state group at laboratory angles of 60°, 90° and 163° over the energy range 3·0 to 5·5 Mev. These varied slowly and suggest, as do the angular distribution measurements, that, even at these relatively low bombarding energies, stripping is the predominant reaction mechanism.

§ 2. EXPERIMENTAL PROCEDURE

Doubly charged ^{3}He particles were accelerated to an energy of 9·84 Mev in the Aldermaston 6 MV electrostatic generator and used to bombard thin targets of separated ^{10}B and natural boron. The energies and angular distributions of the emitted deuterons were measured with a broad-range magnetic spectrograph described in previous communications (Hinds and Middleton 1959, 1960).

The ^{10}B target consisted of a self-supporting foil of about 40 to 50 μgcm^{-2} and was prepared by evaporating enriched ^{10}B isotope. For the ^{11}B investigation a somewhat thicker self-supporting foil of natural boron was used. The thickness of the latter was directly determined by weighing to be 90 μgcm^{-2} and from this value, absolute cross sections have been calculated for the ^{10}B(^{3}He, d)^{11}C and the ^{11}B(^{3}He, d)^{12}C reactions. The relative cross sections for the two reactions are accurate to within ±10% but the absolute values are only considered to be accurate to within ±30%.

§ 3. THE ^{10}B(^{3}He, d)^{11}C REACTION

3.1. *Results*

In Fig. 1 are shown two deuteron energy spectra measured at a laboratory angle of 15°. The upper spectrum was obtained with a magnetic field strength of 13 150 gauss and the lower with a field of 9160 gauss. Groups were identified by their rate of variation of energy with angle and those arising from ^{10}B are labelled numerically, with '0' referring to the ground state. Several groups were also observed arising from target impurities such as ^{11}B, ^{12}C and ^{16}O. These have been labelled by the chemical symbol for the residual nucleus with a subscript referring to the appropriate excited state.

The energy levels of ^{11}C shown in column (*a*) of Table 1 are the mean values of determinations made at laboratory angles of 15°, 30°, 45° and 60° and at two different magnetic field strengths. The experimental error for all levels is ±10 kev. As was expected from a comparison of the level schemes of ^{11}B and

‡ Maslin, Calvert and Jaffe (1956) from the $^{10}B(d, n)^{11}C$ reaction.

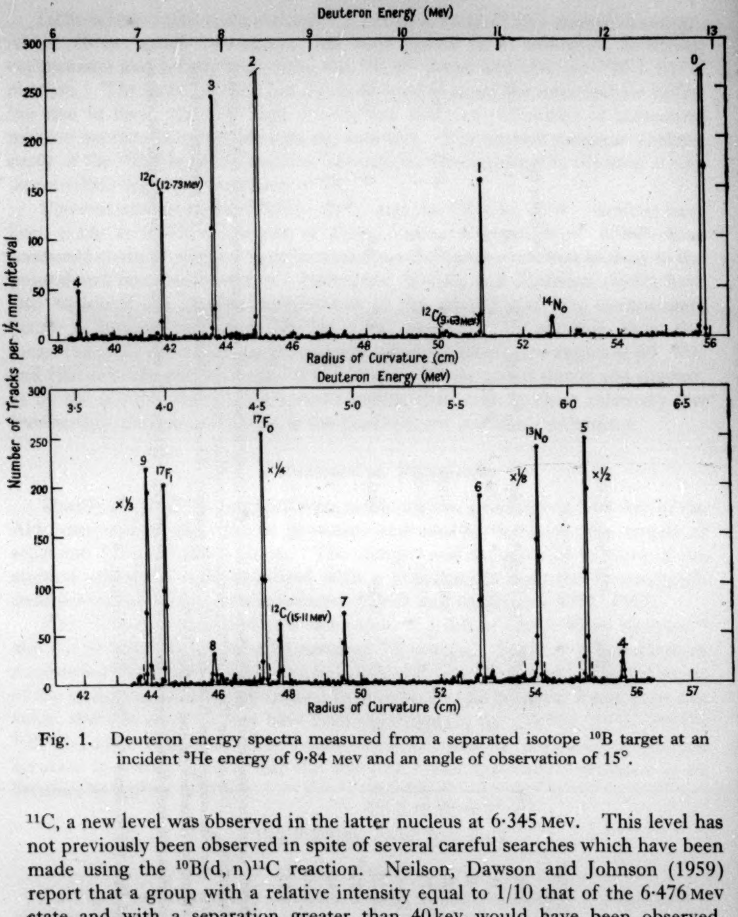

Fig. 1. Deuteron energy spectra measured from a separated isotope ^{10}B target at an incident ^{3}He energy of 9·84 Mev and an angle of observation of 15°.

^{11}C, a new level was observed in the latter nucleus at 6·345 Mev. This level has not previously been observed in spite of several careful searches which have been made using the ^{10}B(d, n)^{11}C reaction. Neilson, Dawson and Johnson (1959) report that a group with a relative intensity equal to 1/10 that of the 6·476 Mev state and with a separation greater than 40 kev would have been observed. Although the new state has a separation of 131 kev it is not surprising that it was not observed since its intensity, over the angular range studied, was always less than 5% of that of the 6·476 Mev state.

In Fig. 2 are shown the angular distributions of the deuteron groups corresponding to the ground and first five excited states of ^{11}C. Also shown are theoretical stripping curves calculated using the method described by Macfarlane and French (1959). These are all for $l=1$ and in the case of the solid curves were obtained using the Gamow radius, i.e. 4·3 fermi. The agreement is good in the cases of the 4·32 and 6·48 Mev angular distributions, but improved fits were obtained for the ground state using a radius of 5·3 fermi and for the 2·00 and

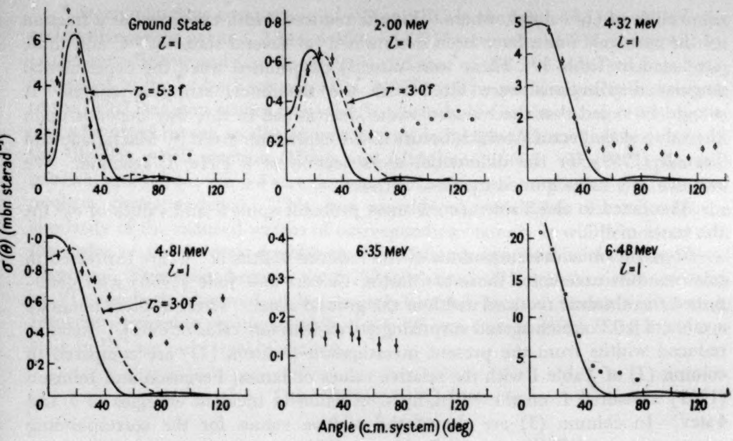

Fig. 2. Angular distributions of the ground and first five excited state deuteron groups from the ^{10}B(^{3}He, d)^{11}C reaction. The curves were calculated from the simple stripping theory.

4·81 Mev states using the extremely small radius of 3·0 fermi. The 6·35 Mev state does not appear to be formed by stripping.

3.2. *Discussion*

The deuteron group corresponding to the 'spin-flip' first excited state of ^{11}C has a peak differential cross section of only 1/10 that of the ground state group. Also the stripping peak is broader and occurs at a larger angle and can only be fitted by stripping theory by assuming an anomalously small radius of interaction. This differs from the results of Maslin, Calvert and Jaffe (1956) for the ^{10}B(d, n)^{11}C reaction obtained at an incident energy of 9 Mev. They observed an excellent stripping pattern with a peak differential cross section of about one half that of the ground state and which they were able to fit using the same radius as required by the ground state. Using incident deuteron energies of 6·2, 7·1 and 8·0 Mev, Evans and Parkinson (1954) have measured angular distributions of the proton group from the ^{10}B(d, p)^{11}B reaction leading to the corresponding state in ^{11}B. These, and in particular, that measured at the higher incident energy, resemble more closely the present (^{3}He, d) results than do the (d, n) angular distributions. This resemblance, however, may be fortuitous since there is evidence that the angular distribution of this group is fairly strongly energy dependent (see also Bilaniuk and Hensel 1960, Bowcock 1958, Zeidman and Fowler 1958).

The similarity in shape and intensity of the angular distributions leading to the 2·00 Mev and 4·81 Mev states suggest that possibly 'spin-flip' or exchange stripping may also be involved in the formation of the 4·81 Mev state. This possibility, however, seems to be precluded by the results of Ferguson *et al.* (1958) which suggests that the mirror state in ^{11}B probably has a spin and parity of $\frac{3}{2}^-$. A $\frac{3}{2}^-$ state could be formed directly by an $l=1$ interaction, and there would be no requirement for 'spin-flip' unless the state was $\frac{1}{2}^-$.

Values of $(2J+1)\theta_p^2$, where θ_p^2 is the reduced width expressed as a fraction of the sum rule limit, have been determined for several states of ^{11}C and these are listed in Table 1. These were directly determined when the experimental angular distributions were fitted with the theoretical stripping curves. It should be noted that the reduced width determined in this way depends upon the value of the factor Λ which occurs in the expression given by Macfarlane and French (1959) for the differential cross section of a (^{3}He, d) reaction. We assumed the value quoted by these authors.

Also listed in the Table are the most probable spins J and values of θ_p^2 for the states of ^{11}C.

Most previous determinations of the reduced widths of ^{11}C are expressed in relative units except for those of Maslin, Calvert and Jaffe (1956) who determined the absolute reduced width of the ground state. These authors obtained a value of 0·023 which agreed surprisingly well with our value of 0·019. Relative reduced widths from the present investigation (column (1)) are compared in column (2) of Table 1 with the relative values of James, Ferguson and Johnson (1961) measured from the $^{10}B(d, n)^{11}C$ reaction at incident energies of 3 and 4 Mev. In column (3) are shown the relative values for the corresponding mirror states of ^{11}B (Evans and Parkinson 1954), and finally in column (4) are the values expected from the extreme *j–j* coupling shell model (Macfarlane and French 1959).

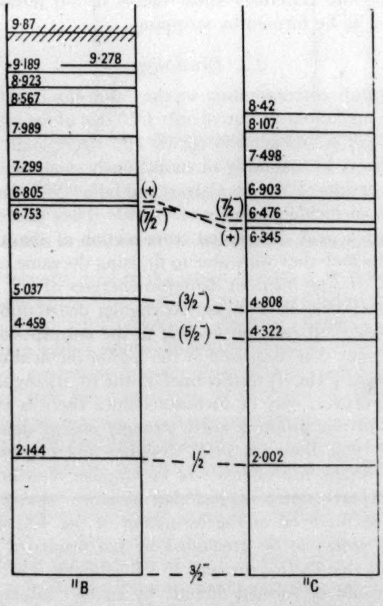

Fig. 3. Mirror nucleus comparison of ^{11}B and ^{11}C.

A mirror nucleus comparison of ^{11}B and ^{11}C is shown in Fig. 3. The spins and parities of the ground, 2·144, 4·459 and 6·753 Mev states of ^{11}B are well known (Ajzenberg-Selove and Lauritsen 1959) and that of the 5·037 Mev state has been suggested to be $\frac{3}{2}^-$ by Ferguson *et al.* (1958). The positive parity assignment to the 6·805 Mev state comes from the (n, γ) study of Groshev *et al.* (1958) and is also supported by the *l*-value assignment made by the authors during a study of the ^{9}Be(^{3}He, p)^{11}B reaction (Hinds and Middleton 1960). The ^{11}C spins and parities, apart from the 6·4 Mev doublet, were assigned on the basis of a mirror nucleus correspondence. This was considered reasonable in view of the similarity of the reduced widths of corresponding states. It will be noticed that the order of the 6·4 Mev doublet in ^{11}C is shown inverted in the energy level diagram. This arises because the 6·753 Mev state in ^{11}B and the 6·476 Mev state in ^{11}C are both observed to be strongly excited by $l = 1$ transitions in their respective stripping reactions, while the 6·805 Mev state in ^{11}B and the 6·345 Mev state in ^{11}C are only weakly excited.

§ 4. The ^{11}B(^{3}He, d)^{12}C Reaction

4.1. *Results*

A deuteron energy spectrum obtained at a laboratory angle of 15° and using a natural boron target is shown in Fig. 4. Groups were identified by their characteristic variation of energy with angle and are labelled by the symbol for the residual nucleus. Apart from groups arising from ^{10}B which is normally present in natural boron, other impurity groups were observed arising from ^{12}C and ^{28}Si. The last mentioned impurity was thought to arise from the inadvertent use of silicon grease either in the target chamber or in the evaporation apparatus used to prepare the target.

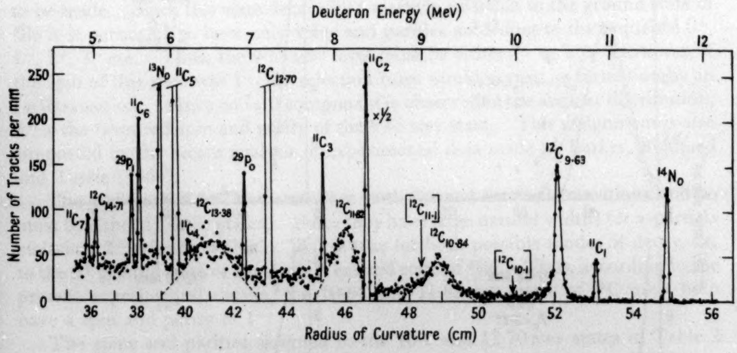

Fig. 4. Deuteron energy spectrum measured from a natural boron target at laboratory angle of observation of 15° and at an incident ^{3}He energy of 9·84 Mev.

The well-known 2 Mev wide state at 10·1 Mev in ^{12}C was not as such observed. However, a continuous background of deuterons was observed to start in roughly the expected position for this state and its existence cannot be precluded. Previously reported states at 11·1 and 13·21 Mev were not observed. Since these excitation energies are very close to those of the broad states at 10·84 Mev and 13·38 Mev, it is possible that they have previously been confused with these states. The state at 14·05 Mev was also not observed, but its existence cannot be precluded, particularly if it has a large natural width, because of the large continuous background of deuterons observed in this region of the spectrum. Narrow states were observed at excitation energies of 12·70 and 14·71 Mev, the latter not having been previously reported. Other known states were observed at 10·84, 11·82 and 13·38 Mev and their widths have been directly measured from the energy spectra to be respectively 320 ± 30, 300 ± 30 and 700 ± 100 kev.

No evidence was found for the state recently reported by Alburger and Pixley (1960) at 9·0 Mev excitation energy. This state would have been observed if its intensity were greater than 4% that of 9·63 Mev state at small angles of emission and if greater than 10% at large angles of emission. The corresponding group would be expected at a radius of curvature of approximately 53·6 cm in the spectrum of Fig. 4.

A summary of the ^{12}C level energies and widths is given in Table 2.

Angular distributions of the groups leading to the states at 9·63, 10·84, 11·82 and 12·70 Mev have been measured and are shown in Fig. 5. These have been fitted with theoretical stripping curves calculated according to the method of Macfarlane and French (1959) for a radius of interaction of 5·3 fermi (full line curve, Fig. 5). Agreement is generally good, but is improved in the case of the 12·70 Mev state by the use of the Gamow radius of 4·4 fermi (broken lines).

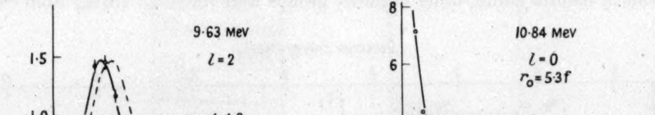

Fig. 5. Angular distributions of four deuteron groups from the ^{11}B(^{3}He, d)^{12}C reaction. The curves were calculated from the simple stripping theory.

4.2. *Discussion*

Values of $(2J+1)\theta_p^2$ have been extracted in a manner similar to that used for the ^{10}B(^{3}He, d)^{11}C reaction and are shown in Table 2. Maslin *et al.* (1956) have previously measured this quantity for the 9·63 Mev state and they obtained a value of 0·259, compared with our value of 0·048. This large discrepancy between the two values is surprising, particularly in view of the good agreement obtained for the ^{11}C ground state. Apart from experimental uncertainties, a possible explanation of this discrepancy may lie in the neglect of Coulomb and resonance effects in the simple stripping theory.

Reduced widths for α-particle emission, θ_α^2, have been calculated for the 10·84 and 11·82 Mev states from the measured total widths. These were extracted using the Coulomb function graphs of Sharp, Gove and Paul (1955) and assuming a radius of interaction of 4·5 fermi. Since both these states are energetically allowed to decay to either the ground or first excited states of ^{8}Be, two values of θ_α^2 were obtained for each and in Table 2 the value in parenthesis corresponds to decay to the first excited state. It will be noticed that $\theta_\alpha^2=700$ for the 10·84 Mev state, assuming decay to the first excited state of ^{8}Be. This is an improbably large value and suggests that the 10·84 Mev state mainly decays to the ground state of ^{8}Be. Similar conclusions cannot be drawn for the 11·81 Mev state, because although the value for θ_α^2, assuming decay to the first excited state, is large, it is not improbably so.

The observation of an $l=2$ transition leading to the 9·63 Mev state agrees with the results of Maslin *et al.* (1956) and enables assignments of 0, 1, 2, 3 or 4 to be made. Since this state decays by α-particle emission to the ground state of ^{8}Be it is permitted to have only spins and parities according to the sequence 0^+, 1^-, 2^+, 3^- etc. Thus, the 9·63 Mev level must be either 1^- or 3^-. However, if the spin of this state was 1^-, the selection rules would permit its formation by an $l=0$ transition. Since no $l=0$ component is observed in the angular distribution, 3^- is the favoured spin and parity of the 9·63 Mev state. This assignment is also supported by the recent analysis of experimental data made by Barker, Bradford and Tassie (1960).

The 10·84 and 11·82 Mev states are both formed by $l=0$ transitions and so must be either 1^- or 2^- states. Since they have large natural widths for α-particle emission, 2^- is inadmissible. This is true for both possible modes of decay, i.e. to the 0^+ ground state or the 2^+ first excited state of ^{8}Be. Thus, according to the present experimental results, the 10·84 and 11·82 Mev states of ^{12}C must both have a spin and parity of 1^-.

The spins and parities assigned to the 10·1 and 12·70 Mev states in Table 2 are the most probable values (see Cook *et al.* 1958 and Almqvist *et al.* 1959).

It is of interest to compare the present spin and parity assignments with the intermediate coupling shell model calculations of Kurath (1956). The latter predicts the existence of three states of configuration s^4p^8 with spins of 4^+, 0^+ and 1^+ in the energy range of 10 to 14 Mev. The predicted 1^+ state can probably be identified with the 12·70 Mev level which was observed to be strongly formed by an $l=1$ transition and has a noticeably large proton reduced width. The 0^+ state is probably the 10·1 Mev level which was not clearly observed in the present investigation because of its exceedingly large width of 2 Mev. A 4^+ state of configuration s^4p^8 cannot directly be formed by a simple stripping reaction

(*a*) Present investigation; (*b*) levels as reviewed by Ajzenberg-Selove and Lauritsen (1959): the 9·0 MEV level was reported by Alburger and Pixley (1960); (*c*) measured by Maslin, Calvert and Jaffe (1956) from the ^{11}B(d, n)^{12}C reaction.

† Present energy levels are normalized to this value.

‡ Present observations are not inconsistent with these previously reported values (see Almqvist *et al.* 1959, and Ajzenberg-Selove and Lauritsen 1959).

§ Calculated on the assumption that all α-particles lead to the ground state of ^{8}Be except for the values in parentheses which are for an assumed decay to the first excited state of ^{8}Be.

proceeding from ^{11}B since the angular momentum selection rules would require an $l=3$ transition. The only way such a state could be formed by an $l=1$ transition would be by 'spin-flip' stripping. Such a process might proceed very weakly and may explain why no further $l=1$ transitions were observed. However, Alburger and Pixley (1960) have recently detected by means of (p, γ, γ) coincidence measurements on the $^{10}B(^3He, p)^{12}C$ reaction a weakly excited level at 9·0 MEV which may possibly be the 4^+ state predicted by Kurath.

ACKNOWLEDGMENTS

We would like to thank Dr. K. W. Allen for his interest in this work and Dr. A. E. Litherland for much helpful discussion. We are indebted to Mr. H. Marchant and Mr. V. Shepherd, and his Van de Graaff operating staff, for assistance in making the exposures.

Note added in proof.—The authors have recently received a preprint of a paper by D. E. Alburger and D. H. Wilkinson reporting the non-existence of the level of ^{12}C at 9·0 MEV excitation, and explaining the previous incorrect assignment of Alburger and Pixley (1960).

Pre-breakdown Ionization in Hydrogen at Low Pressures

By S. C. HAYDON and A. G. ROBERTSON
Department of Physics, University of New England, Armidale, New South Wales, Australia

MS. received 16*th November* 1960, *in revised form 3rd February* 1961

Abstract. Detailed studies of pre-breakdown ionization in hydrogen gas at low pressures have been made in the presence of uniform electric fields and appropriate analytical methods and experimental procedures suitable for similar studies in crossed electric and magnetic fields have been established. The factors influencing determinations of the first Townsend ionization coefficient α/p_0 from pre-breakdown ionization measurements are discussed and an observed pressure dependence of α/p_0 at $E/p_0 = 350$ is shown to be due to the presence of vapour impurities which can give rise to the large values of α/p_0 recently reported. Values of α/p_0 have been measured for the range of values of E/p_0 from 50 to 450 v cm^{-1} (mm Hg)$^{-1}$.

---

§ 1. Introduction

In recent studies of the spatial growth of pre-breakdown ionization in hydrogen in the presence of crossed electric and magnetic fields (Blevin and Haydon 1958 a, b) a knowledge of the variation of the Townsend primary ionization coefficient α/p_0 with the parameter E/p_0, where E is the electric intensity and p_0 the gas pressure at 0°c, has been required. When these studies were initiated, reliable and generally acceptable values of α/p_0 in the absence of magnetic fields and for an extended range of values of E/p_0 were not available. It had been shown however (Blevin, Haydon and Somerville 1957) that for values of E/p_0 up to about 150 v cm^{-1} (mm Hg)$^{-1}$, good agreement existed between our own and other determinations of α/p_0 (Rose 1956), and that small traces of the common gaseous impurities had no significantly large effect on the values obtained in this range. For these reasons our magnetic investigations were confined initially to values of $E/p_0 < 150$ v cm^{-1} (mm Hg)$^{-1}$ but at the same time detailed investigations of the problems arising at the larger values of E/p_0 were initiated.

During the course of these extensive studies two further investigations (Jones and Llewellyn Jones 1958, Davies and Milne 1959) have been reported which have confirmed the good agreement obtained at low values of E/p_0 and explained the inaccuracies in the work of Rose at high values of E/p_0. As E/p_0 increases beyond about 150 v cm^{-1} (mm Hg)$^{-1}$, however, the values of α/p_0 reported by Davies and Milne become increasingly larger than those of Jones and Llewellyn Jones and at $E/p_0 = 350$ the two values differ by about 20%.

Furthermore Davies and Milne found it impossible to account for this large difference in values of α/p_0. They suggested as possible causes, however, the electrode geometry and/or the method of gas preparation.

These two aspects of the experimental investigation of pre-breakdown ionization are particularly important to us for two reasons. Firstly, to avoid lateral loss of electrons from the ionization region in the presence of transverse magnetic fields it is necessary to depart from the conventional plane-parallel geometry with fixed gas pressures and variable electrode separation, and use instead cylindrical geometry with fixed electrode separation and variable gas pressure. Secondly, to avoid electrode distortions in studies with cylindrical symmetry, it is desirable to avoid excessive heat treatment, and rely, if possible, on flushing techniques and liquid-air traps to attain the required gas purity. A knowledge of the effect of small traces of gaseous impurity is therefore necessary.

For these reasons detailed studies in electric fields only have been necessary before extending our measurements in crossed electric and magnetic fields to values of $E/p_0 > 150\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$, and the present paper discusses a number of effects which can influence the evaluation of α/p_0 in hydrogen.

§ 2. EXPERIMENTAL PROCEDURE

In view of our special reasons for this investigation and of Davies and Milne's suggested explanations of the lower values of α/p_0 reported by Jones and Llewellyn Jones, the following details are relevant and important.

2.1. *Vacuum Systems*

Two separate vacuum systems have been used, each employing conventional vacuum techniques with no attempt to achieve ultra-high vacua. Ultimate pressures of about 10^{-5} mm Hg have been attained in each case with an oil diffusion pump using Apiezon A oil backed by a mechanical rotary oil pump. Both systems were completely free of all traces of mercury vapour. No heat treatment for degassing purposes was employed although liquid-air traps were used to condense vapour impurities. In each case hydrogen gas was obtained by diffusion of cylinder hydrogen through a palladium thimble. Hydrogen gas pressures in the range 0·5 to 10 mm Hg were measured with an oil manometer containing Apiezon 'B' oil. After repeated flushing of the whole system with freshly prepared hydrogen in the initial stages of pumping, no detectable change in gas pressure was observed over periods of several weeks and the characteristics of the gas sample as determined by measurements of α/p_0 at a fixed value of E/p_0 remained the same within $\pm 2\%$ throughout these periods, provided the liquid-air traps were maintained at all times.

2.2. *Ionization Chambers*

Two very different ionization chambers have been used and will be referred to subsequently as the glass and brass chambers respectively. With correct analysis of the measured ionization currents (see § 4) each chamber has yielded the same values of α/p_0. The following details concerning electrode geometry and vacuum materials are therefore of interest.

2.2.1. *Glass chamber.*

This chamber was designed for investigations in static electric fields only, and contained two Rogowski profiled copper electrodes, the flat portions having a diameter of 5 cm. These were mounted inside an inverted commercial desiccator which was itself sealed to a copper-coated mild-steel base plate of diameter 27 cm by means of Apiezon N grease. Ultra-violet light from a stabilized mercury arc passed through 49 holes each of diameter 0·5 mm perforated in the anode and covering a disk of diameter 1 cm in the centre. The large number of holes allowed the ultra-violet light intensity at the cathode to be sufficiently high to ensure as large a variation as possible in the initial photoelectric emission from the cathode surface.

The inside diameter of the chamber was 21 cm so that the ionization region between the plane portions of the two electrodes was 8 cm from the nearest glass wall. A check on the lateral spread of electrons into regions of non-uniform electric field was also made by parting the Rogowski profiled cathode at the edge of the plane surface and suitably mounting and insulating the two components to enable the distribution of ionization current across the electrode to be determined. For the range of E/p_0 up to 450 v cm^{-1} (mm Hg)$^{-1}$ no pre-breakdown ionization could be detected with the electrometer connected to the curved portion of the composite assembly, and the values of α/p_0 measured before and after the parting of the two sections were identical.

2.2.2. *Brass chamber.*

This ionization chamber was designed specifically for investigations in the presence of a transverse magnetic field and its dimensions were limited by the available Helmholtz coils used to obtain the required magnetic fields. These coils allowed only 9 cm between the pole faces so that although the plane-parallel copper disks were 5·83 cm in diameter the inside diameter of the surrounding case could not be made larger than 6·92 cm. The brass container could be maintained at any potential less than that applied to the anode by a suitable tapped resistor chain across the power supply.

Initially the anode was perforated with 43 holes each of diameter 1 mm to admit ultra-violet light but for reasons discussed in § 4 this was subsequently replaced by another electrode containing 49 holes each of diameter 0·5 mm. Two quartz windows were sealed to the chamber with 'O'-rings and the component sections of the chamber casing each sealed with W40 wax or araldite to facilitate demounting of the electrode assembly for replacement and modifications as required.

In each chamber sapphire rods were used to achieve the required insulation from the container and the electrode separation could be adjusted and measured by use of a micrometer screw gauge attached externally to copper bellows. At all times the plane electrodes were parallel to better than one-tenth of one degree.

2.3. *Measurements of Ionization Currents*

Initial measurements were made with an electrometer valve and a series of high resistors ranging from 10^7 to 10^{12} ohms (Crompton, Dutton and Haydon 1956).

In a subsequent careful check of all instrumentation, however, and for measurements of the current distribution with a split cathode assembly, both a Keithly 200 B and a Vibron electrometer unit were also used.

With the one exception of a series of experiments specifically designed to study the influence of an increase in the initial photoelectric current I_0 on the α/p_0 determinations, all values of I_0 were about 10^{-12} A or less so that at no stage were ionization currents in excess of 10^{-9} A measured. This avoided any spurious surface effects such as those observed in the work of Davies and Fitch (1959), and enabled determinations of α/p_0 to be made with an accuracy to about ±2%.

Any sudden changes in I_0 or ω/α due to surface changes were clearly detected by the analytical method described below and when these did occur measurements were repeated and re-checked until consistent observations were achieved.

2.4. *Voltage Supply*

The voltages required were obtained from a 0–1000 v high-stability supply with short term stability of 1 in 10000 (Hibbard and Caro 1953) and were measured with a calibrated Sangamo Weston sub-standard voltmeter.

§ 3. ANALYSIS OF IONIZATION DATA

In the present investigation the steady-state ionization current between electrodes distance d apart is given by

$$I=\frac{I_0 \exp[\alpha(d-d_0)]}{1-(\omega/\alpha)[\exp\alpha(d-d_0)-1]} \qquad \ldots\ldots(1)$$

where I_0 is the initial photoelectric current from the cathode, d_0 is a distance correction taking into account the non-equilibrium conditions in the initial stages of the spatial development of the ionization current, α and ω/α are the primary and secondary ionization coefficients.

Equation (1) is the spatial equivalent of the following exponentially time-dependent equation common to many transient phenomena (Mangelsdorf 1959)

$$Y_t=A\exp(-\alpha_1 t)-B \qquad \ldots\ldots(2)$$

and when expressed in this form becomes

$$1/I=Y_d=P\exp(-\alpha d)-Q \qquad \ldots\ldots(3)$$

where

$$P=\frac{(1+\omega/\alpha)\exp(\alpha d_0)}{I_0}$$

$$Q=\frac{\omega/\alpha}{I_0}.$$

The analytical problem of determining the unknown constants in (1) is therefore a general and important one. Furthermore it is clear from Eqn (3) firstly that α may be determined without knowledge of either P or Q provided only that they remain constant and secondly that it is not possible without prior knowledge of either I_0 or d_0 to determine a value for ω/α. Unfortunately (see § 4) it is very difficult to determine I_0 experimentally with a high degree of accuracy so that calculations of ω/α from a knowledge of the currents at three separations $d_3>d_2>d_1$ where $d_1>d_0$ is not as simple as would at first appear. However, it is not the purpose of the present paper to discuss this problem but rather to determine values for the coefficient α. The following method used to do this is very simple and has several advantages over the method used by either Jones and Llewellyn Jones or Davies and Milne. It requires that the measurements of ionization current be made at regular intervals throughout the whole range of electrode separations up to the sparking distance d_s. For a constant value of Δd throughout it is then possible to write for Eqn (3).

$$Y_{d+\Delta d}=P\exp[-\alpha(d+\Delta d)]-Q \qquad \ldots\ldots(4)$$

so that

$$Y_d=Y_{d+\Delta d}\exp(\alpha\Delta d)+Q[\exp(\alpha\Delta d)-1] \qquad \ldots\ldots(5)$$

and a simple plot of Y_d against $Y_{d+\Delta d}$ for a particular value of E/p_0 will yield a value for α/p_0 and Q. With this information and Eqn (3) a value for P and hence of

$$\frac{P}{Q}=\frac{(1+\omega/\alpha)\exp(\alpha d_0)}{\omega/\alpha}$$

can be determined. When the growth of ionization current with increasing pressure is determined for constant electrode separation then Eqn (5) becomes

$$Y_p=Y_{p+\Delta p}\exp(kd\Delta p)+Q\,[\exp(kd\Delta p)-1] \qquad \ldots\ldots(6)$$

where $k=\alpha/p_0$.

The sparking criterion is obtained from the condition $Y_d=0$ or $Y_p=0$ and the sparking distance d_s is therefore given by

$$d_s=\frac{\ln(P/Q)}{\alpha}.$$

Again it should be emphasized that neither I_0 nor d_0 are required to determine, from the pre-breakdown ionization measurements, values of α/p_0 and V_s.

The method outlined (Gosseries 1939) has been particularly useful in the present investigations. The simplicity of the plot reveals changes in I_0 or ω/α very clearly and it has been possible, throughout any particular set of measurements, to ensure that these two quantities have remained substantially constant.

§ 4. RESULTS AND DISCUSSION

A detailed study of many of the factors likely to influence the determination of α/p_0 was carried out at $E/p_0=350$ where the values of α/p_0 obtained by Jones and Llewellyn Jones and by Davies and Milne were 2·56 and 3·09 respectively. Of the factors studied the magnitude of the potential applied to the case of the brass chamber, the magnitude of I_0 ($\sim 10^{-13}$ to 10^{-10} A) and the electrode geometries of the two chambers were found to be unimportant provided, of course, both I_0 and ω/α were constant during a particular set of measurements.

The following factors were, however, more important: (i) the size of the perforations used to admit ultra-violet light into the ionization chamber, (ii) the degree of parallelism of the electrode assemblies, and (iii) the presence of vapour impurities.

At small electrode separations both (i) and (ii) introduce distortions and lack of uniformity of the applied electric field and the relative importance of each is not easy to determine. The analytical method employed, however, clearly revealed the influence of (i) and this is illustrated in Fig. 1 which shows plots of Y_d against $Y_{d+\Delta d}$ at $E/p_0=350$ for two different anodes in the brass chamber.

Each plot was obtained from a set of ionization measurements made at intervals of 0·02 cm throughout the range of electrode separations from 0·05 cm to 0·49 cm which was close to the sparking distance. The initial current I_0 in each case was about 2×10^{-12} A and the value of Δd chosen for each plot was 0·26 cm. The single slope of the full curve, for 0·5 mm diameter perforations, corresponds to a value of $\alpha/p_0=2{\cdot}54$ whereas the two slopes of the broken curve for 1 mm diameter perforations yield values of 2·57 and 3·00 respectively. The low value in each case also corresponds to the value obtained in the glass chamber using anode perforations of 0·5 mm diameter. The point at which the change of slope occurs corresponds to measurements at electrode separations of 0·11 cm and

0·37 cm respectively so that a certain minimum electrode separation must be maintained if consistent values of α/p_0 are to be obtained in different ionization chambers using this particular method for admitting ultra-violet light to the cathode surface. Furthermore, the minimum electrode separation, being dependent on E, will vary with the value p_0 and our experiments have shown that for these particular ionization chambers the minimum value varies from 0·06 cm at $p_0 = 3{\cdot}19$ mm Hg to 0·35 cm at $p_0 = 0{\cdot}48$ mm Hg. Provided always that this appropriate distance is exceeded, α/p_0 values are found to be the same irrespective of the size of the hole of the particular configuration used. The inclusion in the analysis of measurements made at too low a value of electrode separation, however, may yield values of α/p_0 which are high.

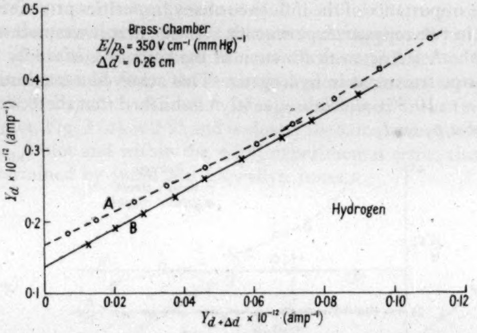

Fig. 1. Y_d plotted against $Y_{d+\Delta d}$ for anodes with different perforations. A, $p_0 = 1{\cdot}405$ mm Hg, anode holes 1 mm diameter; B, $p_0 = 1{\cdot}42$ mm Hg, anode holes 0·5 mm diameter.

The extent of our investigations of the effect of lack of parallelism was determined by the particular requirements of designing a cylindrical ionization chamber for magnetic studies. In this case α/p_0 must be determined from the measured growth of ionization with increasing pressure and we required to know the minimum value of fixed separation d that could be used in our experiments. To obtain this information the dependence of α/p_0 on the fixed value of d was studied at $E/p_0 = 50$.

The dependence observed is illustrated by the $(\alpha/p_0)_1$ values of the Table.

d (cm)	$(\alpha/p_0)_1$	$(\alpha/p_0)_2$
0·1	0·15	0·25
0·15	0·20	
0·20	0·22	0·28
0·30	0·26	0·32
0·40	0·30	0·33

For values of $d > 0{\cdot}4$ cm $(\alpha/p_0)_1$ was independent of electrode separation and equal to 0·33 ± 3%. To check whether the dependence at small separations was due in part to faulty alignment of the electrode assembly the chamber was dismantled and the electrodes readjusted for parallelism. The new value $(\alpha/p_0)_2 = 0{\cdot}33 \pm 3\%$ was again independent of d provided the electrode separation exceeded 0·40 cm and was furthermore the same as the value obtained from the spatial growth of ionization at fixed pressures. At the smaller separations however the dependence of $(\alpha/p_0)_2$ on distance was considerably reduced and this is attributed to the small differences in degree of parallelism to be expected in the two cases. Precision measurements of the degree of parallelism attained were not attempted because we were only interested primarily in establishing the minimum electrode separation that could be used. The value (0·4 cm) obtained is that appropriate to electrodes that can be maintained parallel to at least one-tenth of one degree.

Finally the importance of the influence of any impurities present in our system was observed in two separate experiments. In the first it was necessary to lower the effective photoelectric work function of the cathode surface by subjecting it to glow discharge treatment in hydrogen. This achieved a maximum change in I_0 from 10^{-13} A to 10^{-10} A and subsequently established that there was no marked dependence of α/p_0 on I_0.

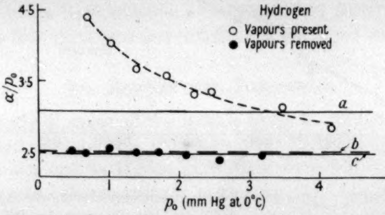

Fig. 2. α/p_0 plotted against gas pressure p_0; brass chamber. $E/p_0 = 350$ v cm^{-1} at 0°c. *a*, Davies and Milne value of α/p_0; *b*, Jones and Llewellyn Jones value of α/p_0; *c*, mean value in present study.

Before the cathode was changed in this way the α/p_0 values measured in the brass chamber at $E/p_0 = 350$ were always $2{\cdot}56 \pm 2\%$ and were identical with those of Jones and Llewellyn Jones. After glow discharge treatment for 5 minutes at a total discharge current of about 3mA no detectable change in pressure occurred and on remeasuring α/p_0 its value was found to have increased to 3·09, the value obtained by Davies and Milne. This characteristically high value was found to be the same after a further period of one hour. Throughout this treatment the glass chamber, which at all times had yielded the lower values of α/p_0, had been isolated and untreated. To establish, therefore, that the high value was a property of the gas itself the sample which had been subjected to a glow discharge in the brass chamber was transferred to the glass chamber and α/p_0 redetermined.

To allow for the difference in volumes of the two chambers it was necessary to add to the 0·08 mm Hg of treated gas transferred, a further 0·33 mm Hg of freshly prepared gas before the appropriate measurements could be made. As was to be expected if the characteristically high value was a property of the gas, the redetermined value of $\alpha/p_0 = 2{\cdot}82$ was between the two values previously measured in the brass chamber. This intermediate value subsequently decreased to the lower value of 2·56 after further dilution of the 0·08 mm Hg with 1·10 mm Hg of freshly prepared hydrogen from the palladium thimble.

In the second experiment a more detailed study of the influence of impurities was made to establish the nature of any dependence of α/p_0 on pressure either with or without liquid air traps applied. The results of these investigations are shown in Fig. 2 and confirm the effectiveness of the liquid air trap in removing the vapours present. From the detailed measurements from which Fig. 2 was compiled it was possible to abstract the growth of ionization current with increasing pressure for a fixed electrode separation $d = 0{\cdot}17$ cm. This is the information required if α/p_0 is to be determined by the experimental procedures adopted by Davies and Milne. Using the analytical method outlined in § 3 the appropriate Y_p against $Y_{p+\Delta p}$ plot for this approach is shown in Fig. 3 (*b*) where again the plots appropriate to the values of 2·56 and 3·09 are given. It is seen clearly that in the presence of vapours this particular approach yields a value for α/p_0 which is identical with the high value of Davies and Milne. When similar information is abstracted from the ionization measurements made with liquid air traps applied, however, the value of α/p_0 calculated from the appropriate $(Y_p, Y_{p+\Delta p})$ plot, Fig. 3 (*a*), is 2·55 and is closely the same as that determined from the $(Y_d, Y_{d+\Delta d})$ plot and within the $\pm 2\%$ experimental error, also the same as the value determined by Jones and Llewellyn Jones.

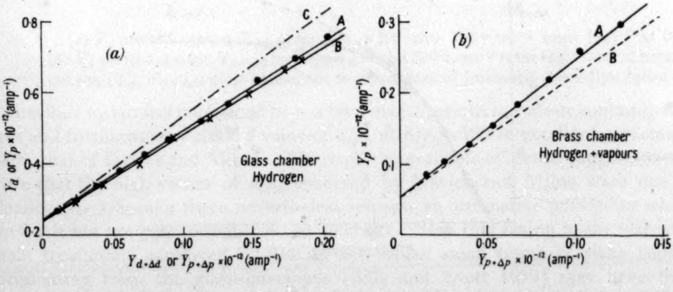

Fig. 3. (*a*) Comparison of two methods for determining α/p_0 in the absence of vapours: A, $p_0 = 2{\cdot}86$ mm Hg at 0°c, $\Delta d = 0{\cdot}12$ cm, $\alpha/p_0 = 2{\cdot}60$; B, $\Delta p_0 = 2{\cdot}64$ mm Hg at 0°c, $d = 0{\cdot}13$ cm, $\alpha/p_0 = 2{\cdot}55$; C, plot corresponding to Davies and Milne value $\alpha/p_0 = 3{\cdot}09$. (*b*) $(Y_p, Y_{p+\Delta p})$ plot for hydrogen gas contaminated with vapours: A, $d = 0{\cdot}17$ cm, $\Delta p = 1{\cdot}25$ mm Hg, $\alpha/p_0 = 3{\cdot}09$; B, plot corresponding to Jones and Llewellyn Jones value $\alpha/p_0 = 2{\cdot}56$.

The effects of the same vapour impurities over an extended range of values of E/p_0 were also studied. For values of E/p_0 less than about 150 v cm^{-1} (mm Hg)$^{-1}$ the α/p_0 values were found to be rather less than those measured in vapour free samples, whereas for E/p_0 greater than 150, α/p_0 became increasingly larger in the contaminated gas. This general trend is to be expected if the important contaminant is water vapour, for at low E/p_0, where the mean electron energy is small, processes of attachment would predominate whereas with increasing E/p_0 and therefore mean electron energy the influence of ionization of impurity molecules would become more important and lead to the observed high values for α/p_0.

Following these detailed studies at $E/p_0=350$ measurements of α/p_0 over an extended range of E/p_0 were made in both chambers and the results summarized in Fig. 4. The measurements in both chambers were made initially on the same vacuum system using common gas samples and later with the brass chamber attached to a second similar vacuum system designed for magnetic investigations. The values of α/p_0 were at all times the same to within the experimental error of $\pm 2\%$. In view of this and the excellent agreement with Jones and Llewellyn Jones at $E/p_0=350$ an explanation of the small but significant differences at lower values is necessary. These differences are never larger than about 8% and fall within the experimental error at E/p_0 values of about 150 and 275. Although it is possible that this may be due to ionization of impurities, it is considered, in view of our detailed studies at $E/p_0=350$, to be unlikely. However a possible explanation for the small differences is illustrated in Fig. 5, which shows details of the analysis of measurements for the values of $E/p_0=200, 250, 300, 350$. Throughout these measurements in the glass chamber the ultraviolet light intensity was monitored and Y_d in this case represents the ratio of monitored current I_m to amplified current I.

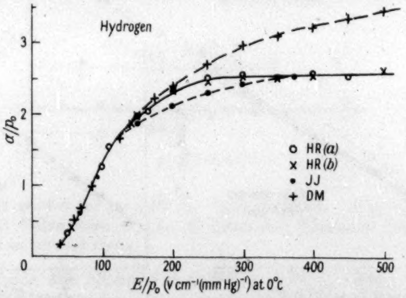

Fig. 4. α/p_0 plotted against E/p_0 (v cm^{-1} (mm Hg)$^{-1}$) at 0°c. HR (*a*), Haydon and Robertson using glass chamber; HR (*b*), Haydon and Robertson using brass chamber; JJ, Jones and Llewellyn Jones; DM, Davies and Milne.

All the measured values have been included in the analysis and the $(Y_d, Y_{d+\Delta d})$ plots show clearly the combined effects of field distortions, lack of parallelism and non-equilibrium at the low values of electrode separation. Also shown for comparison are the appropriate $(Y_d, Y_{d+\Delta d})$ plots for the values of α/p_0 quoted by Jones and Llewellyn Jones. It is clear that unless care is taken to avoid measurements of ionization current at the very small separations indicated by the curved portions of the plots of Fig. 5 the α/p_0 values obtained would be lower than those quoted for the present investigation in Fig. 4. The present analytical method clearly revealed these effects but it seems possible that they may not have been detected by the method used by Jones and Llewellyn Jones and so gave rise to the slightly lower values quoted for their investigations.

In conclusion some comment is necessary concerning the high values of α/p_0 obtained by Davies and Milne, particularly as they took considerable precautions to achieve high gas purity by using elaborate degassing procedures and meticulously excluding all oils and greases from their vacuum system. One would expect that such treatment would remove the common impurities (Hickmott 1960, Craggs and McDowell 1955) likely to be present in our system and because all these impurities have ionization potentials less than hydrogen would result therefore in lower values of α/p_0 at large E/p_0. This expected behaviour was in fact confirmed by our own investigations in vapour contaminated gas and furthermore yielded a value of α/p_0 at $E/p_0 = 350$ in excellent agreement with that of Davies and Milne. Although the available evidence suggests therefore that the high values of α/p_0 observed by Davies and Milne were due to inadequate trapping there nevertheless remains an alternative possibility which so far it has not been possible for us to check. It is that owing to the elaborate heat treatments employed by Davies and Milne small traces of alkali vapour originating from the glass envelopes (Bills and Evett 1959) may have been present in their investigations. This would of course lead to higher values of α/p_0. Finally it should be remembered that although Jones and Llewellyn Jones did not exclude all oils and greases they nevertheless took great care to reduce the background contamination to a minimum. By comparison with our simpler technique of diffusion of cylinder hydrogen through a palladium thimble and passage through a liquid air trap into an unbaked, demountable chamber their techniques, which included oven degassing, were elaborate. Nevertheless the values of α/p_0 are in excellent agreement at $E/p_0 = 350$ and this suggests that provided there is adequate trapping of vapours, small variations in the amount and composition of the background impurities present in such systems have in fact little effect on the measured values of α/p_0.

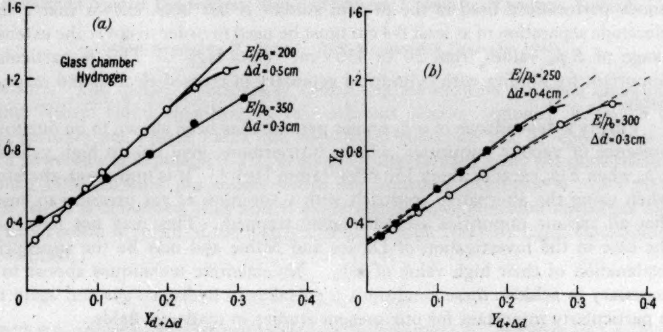

Fig. 5. (*a*) Y_d plotted against $Y_{d+\Delta d}$ for $E/p_0 = 200$ and 350 v cm^{-1} (mm Hg)$^{-1}$ at 0°c; (*b*) Y_d plotted against $Y_{d+\Delta d}$ for $E/p_0 = 250$ and 300 v cm^{-1} (mm Hg)$^{-1}$ at 0°c, broken curves, (Y_d, $Y_{d+\Delta d}$) plots equivalent to α/p_0 values of Jones and Llewellyn Jones.

§ 5. Conclusion

The present investigation has shown that when determining values for the first Townsend coefficient α/p_0 from pre-breakdown ionization measurements it is particularly important to check the validity of including measurements made at very small electrode separations. Not only may non-equilibrium conditions prevail in this region but the measurements may be in error due to the effects of slight non-parallelism and/or the field distortions due to the anode perforations required to admit the ultra-violet light.

Furthermore, when α/p_0 is to be determined from measurements of the growth of ionization with increasing pressure then a certain minimum fixed electrode separation must be maintained. For the specific configuration of anode perforations used in the present studies it has been shown that a fixed electrode separation of at least 0·4 cm must be used in order to cover the extensive range of E/p_0 values from 50 to 450 v cm^{-1} (mm Hg)$^{-1}$. This is particularly important for studies with cylindrical geometry in crossed electric and magnetic fields.

Finally a dependence of α/p_0 on gas pressure has been shown to be due to the presence of vapour impurities, which, furthermore, give rise to high values of α/p_0 when E/p_0 exceeds about 150 v cm^{-1} (mm Hg)$^{-1}$. It is important, therefore, when using the alternative approach with a variation of gas pressure to ensure that all vapour impurities are adequately trapped. This may not have been the case in the investigation of Davies and Milne and may be the appropriate explanation of their high value of α/p_0. No elaborate techniques appear to be necessary to achieve these conditions for studies in hydrogen gas and again this is particularly important for our present studies in magnetic fields.

It should be emphasized, however, that we do not claim that our own values are those appropriate to extremely pure hydrogen. It would seem that in very pure hydrogen the α/p_0 values, if at all different, should be less than those obtained by us (Davies, Milne and Myatt 1960) and we hope to study this problem and similar ones, associated with magnetic studies in the inert gases, more fully with ultra-high vacuum techniques.

ACKNOWLEDGMENTS

The authors are grateful to the Australian Atomic Energy Commission for an equipment grant in aid of this and allied investigations and for the financial assistance given to one of us (A.G.R.). They are also indebted to Professor J. M. Somerville for many helpful discussions.

Communicated by H. Messel; *MS. received* 6*th December* 1960

Abstract. The density spectrum of cosmic-ray air showers has been measured using Wilson cloud chambers in two different density regions. From 50 to 500 particles per square metre the differential spectrum can be approximated by a power law of exponent $-2{\cdot}5$, in good agreement with many previous results. Above 1100 particles per square metre the measured exponent is $-3{\cdot}9 \pm 0{\cdot}5$. The result is compared with recent experiments using emulsion chambers and an explanation in terms of the characteristics of high energy nuclear interactions is outlined.

§ 1. INTRODUCTION

THE majority of electrons observed in extensive air showers and in high energy nuclear interactions result from γ-rays produced by the decay of π^0-mesons. A study of the electrons can, therefore, be expected to throw light on the production of π-mesons in high energy nuclear encounters. In experiments on this subject, generally no attempt is made to determine the energies of individual electrons. Instead the density of electrons, that is, the number per unit area crossing an area perpendicular to the shower axis, is studied. A large number of experiments (Galbraith 1958) has shown that for air showers, in the region 50 to 500 particles per square metre, the number of air showers of density D can be approximated by a power law

$$N(D)\,dD = \frac{A}{D^{2\cdot 5}}\,dD.$$

It is rather difficult to extend this result to higher densities using Geiger counters, but in an experiment in 1956 with proportional counters Norman (1956) produced good evidence for a steeper spectrum in the region of 1000 particles per square metre, which was confirmed by Prescott (1956) using ionization chambers.

More recently a very different approach has produced interesting results. Both the Japanese and Bristol emulsion groups (Fujimoto *et al.* 1960, Duthie *et al.* 1960) used sandwiches of lead and emulsion exposed at high altitudes, and have examined electromagnetic cascades due both to individual γ-rays entering the stack and to nuclear interactions. They have been able to show a direct correlation between density and the primary γ-ray energy in the first case, and have produced good evidence for a change in slope of the density spectrum at densities corresponding to primary γ-ray energies of about 1000 GeV.

---

† This work has been sponsored in part by the Office of Scientific Research of the Air Research and Development Command of the U.S. Air Force, and in part by the Nuclear Research Foundation within the University of Sydney.

The present experiment was begun in 1956 to examine the air shower density spectrum in the high density region. The method used has been to photograph the passage of a small part of the air shower through a Wilson cloud chamber. This method, in the high density region, has a number of advantages: (*a*) the actual number of particles crossing a given area can be counted for each individual shower, (*b*) the direction of the shower is obtained, (*c*) the measurement is a close approximation to a measurement at a point (somewhat surprisingly, it is even a better approximation to a point than is the case in photographic emulsions because of the large ratio of the radiation lengths in air and emulsion–lead sandwiches) and (*d*) it can be used to densities of at least 10 000 particles per square metre.

The experiment has been carried out at stations in Ireland, Jamaica and Australia. As will be seen, it has shown that the slope of the spectrum is much steeper between 1100 and 5000 particles per square metre than below 500 particles per square metre.

§ 2. THE APPARATUS

The apparatus at each station consisted of a pair of counter-controlled Wilson cloud chambers. The chambers had their axes at right angles to each other. The Dublin cloud chambers were of illuminated area 30 cm × 8 cm and 30 cm × 12 cm. Only the latter has been used in the density experiment, for the former was designed for use with an electromagnet and (although it had a clear cone above it) it was thought that the surrounding material might affect the electron density within it. The two Jamaican chambers had illuminated area 30 cm × 18 cm. In Sydney, larger chambers have been used, one was square and of $0{\cdot}11$ m^2 illuminated area, the other was round, of area $0{\cdot}10$ m^2. In all cases the cloud chambers were installed in specially built huts of light construction, maintained at a temperature of $70 \pm 3\,^\circ$F. The illumination was by xenon-filled flash tubes operating at 2000 v from large condenser banks. Each chamber was photographed with stereo cameras. Since, in all cases, the chambers formed part of fairly complicated air shower arrays, a considerable number of triggering criteria could be selected. Five have been used in this experiment. They are:

A. A coincidence between either or both of two penetrating shower sets and an unshielded tray of Geiger–Müller counters of area $0{\cdot}25$ m^2. The penetrating shower set has been described in detail elsewhere (McCusker, Dardis and Wilson 1955); briefly it required at least two Geiger–Müller counters discharged in each of three trays (each of area $0{\cdot}25$ m^2) of twelve counters separated vertically by a total of 35 cm Pb. The separation of the penetrating shower set and the unshielded tray was about 2 m with the cloud chamber about 5 m away. This trigger was fairly sensitive to low density showers and produced 11 284 events in Dublin and 4280 in Jamaica.

B. The second trigger produced a set of events which is a sub-set of A. It was a coincidence between the penetrating shower set, the unshielded tray and a high density detector (called an M-unit) situated within one metre of the cloud chamber. The M-unit consisted of three Geiger–Müller counters, each of area $18{\cdot}3$ cm^2, in horizontal array at the apexes of an equilateral triangle of side 20 cm. This trigger was a high density trigger. It produced 106 events in Dublin and 91 in Jamaica with more than 800 particles per square metre in the chamber.

C. The third trigger consisted of a coincidence between an M-unit placed directly on top of a cloud chamber and an unshielded tray 2 m away. In Sydney this produced 34 events having more than 800 particles per square metre in the chamber.

D. The fourth trigger was obtained by replacing the M-unit over the Sydney chamber with three large counters each of area 124 cm^2 with their centres separated by 65 cm. Again the unshielded tray of area 0·2 m^2 was 2 m away. This trigger was much more responsive to events of low density. 609 events were recorded.

E. Finally the three counters in arrangement D were replaced by three trays each of three counters connected in parallel. The area of each tray was 372 cm^2, again with the distance between centres of 65 cm and the unshielded tray 2 m away. 999 events triggered in this way were obtained.

§ 3. DENSITY DETERMINATION

Two slightly different methods were used to determine the number of electrons crossing the illuminated area. In Dublin and Jamaica all photographs were examined in a stereoscope and the numbers of particles crossing the midplane were counted. Up to a total of 50 particles, this could be done exactly in most cases and hence the density for each individual shower at this value could be determined to $\pm 14\%$ s.d. (50 ± 7). For denser showers the statistical error decreased but accurate counting became more difficult above 100 particles per chamber and it is estimated that above this limit this led to a slow increase in the inaccuracy of density determination with increasing density. For the Dublin cloud chamber, 50 particles crossing the illuminated area vertically corresponds to about 1400 particles per square metre. The projected angle of the shower with respect to a plumb line was measured from a reprojection of the direct view for each chamber and compared with the same angle determined from stereoscopic examination of the other chamber. This procedure was only carried out for sufficiently dense showers (generally those with more than eight tracks in the chamber). In most cases the density estimate was made independently by two observers and an average taken.

The procedure in Sydney was somewhat different, density being found by counting, on the directly projected photograph, the number of straight tracks hitting an iron plate in the chamber.

In Fig. 1 (Plate) four cloud chamber pictures of the showers are shown so that the reader can himself estimate the ease (or difficulty) with which a density measurement can be made. The four pictures correspond to densities of 450, 1450, 4000 and 7500 particles per square metre respectively. This last was the maximum density observed in the experiments.

§ 4. RESULTS

4.1. *Trigger A*

The results from the Dublin station for events obtained with trigger A where more than eight particles were observed in the chamber are shown in Fig. 2. A similar curve was obtained for the same trigger in Jamaica. The graph is based on the 762 most dense events from a total of 11 284, that is, on 7% of the total. From 300 to 1000 particles per square metre the differential spectrum† can be approximated by a power law of exponent $-2{\cdot}1 \pm 0{\cdot}2$. This fit was determined by a series of comparisons, using the χ^2 test, of the observed results and those predicted from spectra having different exponents, the total number of events in the predicted distribution being normalized each time to the observed total. The exponents were varied in steps of 0·1 throughout the range. The computations were carried out on the Sydney University digital computer SILLIAC. No correction for the triggering probability of the apparatus was made. The value of the χ^2 probability for $\gamma = 2{\cdot}1$ was 0·15 and at $\gamma = -2{\cdot}9$ was less than 10^{-6}. It can be seen from Fig. 2, however, that this spectrum is not a good fit for the high density points.

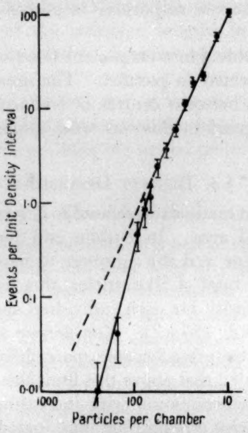

Fig. 2. The differential spectrum obtained using trigger A. The events are those from the Dublin station showing more than eight particles in the chamber. The lines represent power laws of exponents $-2{\cdot}1$ and $-3{\cdot}6$ respectively. The points are uncorrected for triggering probabilities or Poissonian fluctuations in the cloud chambers. It is not suggested that the change of slope occurs suddenly at one point.

4.2. *Triggers B and C*

Since 93% of the events from trigger A show less than eight particles in the chamber it seems likely that the penetrating shower sets exerted only a negligible effect on the selection of higher density events (i.e. events of greater than 40 particles per chamber). This conclusion has been checked in two ways:

(*a*) Trigger C at Sydney does not include a penetrating shower set coincidence but, within the rather large statistical errors, gives the same exponent for the density spectrum in the region above 1100 particles per square metre as trigger B at Jamaica and Dublin. The values were: Dublin, $-3{\cdot}8 \pm 0{\cdot}3$; Jamaica, $-3{\cdot}5 \pm 0{\cdot}6$; Sydney, $-4{\cdot}2 \pm 0{\cdot}8$, with χ^2 probabilities at these values of 0·06, 0·95 and 0·40. The errors give the 5% points.

---

† All the analysis was carried out and all results are stated in terms of the *differential* and not of the integral spectrum.

(*b*) At both Dublin and Jamaica the trigger involved either or both of two penetrating shower sets. If the probability of a given shower triggering a given set is P, then, on average, the probability of both being triggered by this shower (assuming constant density over the apparatus) is P^2, the probability of one but not the other being triggered is $2P(1-P)$ and of neither is $(1-P)^2$. P^2 and $2P(1-P)$ were determined experimentally from the hodoscope records. For showers of observed density greater than 800 particles per square metre at the cloud chambers $(1-P)^2$ was 0·06.

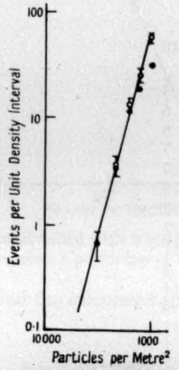

Fig. 3. The differential spectrum obtained with triggers B and C. The lower points represent the experimental values. The upper points have been corrected for the triggering probability of the M-unit. The line is a power law of exponent $-3{\cdot}9$.

Since the results of the three stations are consistent and since the effect of the penetrating shower set trigger is small at high densities, the statistical accuracy of the determination of the exponent has been increased by adding the data for the three stations together. Ignoring the Poissonian corrections the best fit was obtained for the region above 1100 particles per square metre with an exponent of $-3{\cdot}6 \pm 0{\cdot}4$ with a χ^2 probability for this value of 0·3. If the Poissonian corrections are included in the analysis the best exponent is $-3{\cdot}9 \pm 0{\cdot}5$ with a χ^2 probability of 0·24. The χ^2 probability that an exponent $-3{\cdot}0$ is a good fit is 0·004, and that $-2{\cdot}5$ is a good fit is less than 10^{-6}. The experimental points and the $-3{\cdot}9$ power law are shown in Fig. 3.

4.3. *Triggers D and E*

One possible explanation of the steep slope obtained above is that it is due to the cloud chamber technique. This is not likely, since previous workers with cloud chambers (Brown and McKay 1949) obtained a result in the density region 100 to 1000 particles per square metre in good agreement with counter experiments. However, it was thought worth while to carry out subsidiary experiments at these lower densities using the same methods and techniques of analysis as in the high density region. Accordingly the experiments with triggers D and E were made. The results of these together with the result for the C trigger for completeness are given in the Table.

The Results of Three Different Triggering Arrangements at Sydney

Number of particles in cloud chamber	Number of Events		
	Trigger C	Trigger D	Trigger E

The total sensitive times were 3500, 612 and 218 hours respectively. Trigger D gave 10 events and Trigger E 5 events with greater than 60 particles.

The results of triggers C and D were analysed in the same way as those in the high density region, namely, the observed counts were compared, using a χ^2 test on SILLIAC, with the predictions of a power law spectrum whose exponent was varied in steps of 0·1 throughout the range. The comparison was made (*a*) making no Poissonian corrections, (*b*) using the Poissonian corrections for the triggering probability of the counter system $(1-e^{-S\Delta})^3$ where S is the area of one tray and Δ the shower density† and (*c*) correcting both for the triggering probability of the counter array and for the fluctuation in the number of particles seen in the chamber. That is, the rate for n particles in the chamber was computed from

$$R_n = K\int_0^\infty (1-e^{-S\Delta})^3\,\frac{e^{-A\Delta}(A\Delta)^n}{n\,!}\,\frac{d\Delta}{\Delta^\gamma}$$

where A is the cloud chamber area and γ the exponent of the differential spectrum.

For D in the density range 100 to 600 particles per square metre, the values of γ obtained were $-2{\cdot}1 \pm 0{\cdot}3$, $-2{\cdot}7 \pm 0{\cdot}3$ and $-2{\cdot}8 \pm 0{\cdot}3$ for the three methods respectively. For trigger E in the density range 50–500 particles per square metre, the values were $-2{\cdot}3 \pm 0{\cdot}2$ for the uncorrected case, and $-2{\cdot}6 \pm 0{\cdot}2$ for the method using both corrections. The values of the χ^2 probability for these two cases were 0·6 and 0·8. For this last arrangement (which was the larger sample of the two low density runs) γ was also found for the range 40 to 1000 particles per square metre. Again it was $-2{\cdot}6$. For an exponent of $-3{\cdot}0$ the χ^2 probability of a good fit was 0·004.

---

† No correction was made for the large unshielded tray.

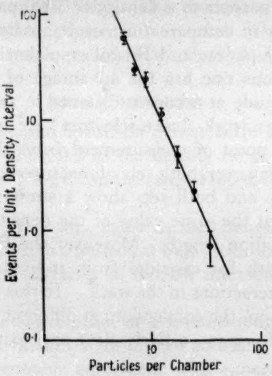

Fig. 4. The differential spectrum obtained with trigger E. The values are uncorrected. The line represents a power law of exponent $-2{\cdot}3$.

The experimental points and the calculated spectrum for arrangement E are given in Fig. 4.

§ 5. DISCUSSION

The results of these experiments show that there is a considerable change in the exponent of the density spectrum of extensive air showers from the region 50 to 500 particles per square metre to the region above 1100 particles per square metre. If the validity of the Poissonian corrections is assumed the change is from $-2{\cdot}6 \pm 0{\cdot}2$ to $-3{\cdot}9 \pm 0{\cdot}5$. If no Poissonian corrections are used the change is from $-2{\cdot}3 \pm 0{\cdot}2$ to $-3{\cdot}6 \pm 0{\cdot}4$. The effect is thus independent of these corrections.

In point of fact there is a wealth of evidence concerning the exponent of the lower density region. Experiments have been performed with Geiger counters (Cocconi and Tongiorgi 1949, Auger and Daudin 1945, Murdoch 1958), proportional counters (Norman 1956), ionization chambers (Prescott 1956) and cloud chambers (Brown and McKay 1949) to quote only a few authors. In many of these experiments the statistical accuracy is considerably better than in ours and it appears likely that in the whole region from 1 to 500 particles per square metre there is a slow change in the exponent. In a recent paper Murdoch (1958) has combined his own data with that assembled by Greisen (1956) to get an exponent varying from $-2{\cdot}31$ at 1 particle per square metre to $-2{\cdot}53$ at 500 particles per square metre.

Results obtained at higher densities have been summarized by Norman (1956) who obtained a value of γ at 1000 particles per square metre of $-3{\cdot}2$. This result has been confirmed by Prescott (1956). If we make the natural assumption that the change between 500 and 1100 particles per square metre is smooth our own results are in excellent agreement with this. Thus, summarizing all data, there is, from 1 to 500 particles per square metre (a range of 500 to 1 in density), a change of about 8% in the exponent of the differential spectrum. From 500 to 1500 (a range of 3 to 1) there is a further change of 50%. As far as we can tell the new steep spectrum persists to a density of 5000 particles per square metre.

It is very interesting to compare this result obtained at sea level with the results obtained by the Japanese and Bristol emulsion groups at high altitudes. In working with emulsions one has the advantage of being able to select the central region of the cascade at a known distance in radiation lengths from the origin. In the air shower work, 'core selectors' are only approximate devices and the distance of the point of measurement from the origin of a particular cascade is not known. However, both sets of measurements are, in the first place, measurements of density and both sets show a similar change in slope of the density spectrum at about the same value of the density, if this is expressed in particles per square radiation length. Moreover the Bristol group have found the same steep slope both for cascades from individual γ-rays and cascades resulting from nuclear interactions in the stack. In this second case the electrons observed have resulted from the conversion, at different distances from the point of observation, of several γ-rays—a fairly close approximation to the conditions in the air shower work.

If these two changes in the spectrum are due to the same cause, then this cause cannot be a change in the slope of the primary cosmic-ray spectrum, for the two experiments consider primary particles from two very different energy ranges. A similar conclusion has recently been drawn by Kameda, Toyoda and Maeda (1960) from a comparison of their results on the number spectrum at mountain altitudes with the work of Nikolskii, Vavilov and Batov (1956). One must therefore look to some change in the character of nuclear interactions in the region around 10^{15} ev to explain this effect. One possibility is that the longitudinal momentum of the produced π-mesons in the centre-of-mass system in a nucleon–nucleon collision is effectively limited. This could be due to a maximum allowed velocity of the 'fireball' in the fireball model, as suggested by Hayakawa and Ogita (1960), or to the preferred production of mesons perpendicular to the line of flight (which would also help to explain a constant transverse momentum) or to some other possibility. This hypothesis of a limited P_L has been included in the theory of the nucleon cascade in the atmosphere developed by Ueda, so far with some success (Ueda and McCusker 1961). It has been possible to derive a change in slope of the γ-ray differential spectrum at 220 g cm^{-2} from $-2{\cdot}9$ to $-4{\cdot}1$ at about 1000 GeV, a change in slope of the density spectrum at sea level and at the same time, a μ-meson spectrum at sea level in reasonable agreement with observations (Owen and Wilson 1955, Ashton *et al.* 1960). This work is continuing.

One further possibility is worth mentioning. The decay of the Σ^0-hyperon is another source of γ-rays. A limitation on the momentum of the π-mesons in the centre-of-mass system would not apply to the hyperon, if this were derived from the incident nucleon. Thus if Σ^0 production remains constant with energy, one might expect that at a sufficiently high energy, the γ-ray spectrum would become flatter. The energy at which this happened would be closely related to the ratio of π^0 and Σ^0 cross sections. So far there is some experimental evidence that might favour this additional hypothesis. A very high energy cascade, possibly due to a Σ^0 hyperon, has been found by the Chicago group (Teucher *et al.* 1960), an extremely dense air shower ($\sim 50\,000$ particles per square metre) was photographed in a cloud chamber at 11 500 ft by Gottlieb (1951), and a flatter slope for γ-rays from high energy nuclear events has been suggested by the Bristol group (Duthie *et al.* 1960). This evidence, while of great interest, is not conclusive and further experiments in this field, possibly with cloud chambers at mountain altitudes, would be worth while.

§ 6. CONCLUSIONS

The slope of the differential spectrum of extensive air showers at sea level changes from a value of $-2{\cdot}6 \pm 0{\cdot}2$ in the density range 50 to 500 particles per square metre to a value of $-3{\cdot}9 \pm 0{\cdot}5$ in the range 1100 to 5000 particles per square metre.

If this change is due to the same cause as the change in slope of the density spectrum of cascades observed in emulsion at high altitudes then both are probably due to a marked change in character of nuclear interactions at energies around 10^{14}–10^{15} ev.

A theory based on the assumption of a limited longitudinal momentum of π-mesons in the centre-of-mass system of two colliding nucleons has produced preliminary results in reasonable agreement with experiment.

ACKNOWLEDGMENTS

We are indebted to Professor H. Messel for the excellent research facilities provided and his constructive comments, to Dr. F. H. Bowen for his hospitality in Jamaica, to Dr. J. Lehane for his help in running the Jamaican station, and to Miss E. Smith for her help in the analysis of events. The paper has benefited from the comments and criticisms of Dr. H. S. Murdoch. One of us (G. W.) was supported by a research studentship from the Australian Atomic Energy Commission.

The Unrestricted Hartree–Fock Method

By W. MARSHALL
Atomic Energy Research Establishment, Harwell, Didcot, Berks.

Communicated by W. M. Lomer; MS. received 9th Janaury 1961

Abstract. The unrestricted Hartree–Fock method is a convenient method of calculating neutron form factors and hyperfine interactions, but because the method gives wave functions which are not eigenfunctions of S^2, the validity of it must be questioned. It is shown that the unrestricted Hartree–Fock method gives spin densities which are approximately correct to first order provided certain exchange energies are small relative to 'promotion' energies. Furthermore, it is shown that the wave functions obtained must be used directly and that it is a poor approximation to project out the unwanted parts after the energy minimization procedure has been performed.

---

§ 1. Introduction

Recently the unrestricted Hartree–Fock method has been used in many calculations of neutron form factors and hyperfine interactions with the nucleus (Wood and Pratt 1957, Heine 1957, Cohen, Goodings and Heine 1959, Watson and Freeman 1960, Goodings and Heine 1960, Freeman and Watson 1960, Goodings 1961). It is an extremely convenient method because it is a very natural extension of the conventional Hartree–Fock method, and the many-electron wave function is written in the form of a single determinant so that calculations are relatively easy. However, because the unrestricted Hartree–Fock method allows the α and β spins to have different wave functions the total wave function obtained is not an eigenfunction of S^2 and hence the validity of the method must be questioned. It has been suggested (Nesbet 1960, Freeman and Watson 1960) that this objection may be overcome by determining the one-electron functions by the unrestricted Hartree–Fock method and then eliminating by means of the appropriate projection operators those parts of the function corresponding to the unwanted values of S^2. The resulting many-electron wave function is of different form from that used in the energy minimization process and may give higher or lower energy expectation values than did the original form. Other derived quantities may be different and in this paper the spin density, and in particular the spin density at the nucleus, are investigated. It is found that the process of projection does not improve the wave function, i.e. the total wave function as derived directly by the minimization procedure is 'better' than the projected function derived from it. This explains, for example, why the unrestricted Hartree–Fock method used directly gives a good value for the hyperfine constant of lithium whereas the projected unrestricted wave function gives a poor value. Furthermore, we show that the calculation of the spin density using the unrestricted wave function directly is justified provided certain exchange integrals are small relative to what we may call 'promotion energies'.

The validity of the unrestricted Hartree–Fock method has previously been discussed by Pratt (1956), but his paper only demonstrated that effects existed in principle and he did not give any arguments for the conditions under which the method could calculate these effects accurately. Of course, the unrestricted Hartree–Fock method does not include correlation effects properly, just as the Hartree–Fock method does not include them properly, and to improve the wave functions in this respect would be difficult and would probably involve using Hylleraas-type wave functions. We shall not discuss these matters in this paper, but we will investigate questions of validity arising solely because the unrestricted Hartree–Fock wave function is not an eigenfunction of S^2. In § 2 we illustrate the argument with a simple three-electron system and in § 3 we show how the argument is generalized to consider any arbitrary case.

§ 2. A SIMPLE EXAMPLE

In this section we consider the simplest possible example which will illustrate the argument. This example is the free lithium atom. The ground state configuration of Li is the ^{2}S state which using the conventional Hartree–Fock method we would describe with a configuration $(1s)^2(2s)^1$. This is a very simple system to start with because it has only three electrons, but for our purposes there is an even simpler system and that is the excited $^2P_{3/2}$ state of Li to which we would assign the Hartree–Fock configuration $(1s)^2(2p)^1$, or more fully, $1s_\alpha 1s_\beta 2p_\alpha$, where it is understood that the 2p orbital involved is that with $l_z = 1$ and the total wave function is that describing the $j = \frac{3}{2}$, $j_z = \frac{3}{2}$ state. The argument we would use for both these states, the ^{2}S and the $^2P_{3/2}$, would be exactly the same in principle but that for the $^2P_{3/2}$ state involves less algebra because the 2p state is automatically orthogonal to the 1s, whereas the ^{2}S state in the 2s orbital is not automatically orthogonal to the 1s orbitals when we start using the unrestricted Hartree–Fock method. We shall therefore, in the interests of simplicity, discuss the $^2P_{3/2}$ state first and then indicate how the argument can be generalized.

The Hartree–Fock wave function for this state is given by

$$\psi_{\mathrm{HF}}(1,2,3) = (3\,!)^{-1/2}\sum_P(-1)^P P\{1s_\beta\, 1s_\alpha\, 2p_\alpha\} \qquad \ldots\ldots(1)$$

where the 2p orbital has $l_z = 1$. It is convenient to use a condensed notation in which we write this as

$$\psi_{\mathrm{HF}} = (1_\beta\, 1_\alpha\, 2_\alpha). \qquad \ldots\ldots(2)$$

If we use the unrestricted Hartree–Fock method we allow the 1_β and 1_α wave functions to be different, i.e. we get a wave function

$$\psi_{\mathrm{UHF}} = (1_\beta'\, 1_\alpha''\, 2_\alpha), \qquad \ldots\ldots(3)$$

where in general the 2_α orbitals appearing in (2) and (3) are different. Let us now suppose that ψ_{UHF} has been used in a calculation of the energy and the orbitals $1_\beta'$, $1_\alpha''$ and 2_α have been determined self-consistently. We now define two new normalized and orthogonal functions P and R and a small parameter x by the equations

$$1' = (1+x^2)^{-1/2}(P - xR) \qquad \ldots\ldots(4)$$

$$1'' = (1+x^2)^{-1/2}(P + xR) \qquad \ldots\ldots(5)$$

$$\frac{2x^2}{1+x^2} = 1 - (1'|1''), \qquad \ldots\ldots(6)$$

and since 1′ and 1″ differ only slightly, the overlap integral (1′|1″) is only a little smaller than unity, and hence x is small. From (4) and (5) we see that P and R are the normalized sum and difference of 1″ and 1′ respectively.

Substituting (4) and (5) into (3) we get

$$\psi_{\mathrm{UHF}}=(1+x^2)^{-1}[(P_\beta P_\alpha 2_\alpha)+x\{(P_\beta R_\alpha 2_\alpha)+(P_\alpha R_\beta 2_\alpha)\}-x^2(R_\beta R_\alpha 2_\alpha)]. \quad \ldots\ldots(7)$$

The first and third terms of (7) have $S^2=\frac{3}{4}$, as they should, but the second term of (7) is not an eigenfunction of S^2. Now using each of the orbitals P, R and 2 once, we can construct two doublet states, namely

$$\phi_1=(6)^{-1/2}[(P_\beta R_\alpha 2_\alpha)+(P_\alpha R_\beta 2_\alpha)-2(P_\alpha R_\alpha 2_\beta)] \quad \ldots\ldots(8)$$

and

$$\phi_2=2^{-1/2}[(P_\beta R_\alpha 2_\alpha)-(P_\alpha R_\beta 2_\alpha)], \quad \ldots\ldots(9)$$

and one quartet state, namely

$$\chi=3^{-1/2}[(P_\beta R_\alpha 2_\alpha)+(P_\alpha R_\beta 2_\alpha)+(P_\alpha R_\alpha 2_\beta)]. \quad \ldots\ldots(10)$$

In terms of these states (7) becomes

$$\psi_{\mathrm{UHF}}=(1+x^2)^{-1}[(P_\beta P_\alpha 2_\alpha)+x(\tfrac{2}{3})^{1/2}\phi_1+x(\tfrac{4}{3})^{1/2}\chi-x^2(R_\beta R_\alpha 2_\alpha)], \quad \ldots\ldots(11)$$

which explicitly displays the admixture of quartet state χ. If we project out of this wave function the quartet component, then we get the projected wave function which, substituting back for ϕ_1, is

$$\begin{aligned}\psi_{\mathrm{PUHF}}=[1+\tfrac{2}{3}x^2+x^4]^{-1/2}\{(P_\beta P_\alpha 2_\alpha)+\tfrac{1}{3}x[(P_\beta R_\alpha 2_\alpha)+(P_\alpha R_\beta 2_\alpha)]\\ -\tfrac{2}{3}x(P_\alpha R_\alpha 2_\beta)-x^2(R_\beta R_\alpha 2_\alpha)\}. \quad \ldots\ldots(12)\end{aligned}$$

In order to consider the validity of the wave functions (7) and (12) it is useful to define a third wave function ψ_{T} constructed out of the same orbitals P, R and 2 and chosen to have a similar form to (7) and (12),

$$\psi_{\mathrm{T}}=(1+6y^2+z^4)^{-1/2}[(P_\beta P_\alpha 2_\alpha)+(6)^{1/2}y\phi_1-z^2(R_\beta R_\alpha 2_\alpha)]. \quad \ldots\ldots(13)$$

The parameters y and z we imagine to have been determined by a variational calculation using the complete wave function ψ_{T}. Therefore within the context that the wave functions P, R and 2 are given we may think of ψ_{T} as the 'true' wave function. Of course we do not mean by this that ψ_{T} is the exact wave function for the ${}^2\mathrm{P}_{3/2}$ state, but only that it is the obvious improvement to (7) and is of similar form and is an eigenfunction of S^2. Notice that we have not included any admixture of ϕ_2 into ψ_{T}. This is because an admixture of ϕ_2 does not produce any change in spin density to first order and therefore for our purposes may be neglected. We must now examine the spin densities given by (7), (12) and (13) respectively. These are

$$\left.\begin{aligned}2S(\mathbf{r})_{\mathrm{UHF}}&=|2(\mathbf{r})|^2+4xP(\mathbf{r})R(\mathbf{r})+\mathrm{O}(x^2)\\ 2S(\mathbf{r})_{\mathrm{PUHF}}&=|2(\mathbf{r})|^2+\tfrac{4}{3}xP(\mathbf{r})R(\mathbf{r})+\mathrm{O}(x^2)\\ 2S(\mathbf{r})_{\mathrm{T}}&=|2(\mathbf{r})|^2+4yP(\mathbf{r})R(\mathbf{r})+\mathrm{O}(y^2)+\mathrm{O}(z^2).\end{aligned}\right\} \quad \ldots\ldots(14)$$

In particular, the spin density at the nucleus is given as $4xP(0)R(0)$, $(4x/3)P(0)R(0)$ and $4yP(0)R(0)$ respectively (correct to first order). We shall now show that under certain conditions x and y are approximately equal and hence, since y has been determined by a strictly correct procedure, that the unrestricted Hartree–Fock wave function when used directly gives a good approximation to the spin density, whereas the projected wave function gives a result which is, in this case, a factor 3 too small. To do this we must first evaluate the expectation value of the Hamiltonian using (13) and (7).

Defining

$$T_{vv}=\int d\mathbf{r}v(\mathbf{r})\{-(\hbar^2/2m)\nabla^2-Ze^2/r\}v(\mathbf{r}) \qquad \ldots\ldots(15)$$

and

$$(vw|Q|v'w')=\int\int d\mathbf{r}_1\, d\mathbf{r}_2 v^*(\mathbf{r}_1)w^*(\mathbf{r}_2)e^2/r_{12}v'(\mathbf{r}_1)w'(\mathbf{r}_2), \qquad \ldots\ldots(16)$$

then we find that

$$E_{\mathrm{T}}=E_0-6y\langle P2|Q|2R\rangle+6y^2b-2z^2\langle PR|Q|RP\rangle+\mathrm{O}(y^3) \qquad \ldots\ldots(17)$$

and

$$E_{\mathrm{UHF}}=E_0-2x\langle P2|Q|2R\rangle+2x^2b'+\mathrm{O}(x^3), \qquad \ldots\ldots(18)$$

where

$$\begin{aligned}b=T_{PP}+T_{RR}+T_{22}+\langle PR|Q|PR\rangle+\langle P2|Q|P2\rangle+\langle R2|Q|R2\rangle \\ -E_0+\tfrac{1}{2}\langle R2|Q|2R\rangle+\tfrac{1}{2}\langle P2|Q|2P\rangle-\langle PR|Q|RP\rangle \qquad \ldots\ldots(19)\end{aligned}$$

and

$$b'=b-\langle PR|Q|RP\rangle-\langle P2|Q|2P\rangle-\langle R2|Q|2R\rangle. \qquad \ldots\ldots(20)$$

Minimizing (17) we get

$$y=\langle P2|Q|2R\rangle/2b \quad \text{and} \quad z=0, \qquad \ldots\ldots(21)$$

whereas minimizing (18) we get

$$x=\langle P2|Q|2R\rangle/2b' \qquad \ldots\ldots(22)$$

where it is understood that (21) and (22) are correct only to first order. We therefore conclude that x is approximately equal to y provided b' is approximately equal to b. Now from (19) we see that b represents the promotion energy from the state $P_\beta P_\alpha 2_\alpha$ to the state ϕ_1, whereas b' and b are different only by the sum of three exchange integrals. If therefore these exchange integrals are small compared with b, i.e. with the promotion energy, then x and y will be approximately equal. It follows therefore from (14) that the unrestricted Hartree–Fock wave functions used directly will give the spin density approximately correct to first order and it is a poor approximation to use the projected wave functions. The origin of this effect is easily traced to the fact that the admixture of the configuration $P_\alpha R_\alpha 2_\beta$ in ϕ_1 makes no contribution to first order in the spin density computed using (13) whereas it makes a large contribution to the first-order energy, and hence the projected wave function introduces a term which would have had a large effect on the energy minimization if this had been performed after the projection rather than before; or looking at it in a different way, if we disregard the energy difference between the excited doublet and quartet states (i.e. if we neglect certain exchange energies) then we may disregard the fact that the admixture $P_\beta R_\alpha 2_\alpha+P_\alpha R_\beta 2_\alpha$ is not the pure doublet, because the matching amount of $P_\alpha R_\alpha 2_\beta$ would be mixed in by a proper procedure if this were performed.

It is not clear from the discussion we have just given whether our conclusions are generally valid or whether they apply only to the special case we have considered. There are two ways in which the above discussion is special, and these are: (i) The outer electron responsible for producing exchange polarization we assumed to be in the 2p state, and this enabled us to take the outer electron wave function to be automatically orthogonal to the core wave functions. Clearly the discussion would be exactly as given above provided that the outer electron were not in an s orbital, but if it were our discussion would have to be changed a little. (ii) We assumed a single outer electron, i.e. a total spin of $\frac{1}{2}$ whereas in general we have several outer electrons and some general spin value S. The second point we shall discuss in detail in the next section and the first point we shall discuss immediately by considering the Li ground state $^2S_{1/2}$ as example.

The unrestricted Hartree–Fock method applied to the $^2S_{1/2}$ state of Li gives a wave function

$$\psi_{\text{UHF}} = (1s_\beta' 1s_\alpha'' 2s_\alpha), \qquad \ldots\ldots(23)$$

where the (1s)″ orbital is orthogonal to the (2s) orbital, but (1s)′ orbital is not orthogonal to either of the other two. It is convenient to rewrite (23) as

$$\psi_{\text{UHF}} = (1s_\beta''' 1s_\alpha'' 2s_\alpha) + (1s'|2s)(2s_\beta 1s_\alpha'' 2s_\alpha) \qquad \ldots\ldots(24)$$

where

$$1s''' = 1s' - (1s'|2s)2s. \qquad \ldots\ldots(25)$$

The second term of (24) gives the admixture of the $1s(2s)^2\ {}^2S$ state included by the unrestricted Hartree–Fock procedure. Since any linear combination of this state and the Hartree–Fock ground state $(1s)^2 2s\ {}^2S$ can be represented by a single determinant, then in principle the unrestricted method gives the correct admixture of this configuration. In the first term of (24) the orbital $1s'''$ is orthogonal to the 2s orbital and hence the discussion concerning this term proceeds exactly as in the example we discussed earlier. The full formulae are somewhat more complicated because of the presence of the second term of (24), but it is easy to show that this term does not produce any essential difference in the argument and the conclusions we come to in this case are exactly those for the earlier example.

§ 3. THE GENERAL CASE

In the general case the total spin of the system is not $\frac{1}{2}$ so that we must consider the unrestricted wave function to be given by

$$\psi_{\text{UHF}} = 1s_\alpha' 1s_\beta'' Q_S, \qquad \ldots\ldots(26)$$

where Q_S represents all the other orbitals in the system. Notice we only consider the case where Q_S stands for a state with spin S and S^z component equal to S. If we considered, say, the state with $S^z = S - 1$ then the wave function could not be written as a single determinant and the whole method would have to be modified. It is the spirit of this method to assume the spin density is a fraction (S^z/S) of that for the state $S^z = S$ just as it would be if the wave functions were true eigenstates. So as to fix ideas let us suppose that the general case is typified by the Fe^{++} ion with Hartree–Fock configuration $(1s)^2(2s)^2(2p)^6(3s)^2(3p)^6(3d)^6$, where if we imagine we are discussing the spin polarization in the 1s shell, Q_S stands for $(2s)^2(2p)^6(3s)^2(3p)^6(3d)^6$. Strictly speaking the unrestricted Hartree–Fock method is not used in this fashion because in the method all the orbitals are varied simultaneously, i.e. the $1s_\alpha$ and $1s_\beta$ orbitals are allowed to differ at the same time that the $2s_\alpha$ and $2s_\beta$, the $2p_\alpha$ and $2p_\beta$, etc., orbitals differ. However, Goodings (1961) has shown that to a good approximation the spin density is additive in the sense that we can consider the contribution to the spin density produced by each shell individually (using wave functions like (26)) and then sum the total. We shall therefore assume that this procedure is valid and will discuss the contribution from the 1s shell. We shall also assume that the unpaired orbitals in Q_S are not s-like, and hence we can take the orbitals in Q_S to be automatically orthogonal to 1s′ and 1s″.

Defining new orbitals P and R and a parameter x using (4)–(6) we recognize that (26) can be rewritten as

$$\psi_{\mathrm{UHF}}=(1+x^2)^{-1}[(P_\beta P_\alpha Q_S)+x\{(P_\beta R_\alpha Q_S)+(P_\alpha R_\beta Q_S)\}-x^2(R_\beta R_\alpha Q_S)], \qquad \ldots\ldots(27)$$

which is clearly analogous to (7). The state analogous to (8) is

$$\psi_1=\left\{\frac{S}{2(S+1)}\right\}^{1/2}\{(P_\alpha R_\beta Q_S)+(P_\beta R_\alpha Q_S)\}-\left\{\frac{1}{S+1}\right\}^{1/2}(P_\alpha R_\alpha Q_{S-1}), \qquad \ldots\ldots(28)$$

and the state analogous to (10) is

$$\chi_1=\left\{\frac{1}{2(S+1)}\right\}^{1/2}\{(P_\alpha R_\beta Q_S)+(P_\beta R_\alpha Q_S)\}+\left\{\frac{S}{S+1}\right\}^{1/2}(P_\alpha R_\alpha Q_{S-1}). \qquad \ldots\ldots(29)$$

Notice that ψ_1 is an eigenfunction with spin S and χ_1 an eigenfunction of spin $S+1$ and that (27) can be rewritten as

$$\begin{aligned}\psi_{\mathrm{UHF}}=(1+x^2)^{-1}\Big[(P_\beta P_\alpha Q_S)&+x\left\{\frac{2S}{S+1}\right\}^{1/2}\psi_1\\&+x\left\{\frac{2}{S+1}\right\}^{1/2}\chi_1-x^2(R_\beta R_\alpha Q_S)\Big],\end{aligned} \qquad \ldots\ldots(30)$$

and projecting on this wave function removes the third term which involves χ_1 (and this, of course, necessitates a renormalization of the wave function).

Following the procedure of § 2 we now define a 'true' wave function given by

$$\psi_{\mathrm{T}}=(1+2y^2+z^4)^{-1/2}[(P_\beta P_\alpha Q_S)+y\sqrt{2}\psi_1-z^2(R_\beta R_\alpha Q_S)]. \qquad \ldots\ldots(31)$$

The spin density at the nucleus associated with (27) and (31) is given, to the first order, by

$$\left.\begin{aligned}2S(0)_{\mathrm{UHF}}&=4xP(0)R(0)\\2S(0)_{\mathrm{T}}&=4\left[\frac{S}{S+1}\right]^{1/2}yP(0)R(0)\end{aligned}\right\} \qquad \ldots\ldots(32)$$

respectively, and we must now compare the energy of (27) and (31). We find

$$E_{\mathrm{UHF}}=E_0-2xA+x^2b'+\mathrm{O}(x^3) \qquad \ldots\ldots(33)$$

$$E_{\mathrm{T}}=E_0-2\sqrt{2}yB+y^2b+\mathrm{O}(y^3)+\mathrm{O}(z^2)+\ldots, \qquad \ldots\ldots(34)$$

where

$$\left.\begin{aligned}A&=\langle(P_\beta P_\alpha Q_S)|H|(P_\beta R_\alpha Q_S)+(P_\alpha P_\beta Q_S)\rangle\\B&=\langle(P_\beta P_\alpha Q_S)|H|\psi_1\rangle.\end{aligned}\right\} \qquad \ldots\ldots(35)$$

In calculating A and B we make use of the fact that Q_S represents a state of maximum multiplicity, i.e. obeys Hund's rule, and then we find that A is given by

$$A=\sum\mu(P\mu|Q|\mu R) \qquad \ldots\ldots(36)$$

where μ runs over singly occupied orbitals in Q_S, i.e. there are $2S$ terms in the sum. When calculating B the only difficulty is to calculate the matrix element involving the last term of (28), and to do this we recall that Q_{S-1} is obtained by operating on Q_S with the usual lowering operator and renormalizing. We find that the second term of (28) makes a contribution to B which is a fraction $1/S$ that of the contribution from the first term, and hence we find

$$B=\left[\frac{S+1}{2S}\right]^{1/2}A. \qquad \ldots\ldots(37)$$

Minimizing (33) and (34) with respect to x and y respectively, we find

$$x=\frac{A}{b'},\quad y=\sqrt{2}\,\frac{B}{b}=\left[\frac{S+1}{S}\right]^{1/2}\frac{A}{b},$$

and hence from (32) we find that the unrestricted Hartree–Fock method gives approximately the correct spin density provided b and b' are approximately equal. We therefore see that the discussion is quite general.

We conclude, therefore, that there is good justification for the unrestricted Hartree–Fock method although only explicit calculation will show how small 'exchange energies' are relative to the 'promotion energies'. Also there is no justification for supposing that the wave function can be improved by projecting out the unwanted parts after the energy minimization process has been performed; on the contrary the wave function as determined directly is a better approximation even though it is not an eigenfunction of S^2.

ACKNOWLEDGMENTS

I would like to thank Dr. A. J. Freeman for bringing this problem to my attention and Dr. V. Heine and Dr. D. A. Goodings for several useful discussions.

The Faraday Effect in Non-degenerate Semiconductors

By B. DONOVAN and JANET WEBSTER
Department of Physics, Bedford College, London

MS. received 3rd *October* 1960, *in revised form* 13*th December* 1960

Abstract. The theory of the Faraday effect, due to free charge carriers, is developed for non-degenerate semiconductors with spherical energy surfaces. General expressions for the Faraday rotation θ and the ellipticity δ are given, which are valid for all frequencies from the microwave region to the infra-red, and for all magnetic field strengths within the limitations of the Boltzmann equation.

The cases of lattice scattering and impurity scattering are considered separately and the numerical calculations are based on experimental data for n-type germanium. The rotation θ changes sign at the cyclotron resonance frequency in strong fields and at a lower frequency (determined by the relaxation time) in weak fields. The ellipticity δ passes through zero at a frequency corresponding to maximum θ, and reaches a maximum when θ is zero. In the limit of high frequencies and weak fields θ (but not δ) is independent of the relaxation mechanism. Both θ and δ vary linearly with field strength in weak fields but subsequently pass through a maximum.

The temperature dependence of θ and δ is examined in the range 100–300°K for lattice scattering and 15–100°K for impurity scattering. As the temperature is lowered, in general θ and δ both increase in the case of lattice scattering, and both decrease in the case of impurity scattering.

§ 1. INTRODUCTION

When a plane polarized electromagnetic wave passes through a medium in the presence of a constant magnetic field parallel to the direction of propagation, a rotation of the plane of polarization takes place. This effect is known as the Faraday rotation and its exploitation in connection with semiconductors is a comparatively recent development. The rotation was observed at microwave frequencies in germanium by Rau and Caspari (1955) and, more recently, it has been investigated in the infra-red region in indium antimonide (Smith, Moss and Taylor 1959), in germanium (Walton and Moss 1959) and in bismuth telluride (Austin 1960). In these experiments the rotation is due to the free charge carriers and the infra-red Faraday effect has provided a valuable additional method for obtaining information on the effective mass parameters (for a detailed account see Moss 1959).

For a degenerate system of free electrons the theory of the Faraday effect follows straightforwardly from the high frequency modification of the Boltzmann equation, and the complex propagation constants, which determine the rotation, have been given for this case (but excluding the displacement current) by Donovan (1954). The free-electron model has also been used by Stephen and Lidiard (1959, to be referred to as SL) to discuss the frequency dependence of the Faraday rotation and they have also derived particular results applicable to non-spherical energy surfaces.

The purpose of the present paper is to put forward a theory more appropriate to semiconductors, in which the relaxation time of the carriers is given the proper dependence upon energy in the cases of lattice scattering and impurity scattering. The behaviour of the Faraday rotation as a function of frequency, magnetic field strength and temperature is discussed, and a similar study is made of the ellipticity of the radiation, which has so far received little attention. For the purposes of numerical calculation, experimental data relevant to n-type germanium have been incorporated where necessary. The present calculations are based on the simple quasi-free electron model, for which the surfaces of constant energy are spherical and the density of states has the normal parabolic form. The additional complications arising from anisotropic energy surfaces will be dealt with in a subsequent paper.

§ 2. General Formulation

A system of axes is chosen such that the incident radiation is propagated along the positive z direction. The electric field in the medium is then specified by $(\mathscr{E}_x, \mathscr{E}_y, 0) \exp(i\omega t)$, where ω is the angular frequency, and the constant magnetic field has components $(0, 0, H)$. Inside the medium the initially plane polarized radiation may be regarded as split into two circularly polarized waves, rotating in opposite senses and represented by $\mathscr{E}_{\pm} = \mathscr{E}_x \pm i\mathscr{E}_y$, where the positive sign denotes clockwise rotation to an observer looking along the positive z direction. These two circularly polarized waves travel with different velocities and undergo different attenuations so that, in general, the resultant wave is elliptically polarized. We define the ellipticity δ as the ratio of the minor to the major axis of the ellipse, and the rotation θ as the angle between the major axis of the ellipse and the initial direction of the electric vector.

The essential problem is the evaluation of the complex propagation constants for the two component waves and we now give a general formulation for a system of carriers with relaxation time τ and effective mass m^*, described by the Fermi–Dirac function $f_0(E)$, where the energy E is a quadratic function of momentum. The calculation of the current density from the Boltzmann equation follows standard lines and the analysis may be rendered more concise if, as first pointed out by Dingle (1956), the symbol i is reserved for phase displacement and the operator j is introduced for spatial rotation round the magnetic field. Thus, if a and b are two harmonically varying quantities confined to the (x, y) plane, the combination $a+ib$ signifies that a and b differ in phase by $\frac{1}{2}\pi$, whereas $a+jb$ signifies an angular displacement of $\frac{1}{2}\pi$ between the directions of a and b. Since $i^2=j^2=-1$, but $ij \neq -1$, the process of rationalization must be carried out separately for i and j.

Thus, by introducing $\mathbf{E}=\mathscr{E}_x+j\mathscr{E}_y$ and $\mathbf{J}=J_x+jJ_y$, we have (cf. Moore 1958)

$$\mathbf{J}=-\left[\frac{16\sqrt{2}\,\pi e^2 m^{*1/2}}{3h^3}\int_0^\infty \frac{\tau E^{3/2}}{1+(i\omega+j\Omega)\tau}\frac{\partial f_0}{\partial E}\,dE\right]\mathbf{E}, \qquad \ldots\ldots (1)$$

where $\Omega=-eH/m^*c$, i.e. the cyclotron resonance frequency (Gaussian units are used throughout).

It is thus possible to express $\mathbf{J}$ in the form

$$\mathbf{J}=(M+jN)\mathbf{E} \qquad \ldots\ldots (2)$$

where $$2M = I_1(\omega+\Omega) + I_1(\omega-\Omega) - i[(\omega+\Omega)I_2(\omega+\Omega) + (\omega-\Omega)I_2(\omega-\Omega)] \qquad \ldots\ldots(3)$$

$$2N = -[(\omega+\Omega)I_2(\omega+\Omega) - (\omega-\Omega)I_2(\omega-\Omega)] - i[I_1(\omega+\Omega) - I_1(\omega-\Omega)] \qquad \ldots\ldots(4)$$

and $$I_s(\xi) = -\frac{16\sqrt{2}\pi e^2 m^{*1/2}}{3h^3}\int_0^\infty \frac{\tau^s E^{3/2}}{1+\xi^2\tau^2}\frac{\partial f_0}{\partial E}\,dE. \qquad \ldots\ldots(5)$$

If we now combine these results with Maxwell's equations, we obtain

$$\frac{d^2\mathbf{E}}{dz^2} = (A+jB)\mathbf{E} \qquad \ldots\ldots(6)$$

where $$A = \frac{4\pi\omega i}{c^2}\left(M + \frac{i\omega\epsilon}{4\pi}\right), \quad B = \frac{4\pi\omega i}{c^2}N,$$

and ϵ is the dielectric constant.

At this stage we may conveniently obtain the two circularly polarized waves by setting $j = \pm i$, and if we write

$$\mathscr{E}_\pm(z) = \mathscr{E}_\pm(0)\exp(-\mu_\pm z), \qquad \ldots\ldots(7)$$

we may derive the complex propagation constants from (6) in the form

$$\mu_\pm = \alpha_\pm + i\beta_\pm = (A \pm iB)^{1/2}. \qquad \ldots\ldots(8)$$

Substitution from (3) and (4) leads finally to the expressions

$$\mu_\pm{}^2 = -\frac{\omega^2\epsilon}{c^2} + \frac{4\pi\omega}{c^2}(\omega\pm\Omega)I_2(\omega\pm\Omega) + \frac{4\pi\omega i}{c^2}I_1(\omega\pm\Omega), \qquad \ldots\ldots(9)$$

and the problem reduces to the extraction of the real and imaginary parts of the $\mu_\pm$, following evaluation of the integrals in (5). For a highly degenerate electron gas, we may note that, from (5):

$$I_1(\xi) = \frac{\sigma_0}{1+\xi^2\tau^2}, \quad I_2(\xi) = \frac{\sigma_0\tau}{1+\xi^2\tau^2},$$

where σ_0 is the d.c. conductivity, and in this case (9) is identical with Eqn (2.6) of SL.

Having evaluated $\alpha_\pm$ and $\beta_\pm$ (all of which must be positive), the parameters of the Faraday effect may be obtained for a given distance z travelled in the specimen. The rotation is given by

$$\theta = \tfrac{1}{2}(\beta_- - \beta_+)z, \qquad \ldots\ldots(10)$$

and is positive when it appears clockwise to an observer looking along the positive z direction (i.e. in sense of rotation of $\mathscr{E}_+$)†. The ellipticity is given by

$$\delta = \frac{\exp(-\alpha_- z) - \exp(-\alpha_+ z)}{\exp(-\alpha_- z) + \exp(-\alpha_+ z)} = \tanh\{\tfrac{1}{2}(\alpha_+ - \alpha_-)z\}, \qquad \ldots\ldots(11)$$

and the choice of sign is entirely arbitrary. With the convention of (11), θ and δ tend to the same expression at very low frequencies and in this region both are negative for electrons. If the attenuations are nearly equal a plane polarized wave will be obtained ($\delta \to 0$), but if they are widely different δ will approach unity, corresponding to the suppression of one of the circularly polarized components. The expressions (10) and (11) are both *exact*, but the ellipticity may be written in the approximate form

$$\delta = \tfrac{1}{2}(\alpha_+ - \alpha_-)z \qquad \ldots\ldots(12)$$

provided that $|(\alpha_+ - \alpha_-)z| \ll 1$.

---

† The sign convention is stated incorrectly in SL

§ 3. SINGLE BAND MODEL WITH LATTICE SCATTERING

We now apply the results of the previous section to a semiconductor in which conduction is due predominantly to a single type of carrier and the system is described by Boltzmann statistics. Accordingly, for the distribution function we write

$$f_0(E) = \tfrac{1}{2}nh^3(2\pi m^* kT)^{-3/2}\exp(-E/kT), \qquad \ldots\ldots(13)$$

where n is the carrier density.

For the case of scattering by the lattice vibrations we assume the mean free path l to be independent of energy and the relaxation time may be expressed as

$$\tau = ax^{-1/2}, \qquad \ldots\ldots(14)$$

where $x = E/kT$ and $a = l(m^*/2kT)^{1/2}$. Substituting (13) and (14) in (5) leads to the essential integrals, in terms of $\xi = \omega \pm \Omega$,

$$I_1(\xi) = \sigma_0 \int_0^\infty \frac{x^2 \exp(-x)\,dx}{x + a^2\xi^2} \qquad \ldots\ldots(15)$$

and

$$I_2(\xi) = a\sigma_0 \int_0^\infty \frac{x^{3/2} \exp(-x)\,dx}{x + a^2\xi^2}, \qquad \ldots\ldots(16)$$

where we have introduced the d.c. conductivity

$$\sigma_0 = \frac{4ne^2 l}{3(2\pi mk^* T)^{1/2}} = \frac{4ne^2 a}{3\pi^{1/2} m^*}. \qquad \ldots\ldots(17)$$

The above integrals have been discussed previously in connection with high frequency conductivity in semiconductors (Donovan and March 1956). They have since been tabulated by Dingle, Arndt and Roy (1957), but at some stages of the present calculation, particularly for small values of ξ, the tables were found to be insufficiently detailed and additional numerical integration was required.

In general the expressions (10) and (11) must be evaluated numerically but approximate forms may be derived in certain limiting cases. For very low frequencies (such that the displacement current is negligible) and weak fields, we have

$$\frac{\theta}{zH} = \frac{\delta}{zH} = \frac{R_0}{c}\left(\frac{\pi\omega\sigma_0{}^3}{2}\right)^{1/2}, \qquad \ldots\ldots(18)$$

where R_0 is the Hall constant ($= -3\pi/8nec$). A similar expression for θ was derived for the degenerate case by SL (Eqn (2.16)). For high frequencies and weak fields ($\omega a \gg 1$, $\omega \gg \Omega$), we find

$$\frac{\theta}{zH} = \frac{2\pi ne^3}{c^2\epsilon^{1/2} m^{*2}\omega^2}, \qquad \ldots\ldots(19)$$

and

$$\frac{\delta}{zH} = \frac{32\pi^{1/2} ne^3}{3c^2\epsilon^{1/2} m^{*2}\omega^3 a}. \qquad \ldots\ldots(20)$$

It should be noted that in these circumstances the rotation is independent of a whereas the ellipticity is not.

3.1. *Faraday Rotation*

For specific numerical calculation we take initially $\sigma_0 = 10^{11}$ e.s.u., $a = 10^{-12}$ sec, $\epsilon = 16$, and we shall consider these values as applying at $T = 300$°K to a typical specimen of n-type germanium satisfying the conditions of the present section.

Thus the room temperature parameters are:

$$\text{resistivity} = 9\,\text{ohm cm}, \quad n \simeq 1{\cdot}3 \times 10^{14}\,\text{cm}^{-3}, \quad m^* = \tfrac{1}{4}m$$

(Debye and Conwell 1954; our data correspond closely to sample 51).

Figure 1 shows the Faraday rotation plotted as a function of frequency for various values of the field strength (with the effective mass quoted above, $\Omega = 10^{11}$ corresponds to $H \simeq 1400$ Oe). The general behaviour of θ is similar to that described by SL; in particular, a change in sign occurs at $\omega \sim a^{-1}$ for weak fields ($a\Omega \ll 1$) and at the cyclotron resonance frequency, $\omega \sim \Omega$, for strong fields ($a\Omega \gg 1$). An additional feature exhibited in strong fields is the small minimum at low frequencies ($\omega \sim 10^{10}$ in curve c). This is a consequence of the cancellation of the first two terms on the right-hand side of expression (9) and hence, in the present instance, it occurs (provided $\omega \ll \Omega$) at $\omega \sim 3\pi^{3/2}\sigma_0/\epsilon\Omega a$. Above this frequency θ is independent of ω almost up to the cyclotron resonance frequency.

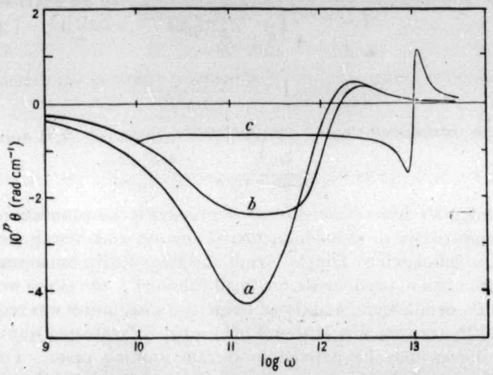

Fig. 1. Variation of Faraday rotation ($10^p\ \theta$ rad cm^{-1}) with frequency for n-type germanium specimen with $\sigma_0 = 10^{11}$ e.s.u., $a = 10^{-12}$ sec, $m^* = \frac{1}{4}m$, $\epsilon = 16$ (lattice scattering only): a, $\Omega = 10^{11}$ ($p = 1$); b, $\Omega = 10^{12}$ ($p = 0$); c, $\Omega = 10^{13}$ ($p = 0$).

The dependence of the Faraday rotation upon field strength is complicated by the change in sign illustrated in Fig. 1. For small fields ($\Omega \leqslant 10^{11}$) θ is proportional to H over the entire frequency range shown in Fig. 1. For $\omega < a^{-1}$ the rotation is always negative and the variation with field strength is shown in Fig. 2. The rotation reaches a maximum value in the neighbourhood of $\Omega a = 1$ and subsequently decreases to zero. For $\omega > a^{-1}$ the rotation is positive for small fields and proportional to H, in accordance with (19); as the field is increased θ will eventually change sign abruptly at $\Omega \sim \omega$, pass through a minimum and ultimately decrease to zero. For very strong fields, such that $\Omega a \gg 1$, conclusions based on the Boltzmann equation must, however, be treated with reserve.

It is also of interest to consider the variation of θ with temperature, at a fixed frequency and field strength. For this purpose we have taken the mean free path to be inversely proportional to T, so that $a \propto T^{-3/2}$; furthermore, over the temperature range considered, the carrier density may be regarded as sensibly constant (Debye and Conwell 1954, Fig. 10). Some typical results are illustrated in Fig. 3 (the data of Fig. 1 corresponding to $T = 300\,^\circ\mathrm{K}$) and it will be seen that, in general, the magnitude of θ increases steadily as the temperature decreases. In the microwave region, with $\Omega = 10^{11}$, θ increases by a factor of 10 in cooling from room temperature to 100°K. For the same field strength and $\omega = 10^{12}$, θ is negative at 300°K but passes through zero and becomes appreciably larger and positive with decreasing temperature. In strong fields the variation with T is

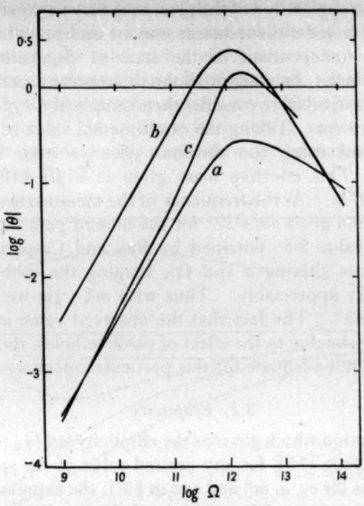

Fig. 2. Variation of Faraday rotation with field strength for n-type germanium specimen with details as for Fig. 1 (lattice scattering only): a, $\omega = 10^{9}$; b, $\omega = 10^{11}$; c, $\omega = 10^{12}$ (Note: all values of θ are negative.)

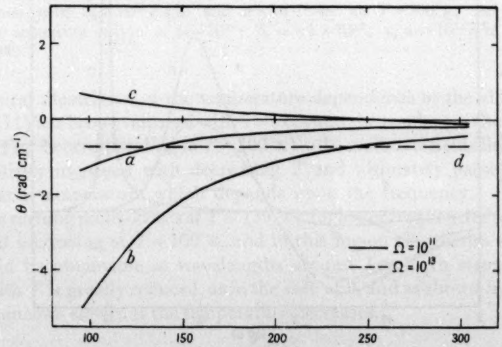

Fig. 3. Variation of Faraday rotation with temperature for n-type germanium specimen with $\sigma_0 = 10^{11}$ e.s.u. and $a = 10^{-12}$ sec at $T = 300$°K; $m^* = \frac{1}{4}m$; $\epsilon = 16$ (lattice scattering only): a, $\omega = 10^{10}$; b, $\omega = 10^{11}$; c, $\omega = 10^{12}$; d, $5 \times 10^{10} < \omega < 10^{12}$.

extremely small (except in the vicinity of cyclotron resonance) as shown by the broken line, which represents all frequencies on the flat portion of Fig. 1, curve *c*.

In considering the application of the present theory to experimental results, we may note that the infra-red measurements may be interpreted in terms of expression (19), which is independent of the state of degeneracy. A significant comparison may, however, be made with the microwave experiments of Rau and Caspari (1955); in particular we consider their sample of n-type germanium, with a resistivity of 16 ohm cm. Taking the experimental value of the mobility to be 3900 $\text{cm}^2\,\text{v}^{-1}\,\text{sec}^{-1}$ and using the previous effective mass $m^* = \frac{1}{4}m$, we find $a = 7{\cdot}44 \times 10^{-13}$ sec. This effective mass gives $\Omega = 1{\cdot}01 \times 10^{11}$ for the quoted field strength of 1430 Oe. At the frequency of the measurement ($\omega = 5{\cdot}49 \times 10^{10}$) the present theory then gives $\theta = 4{\cdot}37^\circ$ for the quoted path length of 0·46 cm, as compared with the value 3·5° obtained by Rau and Caspari. If the effective mass is changed (thus altering a and Ω), keeping the mobility constant, the rotation does not vary appreciably. Thus with $m^* = \frac{1}{8}m$ we find $\theta = 4{\cdot}30^\circ$ and with $m^* = \frac{1}{2}m$, $\theta = 4{\cdot}43^\circ$. The fact that the observed value is smaller than this estimate may possibly be due to the effect of positive holes, thus indicating that a single-band model is not adequate for this particular specimen.

3.2. *Ellipticity*

The essential function which governs the ellipticity is $\frac{1}{2}(\alpha_+ - \alpha_-)$ and from this δ may be obtained, using (11), for any desired value of the specimen thickness. Using the same values for σ_0, a, m^* and ϵ as in § 3.1, the expression $\frac{1}{2}(\alpha_+ - \alpha_-)$ has been evaluated as a function of frequency and the results are shown in Fig. 4.

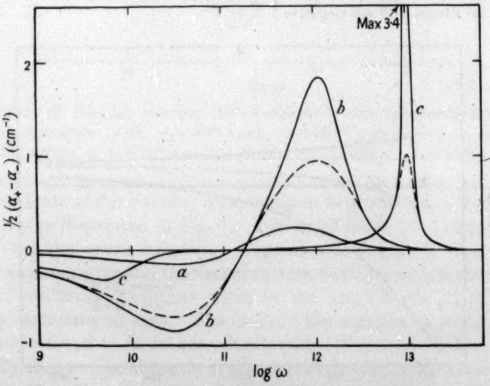

Fig. 4. Variation of $\frac{1}{2}(\alpha_+ - \alpha_-)$ with frequency for n-type germanium specimen with details as for Fig. 1 (lattice scattering only): *a*, $\Omega = 10^{11}$; *b*, $\Omega = 10^{12}$; *c*, $\Omega = 10^{13}$. The broken lines represent ellipticities calculated for 1 cm path length.

Curves for the ellipticity would have the same general characteristics, but with the peaks flattened; as an illustration the broken lines in Fig. 4 show δ calculated for a path length z of 1 cm. In moderate fields the ellipticity passes through zero at a frequency corresponding to the maximum negative value of θ and rises to a maximum in the neighbourhood of zero θ. In the optical region the radiation is effectively plane polarized.

In strong fields δ is very small over a wide band of frequencies, corresponding roughly to the flat portion of Fig. 1, curve *c*, and exhibits a sharp peak at cyclotron resonance. Here δ attains the value unity, which is to be expected in view of the absorption of one of the circularly polarized components. It should be noted that the polarization may be almost circular also at $\omega a \sim 1$, for appropriate values of the field, as shown in curve *b*. At constant frequency δ varies linearly with field strength for small Ω and subsequently passes through a maximum and decreases to zero after the manner of Fig. 2.

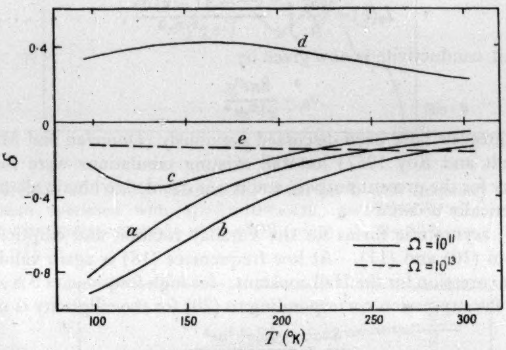

Fig. 5. Variation of ellipticity with temperature for 1 cm path length in n-type germanium specimen with $\sigma_0 = 10^{11}$ e.s.u. and $a = 10^{-12}$ sec at $T = 300$°K; $m^* = \frac{1}{4}m$, $\epsilon = 16$ (lattice scattering only): *a*, $\omega = 10^{10}$; *b*, $\omega = 5 \times 10^{10}$; *c*, $\omega = 10^{11}$; *d*, $\omega = 10^{12}$; *e*, $\omega = 10^{10}$.

As a typical illustration of the temperature dependence of the ellipticity, the expression (11) has been evaluated with $z = 1$ cm and the results are shown in Fig. 5 (the data of Fig. 4 corresponding to $T = 300$°K). In moderate fields the magnitude of the ellipticity increases with decreasing T and ultimately passes through a maximum at a temperature which depends upon the frequency. For $\omega = 10^{11}$ (curve *c*) the turning point occurs at $T \sim 130$°K; for lower frequencies (curves *a* and *b*) $|\delta|$ is still increasing at $T \sim 100$°K, and in this region ellipticities approaching unity should be obtainable at wavelengths around 3 cm. In strong fields the variation with T is greatly reduced, as in the case of θ, and as shown by the broken line $|\delta|$ diminishes slowly as the temperature decreases.

§ 4. SINGLE BAND MODEL WITH IMPURITY SCATTERING

We now take up the case of an impurity semiconductor, in which the predominant scattering mechanism is that due to the impurity ions. The calculations in the present section are based on the treatment of Conwell and Weisskopf (1950), which leads to a mean free path proportional to the square of the electronic energy. Thus for the relaxation time we write

$$\tau = g x^{3/2}, \qquad \ldots\ldots (21)$$

with $x = E/kT$ as before and

$$g = \frac{(2m^*)^{1/2}\,(kT)^{3/2}\,\epsilon^2}{\pi N e^4 \log\{1 + 36\epsilon^2 d^2 k^2 T^2/e^4\}},$$

where N is the number of impurity ions per unit volume and $2d$ their average separation.

The essential integrals for this case are obtained by substituting (21) in (5), together with the distribution function (13); in this way we find

$$I_1(\xi) = \frac{\sigma_0}{6}\int_0^\infty \frac{x^3 \exp(-x)\,dx}{1 + g^2\xi^2x^3} \qquad \ldots\ldots (22)$$

and

$$I_2(\xi) = \frac{g\sigma_0}{6}\int_0^\infty \frac{x^{9/2} \exp(-x)\,dx}{1 + g^2\xi^2x^3}, \qquad \ldots\ldots (23)$$

where the d.c. conductivity is now given by

$$\sigma_0 = \frac{8ne^2g}{\pi^{1/2}m^*}. \qquad \ldots\ldots (24)$$

The above integrals have been discussed previously (Donovan and March 1956, Dingle, Arndt and Roy 1957) but the existing tabulations were found to be unsatisfactory for the present purpose and it was decided to obtain all the required values numerically *ab initio*.

As in § 3, asymptotic forms for the Faraday rotation and ellipticity may be obtained from (10) and (11). At low frequencies (18) is again valid, with the appropriate expression for the Hall constant; for high frequencies θ is again given by (19), but the expression corresponding to (20) for the ellipticity is now

$$\frac{\delta}{zH} = \frac{32\pi^{1/2}ne^3}{3c^3\epsilon^{1/2}m^{*2}\omega^3 g}. \qquad \ldots\ldots (25)$$

4.1. *Faraday Rotation*

For numerical presentation of the results we again choose parameters relevant to n-type germanium and the following calculations are based on sample 61 studied by Debye and Conwell (1954). In particular, we consider the temperature range 15–100°K where the observed behaviour is representative of impurity scattering only. Thus at $T = 100$°K we take

$$\sigma_0 = 3 \times 10^{13}\,\text{e.s.u.}, \quad n = 4 \times 10^{16}\,\text{cm}^{-3}, \quad g = 1{\cdot}6 \times 10^{-13}\,\text{sec},$$

together with the previous values $\epsilon = 16$ and $m^* = \frac{1}{4}m$.

The Faraday rotation at $T = 100$°K is shown in Fig. 6 as a function of frequency, for various values of the field strength, and the behaviour differs markedly in several respects from that shown in Fig. 1. Firstly, as a consequence of the higher values for σ_0 and n, the magnitudes of θ are considerably larger; for example, in the microwave region ($\lambda \sim 1$ cm) rotations of the order of 50 rad cm^{-1} should be obtainable with a field of 15 000 Oe. For the strongest field represented (curve *c*), θ varies extremely rapidly between large negative and positive values in the neighbourhood of cyclotron resonance, and only a vestigial flat region appears on the low frequency side. In smaller fields, such that $\Omega g < 1$, θ changes sign at a frequency slightly lower than g^{-1}.

The variation of θ with field strength is similar to the case of lattice scattering ($\theta \propto H$ up to $\Omega \sim 10^{11}$ for all frequencies) and need not be discussed in detail. The temperature dependence of θ is, however, entirely different, as is apparent from

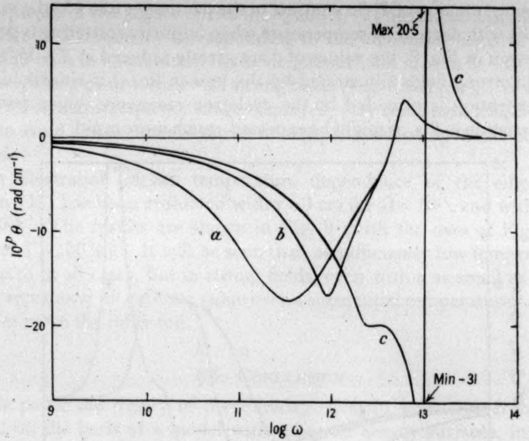

Fig. 6. Variation of Faraday rotation ($10^p\ \theta$ rad cm^{-1}) with frequency for n-type germanium specimen with $\sigma_0 = 3\times10^{13}$ e.s.u., $g = 1{\cdot}6\times10^{-13}$ sec, $m^* = \frac{1}{4}m$, $\epsilon = 16$ (impurity scattering only): *a*, $\Omega = 10^{11}$ ($p=0$); *b*, $\Omega = 10^{12}$ ($p=-1$); *c*, $\Omega = 10^{13}$, ($p=-1$).

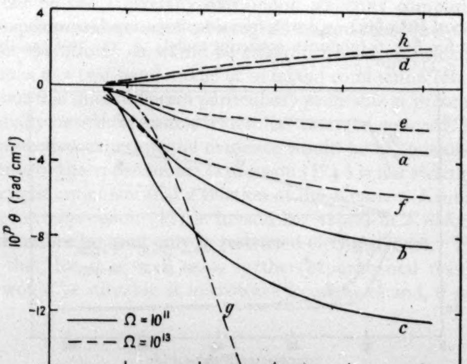

Fig. 7. Variation of Faraday rotation ($10^p\ \theta$ rad cm^{-1}) with temperature for n-type germanium specimen with $\sigma_0 = 3\times10^{13}$ e.s.u. and $g = 1{\cdot}6\times10^{-13}$ sec at $T = 100$°K; $m^* = \frac{1}{4}m$, $\epsilon = 16$ (impurity scattering only):

a, $\omega = 10^{10}$ ($p=0$); *d*, $\omega = 10^{13}$ ($p=0$); *g*, $\omega = 10^{13}$ ($p=-1$);
b, $\omega = 5\times10^{10}$ ($p=0$); *e*, $\omega = 5\times10^{10}$ ($p=-1$); *h*, $\omega = 10^{14}$ ($p=0$).
c, $\omega = 10^{12}$ ($p=0$); *f*, $\omega = 3\times10^{11}$ ($p=-1$);

Fig. 7. For the purposes of calculation σ_0 and n were obtained as functions of T from the data of Debye and Conwell; the values of g subsequently given by (24) were found to be in reasonable agreement with those calculated directly. Since g

is an increasing function of T (in contrast to the parameter a in § 3) the magnitude of θ decreases with decreasing temperature when impurity scattering is predominant. As shown in Fig. 7, the values of θ are greatly reduced at $T \sim 15\,^{\circ}\mathrm{K}$ and the behaviour in strong fields (illustrated by the broken lines) is similar in general. The only exception is provided by the cyclotron resonance region (curve g) in which the variation in θ is, as might be expected, much more rapid.

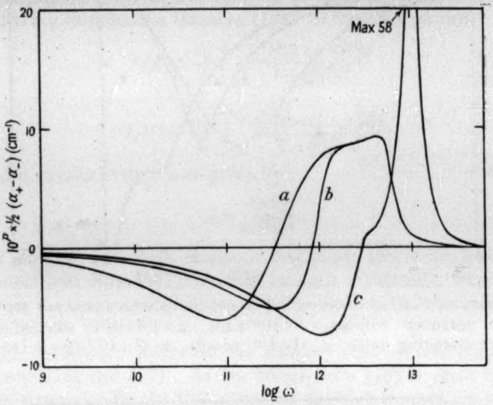

Fig. 8. Variation of $10^p \times \frac{1}{2}(\alpha_+ - \alpha_-)$ with frequency for n-type germanium specimen with details as for Fig. 6 (impurity scattering only): a, $\Omega = 10^{11}$ ($p = 0$); b, $\Omega = 10^{12}$ ($p = -1$); c, $\Omega = 10^{13}$ ($p = -1$).

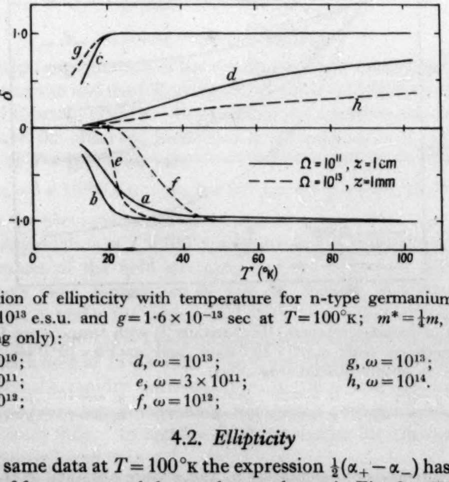

Fig. 9. Variation of ellipticity with temperature for n-type germanium specimen with $\sigma_0 = 3 \times 10^{13}$ e.s.u. and $g = 1{\cdot}6 \times 10^{-13}$ sec at $T = 100\,^{\circ}\mathrm{K}$; $m^* = \frac{1}{4}m$, $\epsilon = 16$ (impurity scattering only):

a, $\omega = 10^{10}$;
b, $\omega = 10^{11}$;
c, $\omega = 10^{12}$;
d, $\omega = 10^{13}$;
e, $\omega = 3 \times 10^{11}$;
f, $\omega = 10^{12}$;
g, $\omega = 10^{13}$;
h, $\omega = 10^{14}$.

4.2. *Ellipticity*

Using the same data at $T = 100\,^{\circ}\mathrm{K}$ the expression $\frac{1}{2}(\alpha_+ - \alpha_-)$ has been evaluated as a function of frequency and the results are shown in Fig. 8. The same general features are exhibited as in Fig. 4, but the orders of magnitude are very much larger as a consequence of the higher values for σ_0 and n. The function in Fig. 8 passes through zero at a frequency corresponding to the maximum negative value of θ in Fig. 6 and rises to a maximum in the neighbourhood of zero θ. In particular, an extremely sharp peak occurs with strong fields (Fig. 8, curve c). It will be seen that, over most of the frequency range displayed, very small path lengths would be required to avoid one or other of the circularly polarized components being totally attenuated.

As an illustration of the temperature dependence of the ellipticity, the expression (11) has been evaluated with $z = 1$ cm for $\Omega = 10^{11}$, and with $z = 1$ mm for $\Omega = 10^{13}$. The results are shown in Fig. 9 (with the data of Fig. 8 corresponding to $T = 100^\circ$K). It will be seen that, at sufficiently low temperatures, $|\delta|$ tends to zero in all cases, but in strong fields, even with z as small as 1 mm, the ellipticity remains at an extreme value over a substantial temperature range for all frequencies up to the infra-red.

§ 5. CONCLUSION

In this paper the theory of the Faraday effect in semiconductors has been developed on the basis of a model with spherical energy surfaces, in which the free carriers constitute a non-degenerate system. The object has been to consider an energy-dependent relaxation time, for the cases of lattice scattering and impurity scattering, and to investigate the behaviour of the rotation and ellipticity as functions of frequency, field strength and temperature. The numerical calculations were carried out on the University of London MERCURY computer, which was programmed to perform the numerical integrations and subsequent calculations in one continuous operation. It would be straightforward, in principle, to extend these calculations to a two-band model or to mixed conduction (cf. Donovan and March 1956) but this does not seem particularly profitable at present.

The essentially new information which has emerged concerns the ellipticity, and in this connection experimental evidence would be of considerable interest. Within the limits of the approximate expression (12) δ is not strictly independent of θ and one might anticipate that a relation of the Kramers–Kronig type would apply. However, expression (12) is invalid for values of δ exceeding roughly 0·2 and may therefore be used only in restricted circumstances. Finally, it may be remarked that, for θ as well as δ, further experimental results at various temperatures would be valuable at microwave frequencies and, if possible, in the far infra-red.

ACKNOWLEDGMENTS

The authors would like to express warm thanks to Dr. P. M. Lee for much valuable advice in connection with the programming of the calculations. Thanks are due also to the University of London Computer Unit for the allocation of computer time. One of us (J.W.) is indebted to the Department of Scientific and Industrial Research for the award of a Research Studentship.

The Tensile Strength of Liquids in Berthelot Tubes

By G. M. LEWIS†

Department of Physics, University College of Wales, Aberystwyth

MS. received 18*th November* 1960, *in revised form* 2*nd January* 1961

Abstract. Experiments are described in which Berthelot tubes containing water are used in an attempt to estimate the maximum tension that can be sustained by a water–glass system under static conditions. The Berthelot tube is sealed at both ends and is almost completely filled with the liquid under investigation. On heating the tube the liquid expands until it completely fills the tube, but when it is subsequently allowed to cool the adhesion of the liquid to the walls of the tube prevents the liquid from contracting at a greater rate than the internal volume of the tube. Consequently a progressively increasing tension is set up in the liquid until it eventually ruptures. The tension in the liquid immediately prior to the instant of rupture is measured by estimating the sudden increase in the external volume of the Berthelot tube at this instant.

The results show that the critical tension occurring in any one tube varies considerably in successive experiments; this variation is liable to be as great as thirty atmospheres. Furthermore, the magnitude of this tension varies from tube to tube; some tubes can sustain sixty atmospheres while others are incapable of sustaining even five atmospheres.

Experiments with tubes constructed from steel gave substantially similar results. So also did glass tubes containing suspensions of ultramarine powder in water and carbontetrachloride with water.

Furthermore, pre-compression of the liquid has no detectable effect on the critical tension. Neither has rate of build-up of the applied tension, nor mechanical shock.

An incidental result has been the verification of the equality of the extensibility and compressibility of water.

§ 1. INTRODUCTION

THE tensile strength of liquids under various conditions has been the subject of a considerable number of investigations. Broadly speaking the experiments fall into one of two categories, namely those in which the liquid under investigation is subjected to a stress under static conditions and, secondly, those in which a rapidly varying stress is applied to the liquid. This paper is concerned with experiments of the former type, using the so-called Berthelot tube method of applying tension to a liquid. The original intention was to employ the Berthelot tube method for the purpose of making a comparative study of the tensile strength of various liquids and suspensions, and a large number of test experiments was carried out, mainly on water, to examine the suitability of the method for this particular purpose. However, during the course of these experiments it became increasingly clear that the Berthelot tube method gives quite unreliable and inconsistent results.

---

† Now at the Central Electricity Research Laboratories, Leatherhead.

The first experiments of this type were performed by Berthelot (1850). He used a short length of capillary glass tubing sealed at both ends and almost completely filled with the liquid under investigation. On heating the tube the liquid expanded until it completely filled the tube, but when it was subsequently allowed to cool the adhesion of the liquid to the walls of the tube prevented the liquid from contracting at a greater rate than the internal volume of the tube. Consequently a progressively increasing tension was set up in the liquid until it eventually ruptured, producing cavitation in the form of a large number of little bubbles. Berthelot deduced the tension at rupture from a visual estimation of the sudden change in volume of the liquid accompanying the rupture. Temperley (1947), Temperley and Chambers (1946) used glass tubes of the type described by Berthelot, but he employed a different method of estimating the tension existing in the tube when the liquid ruptures. At rupture the stress on the inner wall of the tube is suddenly reduced and the tube consequently increases in volume; Temperley's method consists essentially of measuring this sudden increase in the external volume of the tube. The magnitude of this increase, together with a knowledge of the dimensions and elastic properties of the material of the Berthelot tube, enables the tension at rupture to be calculated.

In the experiments described in this paper both Berthelot tubes and steel tubes were used. The experimental method employed was the same as that of Temperley, but a different equation was used in the calculation of the rupture tension.

§ 2. THEORY

The relationship between the increase in the external volume of a Berthelot tube and the magnitude of the rupture tension may be derived by first considering an infinitely long cylindrical tube, and then proceeding to the case of a finite tube with closed ends.

2.1. *Infinitely Long Tube*

Consider an infinitely long tube, of internal and external radii a and b respectively, which is initially unstressed and is then subjected to uniform normal pressures p_1 and p_0 internally and externally respectively. Assume (a) that the strain is constant along the length of the tube and (b) that displacement normal to its axis is radial. Under these conditions no shear stresses or strains exist.

Application of standard elasticity theory (e.g. Love 1934, Chree 1904) to the above set of conditions leads to the following expressions for the radial displacement u_r at a distance $r(a \leqslant r \leqslant b)$ from the axis of the tube and the longitudinal strain ϵ parallel to the axis:

$$u_r = \frac{1}{E}\left[\frac{r(a^2p_1 - b^2p_0)}{b^2-a^2} - \frac{a^2b^2(p_0-p_1)}{r(b^2-a^2)} - \frac{\nu r(a^2p_1-b^2p_0)}{b^2-a^2} - \frac{\nu a^2b^2(p_0-p_1)}{r(b^2-a^2)} - \nu\sigma r\right] \qquad \ldots\ldots(1)$$

$$\epsilon = \frac{1}{E}\left[\sigma - \frac{2\nu(a^2p_1-b^2p_0)}{b^2-a^2}\right] \qquad \ldots\ldots(2)$$

where E is Young's modulus, ν is Poisson's ratio and σ is the longitudinal stress.

2.2. *Finite Tube with Plane Closed Ends*

Assume the radial restrictive effect of the ends of the tube is negligible.

The resultant force on each end is

$$F=\pi a^2 p_\mathrm{i}-\pi b^2 p_\mathrm{o}.$$

Hence the longitudinal stress σ is

$$\sigma=\frac{a^2 p_\mathrm{i}-b^2 p_\mathrm{o}}{b^2-a^2}. \qquad \ldots\ldots(3)$$

Substituting this value of σ in Eqns (1) and (2), and writing $E/3(1-2\nu)=K$ and $E/2(1+\nu)=\mu$,

$$u_r=\frac{1}{b^2-a^2}\left[\frac{r(a^2 p_\mathrm{i}-b^2 p_\mathrm{o})}{3K}-\frac{a^2 b^2(p_\mathrm{o}-p_\mathrm{i})}{2\mu r}\right] \qquad \ldots\ldots(4)$$

$$\epsilon=\frac{a^2 p_\mathrm{i}-b^2 p_\mathrm{o}}{3K(b^2-a^2)} \qquad \ldots\ldots(5)$$

where K, μ are respectively the bulk and rigidity moduli.

2.3. *Change in External Volume due to Internal Stress*

The unstressed external volume $V_0=\pi b^2 l$, where l is the tube length.

The stressed external volume $V_0+\Delta V_0$ is given by

$$V_0+\Delta V_0=\pi(b+u_b)^2 l(1+\epsilon)=\pi b^2 l(1+2u_b/b+\epsilon),$$

neglecting second and third order quantities. Hence the change in external volume is

$$\Delta V_0=\pi b^2 l\left[\frac{2u_r}{b}+\epsilon\right]$$

or

$$\frac{\Delta V_0}{V_0}=\frac{2u_r}{b}+\epsilon.$$

Substituting for u_r and ϵ from Eqns (4) and (5),

$$\frac{\Delta V_0}{V_0}=\frac{1}{b^2-a^2}\left[\frac{a^2 p_\mathrm{i}-b^2 p_\mathrm{o}}{K}+\frac{a^2(p_\mathrm{i}-p_\mathrm{o})}{\mu}\right]. \qquad \ldots\ldots(6)$$

This equation leads directly to an expression for the tension existing in a Berthelot tube just before the liquid ruptures (i.e. the rupture tension T) in terms of the measured change in external volume of the tube at the moment of rupture. This change is the difference between $(\Delta V_0)_1$ and $(\Delta V_0)_2$, where $(\Delta V_0)_1$ is the difference between the unstressed external volume and the external volume when subjected to an internal tension T, and $(\Delta V_0)_2$ is the difference between the unstressed external volume and the external volume when subjected to an internal pressure P_V. P_V is the pressure inside the Berthelot tube after rupture, and is clearly the vapour pressure of the liquid at the rupture temperature. From Eqn (6)

$$\frac{(\Delta V_0)_1}{V_0}=\frac{Ta^2}{b^2-a^2}\left(\frac{1}{K}+\frac{1}{\mu}\right) \qquad \ldots\ldots(7)$$

$$\frac{(\Delta V_0)_2}{V_0}=-\frac{P_\mathrm{V} a^2}{b^2-a^2}\left(\frac{1}{K}+\frac{1}{\mu}\right) \qquad \ldots\ldots(8)$$

using the convention that tensions are positive and pressures negative. The measured change ΔV_0 in the external volume of the Berthelot tube when rupture occurs is

$$\Delta V_0=(\Delta V_0)_1-(\Delta V_0)_2.$$

Therefore the required expression for the tension at rupture is

$$\frac{\Delta V_0}{V_0}=\frac{Ta^2}{b^2-a^2}\left(\frac{1}{K}+\frac{1}{\mu}\right)+\frac{P_V}{b^2-a^2}\left(\frac{1}{K}+\frac{1}{\mu}\right)$$

or

$$T=\frac{\Delta V_0(b^2-a^2)}{V_0a^2(K^{-1}+\mu^{-1})-P_V}. \qquad \ldots\ldots(9)$$

The equation used by Temperley in calculating the rupture tension is

$$T=\frac{\Delta V_0(b^2-a^2)}{V_0(a^2K^{-1}+b^2\mu^{-1})}. \qquad \ldots\ldots(10)$$

This equation, however, is incorrect.† Eqn (9) does not apply strictly to the present case, since it does not take into account the effect of the ends of the tube, but the Berthelot tubes used in this work were long compared with their diameter and the rounded shape of the ends was such as not to hinder greatly the radial forces acting in the neighbourhood of the ends. It was reasonable therefore to suppose that the error arising from neglecting the effect of the ends would be quite small. Furthermore, since the experiments showed that the Berthelot tube method is not suitable for comparing the tensile strength of liquids, it was considered to be unnecessary to work out a more accurate theory. Finally we may note that the good agreement between the values of T obtained by Eqn (9) and the values of T which it was later possible to deduce from temperature readings, for the same experiments, confirms that the error due to neglecting the effects of the ends is small.

In the case of the steel tubes it is probable that the calculated values are appreciably smaller than the actual values, due to the end effects. But these experiments were meant to be comparative rather than quantitative.

§ 3. GENERAL DESCRIPTION OF THE METHOD

The basic measurement in the experiments was that of the sudden increase in the external volume of the Berthelot tube occurring at rupture. The method employed in this work was essentially the same as that of Temperley, in which the Berthelot tube is surrounded by a horizontal glass water jacket which ends in a fine capillary open to the atmosphere. The water jacket and its contents are heated until the temperature is just above the filling temperature t_f of the Berthelot tube, and then slowly cooled. This results in the meniscus falling gradually in the capillary. Its position h is read at 15-second intervals and a cooling curve of h against time is plotted. When the rupture temperature is reached the stress on the Berthelot tube wall is suddenly released as the tension vanishes, and the tube consequently increases in volume. This increase produces a rise in the level of the meniscus, resulting in a discontinuity in the cooling curve. This discontinuity is not sharp because, owing to viscosity effects, the response of the meniscus in the capillary tube is not instantaneous. The difficulty however can easily be overcome by extrapolating the two parts of the curve to the instant of rupture. An example of an (h, t) curve is given in Fig. 1.

Construction of the Berthelot tubes was a delicate process. In the majority of cases the tubes cracked either during the heating to the filling temperature or when the liquid ruptured. However, it was found possible to construct a hundred or so Pyrex glass tubes which could withstand the various stresses set up during all stages of the experiment. The tube length was about 10 cm, the internal radius 0·13 cm, the external radius 0·24 cm and the volume of the enclosed bubble at room temperature was approximately 1 mm^3. The smallness of this bubble was the major cause of the difficulty in the construction of the tubes. Fig. 2 contains an illustration of the type of Berthelot tube used. The steel tubes used in this work are also illustrated in Fig. 2.

---

† The author has discussed this matter with Dr. Temperley in a private communication.

§ 4. EXPERIMENTS WITH BERTHELOT TUBES

About 120 experiments were carried out on Berthelot tubes, mostly with distilled water. Over a hundred tubes were constructed, but preliminary tests indicated that the contents of most of them were capable of withstanding only comparatively small tensions of the order of 5 atmospheres. However, in a dozen or so of the tubes tensions of the order of 50 atmospheres were obtained; these tubes were accordingly employed in the main series of experiments.

Tap water was used in the preliminary work of developing the technique. The highest tensions sustained by the tap water in these initial experiments were of the order of 50 atmospheres. This was followed by six sets of experiments on Berthelot tubes containing distilled water. The results of these experiments are summarized in Table 1.

The scatter in the observed values of tension were at first taken to be due to experimental error, in view of the smallness of the change in volume to be measured ($\Delta V_0 \simeq 2 \times 10^{-4}$ cm^3). The magnitude of the scatter in set III, however, appeared to be rather large, and so the water-jacket was broken open and the Berthelot tube re-enclosed in a new jacket. The maximum deviation from the mean value in the subsequent series (set IV) was 8%. On repeating the experiments once more with the same Berthelot tube enclosed in yet another jacket (set V) the maximum deviation was 11%.

Table 1. Results of the Initial Experiments with Distilled Water

Set No.	Tube	No. of runs	$T_{\max}$ (atm)	$T_{\min}$ (atm)	T_{mean} (atm)	Max. deviation (%)
I	A	10	49·9	40·5	43·8	12
II	B	2	44·1	36·6	40·4	9
III	C	7	43·1	31·1	37·2	16
IV	C	7	41·0	34·6	37·8	8
V	C	11	36·7	31·1	34·8	11
VI	D	13	42·1	28·8	35·8	20

The results of sets IV and V suggested that the comparatively large variation in the measured values of tension in set III was due to some defect of the water-jacket or capillary. But a further series of experiments with yet another tube produced a scatter of up to 20% of the mean value, and it was therefore considered advisable to investigate the possibility that this scatter was genuine and not due to experimental error.

4.1. *Investigation of the Scatter in the Measured Values of T*

The interdependence of the rupture tension and the rupture temperature provided a means of determining whether the scatter was genuine or not. The expression for this interdependence is

$$T = \frac{1 - 3\alpha(t_z - t_r) - D_z/D_r}{eD_z/D_r} \qquad \ldots\ldots(11)$$

where α is the linear coefficient of expansion of the glass, t_z the temperature at which the pressure in the tube is zero, during cooling, t_r the temperature at which the water ruptures during cooling, D_z, D_r the densities of the water at t_z and t_r respectively and e the volume elasticity of the water.

The value of T for any one particular Berthelot tube is thus a function of t_z and t_r only, since D_z and D_r are also functions of these. If it is assumed that the same temperature is required to fill the tube in each experiment (this has been established within experimental error provided the initial filling process is discounted and provided the successive fillings occur at fairly short intervals of time) then it follows that the value of t_z is also the same in each experiment. Therefore any variation in the rupture tension T must be accompanied by a variation in the rupture temperature t_r.

In a set of twenty-two experiments carried out on a new tube the lowest rupture temperature that occurred in these experiments was 27·05°C, while the highest was 31·40°C; a variation of 4·35°C. This was far greater than the maximum possible error in reading the rupture temperature, therefore this was accepted as conclusive evidence that the rupture tension had not remained constant from one experiment to another. It was later found possible to establish that the probable error in the determination of the rupture tension in these experiments was a little over one atmosphere, which meant that in this series of experiments the tension at rupture varied by 20 atmospheres or more.

It was reasonable to assume that the experimental errors in the previous experiments with similar Berthelot tubes must also have been about one atmosphere, and that the scatter in those measured values of tension were largely due to genuine variation in the rupture tension. Evidently the maximum tension that any Berthelot tube was capable of sustaining varied from one experiment to another, and consequently the method was inherently incapable of producing consistent results.

The degree of inconsistency in the values of rupture tension could be determined only if the limits of experimental accuracy were known, but it was found possible to use the inconsistent values of rupture tension themselves to determine these limits. Eqn (11) may be written as

$$TeD_z = D_r[1 - 3\alpha(t_z - t_r)] - D_z.$$

Therefore, to a fair degree of accuracy, $T = aD_r + b$, or $T = a't_r + b'$ where a, b, a' and b' are constants. In other words, the actual (as distinct from experimental) value of the rupture tension T varies approximately linearly with the rupture temperature t_r. Therefore if the experimental values of T are plotted against the accurately known values of t_r, then the magnitude of the non-linearity should be a measure of the experimental error involved in the measurement of T.

The plotted values are shown in Fig. 3 together with the best straight line through these plotted points, obtained by Awbery's method. On measuring the magnitude of the departures of the plotted values from this straight line, as measured parallel to the T axis, the values obtained (expressed in atmospheres) were 4·3, 3·4, 3·0, 2·6, 2·1, 1·9, 1·6, 1·5, 1·0, 1·0 and eleven less than 1. These yield an average value of 1·12 atmospheres.

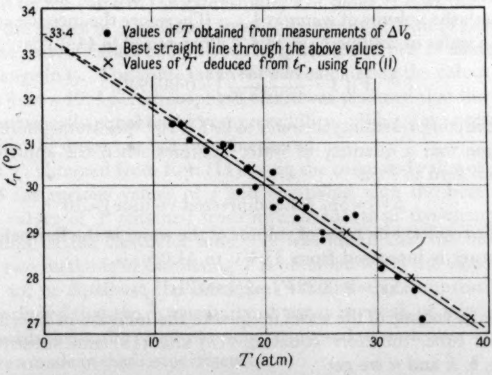

Fig. 3. Rupture tension T plotted against rupture temperature t_r.

These values of departure from the best straight line represent the experimental errors in the determination of T. We may therefore safely conclude, since the experimentally-observed values of T varied from 11·8 to 34 atmospheres, that the range of variation in the actual value of T was certainly not less than 15 atmospheres, and probably over 20 atmospheres.

An interesting point about Fig. 3 is that if the straight line is extrapolated to $T = 0$ then the intercept of this line with the t_r axis represents the temperature at which the tension in the Berthelot tube is zero, i.e. t_z. This determination of the value of t_z for the particular Berthelot tube concerned with here can be used to (i) estimate the pressure existing inside the Berthelot tube at the filling temperature, i.e. the pressure required to completely fill the tube, (ii) determine the magnitude of the rupture tension independently (except for the initial determination of t_z) of the measured change in external volume of the Berthelot tube, and (iii) determine the extensibility of water.

4.2. *The Internal Pressure p_f required to Fill the Berthelot Tube*

The pressure p_f required to fill the Berthelot tube is a function of the filling temperature t_f, t_z, the dimensions and the elastic properties of the Berthelot tube. It can be calculated in the following way.

(*a*) The change V_i in the internal volume of the Berthelot tube when the internal pressure changes from zero to p_f may be derived in the same way as the change ΔV_0 in the external volume when the internal pressure changes from T to P_v. The derived expression is

$$\frac{\Delta V_i}{V_i} = \frac{p_f}{b^2 - a^2}\left(\frac{a^2}{k} + \frac{b^2}{n}\right) \qquad \ldots\ldots(12)$$

where V_i is the internal volume of tube at zero pressure, a, b the internal and external radii of the Berthelot tube, respectively, and k, n the bulk modulus and rigidity modulus of the Berthelot tube, respectively.

(*b*) The experimentally-determined value of t_f is 44·0°c, and the value of t_z obtained from the extrapolation in Fig. 3 is 33·4°c. The relative volumes of uncompressed water at 44·0°c and 33·4°c are 1·009387 and 1·005439, when compared with the volume of water at 4°c. Therefore the increase in volume that takes place in water of volume V_i at 33·4°c when raised to 44·0°c is

$$V_i\left(1 - \frac{1{\cdot}009387}{1{\cdot}005439}\right) = 0{\cdot}0039\,V_i. \qquad \ldots\ldots(13)$$

Taking the compressibility of water to be 5×10^{-5} per atomsphere, the decrease in the volume that a quantity of water occupies when the applied pressure is changed from zero to P_f is

$$\Delta V_f = 5p_f\,(\text{uncompressed volume}) \times 10^{-5}. \qquad \ldots\ldots(14)$$

Therefore the resultant increase of volume of the water in the Berthelot tube, when the temperature is increased from 33·4°c to 44·0°c, is

$$\Delta V = 0{\cdot}0039\,V_i - 5(1{\cdot}0039)\,V_i p_f \times 10^{-5}. \qquad \ldots\ldots(15)$$

This increase in volume of the water is equal to the increase in internal volume of the Berthelot tube, therefore equating (12) and (15) and substituting known values for a, b, k and n we get

$$p_f = 68{\cdot}2 \text{ atmospheres.}$$

4.3. *Deduction of the Rupture Tension from the Rupture Temperature*

Since

$$T = \frac{1 - 3\alpha(t_z - t_r) - D_z/D_r}{eD_z/D_r} \qquad \ldots\ldots(11)$$

it is clear that a knowledge of t_z, α and e will enable T to be calculated from the rupture temperature t_r. The values of T derived in this way for seven observed values of t_r are plotted in Fig. 3, which provides a direct comparison between the values of the rupture tension deduced from the elastic properties of the tube wall and those deduced from the elastic and thermal properties of the water enclosed. The agreement between them is surprisingly good, considering the sources of error involved in the derivation of these values.

It will be observed that all the plotted values deduced from the value of the rupture temperature differ by less than one atmosphere from the best straight line drawn through the values of the tensions deduced from the change ΔV_0 in the external volume of the Berthelot tube. The differences that do occur can be accounted for by the fact that the relationship between T and t_r is not quite a linear one. The rate of change of T with t_r slowly decreases as the value of T increases; the order of magnitude of this effect is indicated by the broken curve in Fig. 3 drawn through the plotted values derived from Eqn (11), assuming $t_z = 33{\cdot}4$°c. From this broken curve it is obvious that the intercept obtained on the t_r axis by extrapolating the best straight line to $T = 0$ does not represent the true value of t_z, since this extrapolation presumes a linear relationship between T and t_r; the true value of t_z is clearly a little less (of the order 0·2°c) than the value of 33·4°c obtained by means of the straight line extrapolation. On substituting 33·2°c for t_z in Eqn (11) the values of T obtained from different values of t_r differ by less than 4 per cent from the best straight line through the values of T obtained from V_0.

4.4. *Determination of the Extensibility of Water*

It follows from Eqn (11) that both the magnitude of the tension T corresponding to any particular value of t_r and the rate of change of T with change in t_r are dependent on the value of the extensibility e of water. If an incorrect value is chosen for e the values of T deduced from t_r by means of Eqn (11) will therefore differ from the correct values of T in both magnitude and rate of change of magnitude with change in t_r. The value taken for e in calculating the values of T plotted in Fig. 3 was $4{\cdot}91 \times 10^{-5}$ per atmosphere, i.e. it was assumed that the extensibility of water is numerically equal to the compressibility. This was necessary because the extensibility of water has not been measured.

Values of T, obtained from Eqn (11) using the corrected value of 33·2°c for t_z, were plotted for various values of e and compared with the best straight line through the values of T obtained from measurements of the change V_0 in the external volume of the Berthelot tube. It was found that the best agreement between the two methods of estimating T is obtained when the value chosen for e is very near to, or equal to, the numerical value of the compressibility. It is therefore concluded that the extensibility of water is equal, or very nearly equal, to its compressibility in the range of temperature and tension over which observations have been made in these experiments.

§ 5. EXPERIMENTS WITH STEEL TUBES

It was considered possible that the inconsistency in the value of the rupture tension in Berthelot tubes was due to the peculiarities which glass shows in its physical and chemical properties. The successful construction of similar tubes made from steel enabled this possibility to be investigated.

Twenty-six experiments with the first steel tube gave values of rupture tension ranging from 13·5 to 23·7 atmospheres, with a mean of 19·6 atmospheres. The rupture tensions obtained in nine experiments with the second steel tube ranged from 8·0 to 12·4 atmospheres, the mean value being 10·2 atmospheres. There is thus no significant difference between the variation in the values of rupture tension obtained with steel tubes and those obtained with glass tubes. Hence the peculiar properties of glass as compared with other materials clearly are not the cause of this variation.

However, though the experiments with steel tubes failed to produce consistent results they were not more inconsistent than those obtained with glass tubes. Indeed, the advantages of using steel instead of glass indicate that future Berthelot tube experiments might be better and more conveniently performed with steel, rather than glass, tubes. One advantage of steel tubes is that they are far less liable to burst than glass ones; this liability to burst is one of the main practical inconveniences of the Berthelot tube experiment. Another advantage is that, since the steel tube is sealed by means of a cone-tipped screw, experiments on different liquids may be carried out using the same tube, making the reproducibility of conditions a simpler matter and doing away with the necessity of constructing a number of tubes. On the other hand there is, of course, the disadvantage that the contents of the steel tube cannot be observed visually. In practice this is not a great handicap since it is fairly easy to determine the temperature at which the liquid fills the tube by trial and error, and the precise moment at which the liquid ruptures is revealed by the characteristic click that accompanies the phenomenon. The greatest difficulty in connection with steel tubes is to produce an air-tight seal; in order to achieve this it is necessary for the sealing screw to be an accurate fit.

§ 6. OTHER EXPERIMENTS

Subsidiary experiments carried out during the course of the work included measurements of the rupture tensions in tubes containing suspensions of ultramarine particles in water, and also carbontetrachloride with water. In addition, an investigation was made into the influence on the rupture tension of mechanical shock, rate of cooling and application of pressure to the liquid before subjecting it to tension. An attempt was also made to observe where the rupture took place.

In the experiments on tubes containing ultramarine particles in water the contents ruptured at values of tension ranging from 13·8 atmospheres to 64·3 atmospheres, and behaved in no way differently from tubes containing water only.

The interesting feature of the experiments with a tube containing carbontetrachloride with water is that the clear-cut interface between the two liquids is able to withstand a tension of at least 60 atmospheres. Not once was the rupture observed to take place at this interface. This sustains Marboe's (1949) contention that for a foreign body to enhance cavitation it is not enough for it to have a different atomic structure to that of water, but must also be sufficiently rigid to provide a structural discontinuity at the interface.

The investigation of the effect, on the rupture tension, of varying the maximum pressure set up in the tube prior to application of tension was accomplished by varying the amount by which the temperature of the tube was raised above the filling temperature. The steel tubes were capable of withstanding considerable pressure, and it was possible to apply a range of pressures up to about 100 atmospheres above the pressure existing at the filling temperature. In 26 successive experiments where the maximum temperature to which the tube was raised varied from 47·5 °c to 60 °c and was maintained at the maximum temperature for durations of time ranging from 5 minutes to 35 minutes, there was no apparent correlation between the magnitude of the rupture tension and the magnitude and duration of the applied pressure.

It was impractical to apply shocks of appreciable magnitude during the usual type of experiment owing to the presence of the delicate glass–water jacket, so the investigation was carried out indirectly by observing the effect of mechanical shock on the temperature at which rupture took place. The method employed was to remove the Berthelot tube from the jacket, heat it up to the filling temperature in a bath and then allow it to cool gradually; during this latter process the tube was tapped sharply at frequent intervals with a steel rod, and a close observation made of the temperature at which the contents of the tube ruptured. The results of these experiments were entirely negative, in that the temperatures at which the ruptures took place in these experiments were not significantly different from the rupture temperatures occurring when no mechanical shocks were applied. From this it follows that the rupture tensions were not significantly different either.

It appeared possible that the variability of the rupture tension might be due to chance encounters, either between stray nuclei which are in motion in the liquid, or between such a nucleus and some weak link in the system. If this were a major cause of the variability then the slower the rate of cooling (i.e. the longer the application of tension) the lower the rupture tension would tend to be. A series of tests was carried out to observe whether the rate of cooling influenced the rupture tension, but no such tendency was detected. It was found that a Berthelot tube could withstand indefinitely a tension only slightly less than the rupture tension. This was established by lowering the temperature in small controlled steps.

The rupture process always commenced with the sudden appearance and collapse of a single bubble, which was immediately followed by the formation of a large number of tiny bubbles along the length of the tube. After numerous close observations of this phenomenon it was concluded that though the location of the initial rupture was not constant it always occurred in the proximity of the liquid–glass interface.

§ 7. CONCLUSIONS

The conclusions derived from the experiments described in this paper are these:

(1) In the case of Pyrex Berthelot tubes containing water, ultramarine powder in water, water and carbontetrachloride, and steel tubes containing water, each tube is capable of withstanding tension.

(2) The magnitude of the tension which any one tube can withstand is not a fixed quantity. The range of variation is liable to be as great as 30 atmospheres.

(3) The range of the tensions withstood varies considerably from tube to tube. Some tubes are capable of sustaining tensions of 50 atmospheres and more, while others seem incapable of sustaining even 5 atmospheres of tension.

(4) Compression of the liquid up to 100 atmospheres above its pressure at filling has no significant effect on the value of the rupture tension. Neither have quite sharp mechanical shocks nor rate of build-up of the applied tension.

(5) Water, carbontetrachloride and a water–carbontetrachloride interface can all sustain tensions of at least 60 atmospheres.

A possible explanation of the inherent irreproducibility of the rupture tension in a Berthelot tube is that during the cavitation process a part of the tube wall is torn away. This produces fresh surfaces, so that in effect a slightly different Berthelot tube is being subjected to tension in each subsequent experiment. This explanation is consistent with that put forward by Marboe (1949) to account for the corrosion of marine propellers, where it is reasoned that the weakest link in the metal–liquid system is a bond somewhere within the interior of the metal.

ACKNOWLEDGMENTS

The author wishes to acknowledge his debt to the late Professor R. M. Davies for his guidance and inspiration. He also wishes to express his gratitude to Dr. H. N. V. Temperley for his considerable help and interest in the work, and to the Department of Scientific and Industrial Research for the award of a maintenance grant.

LETTERS TO THE EDITOR

Magnetic Properties of Nickel

Dr. S. Katsuki of Kyusyu University has recently drawn the author's attention to an error in the paper by the author (Fletcher 1954) on ferromagnetic anisotropy and allied effects in nickel. In this a spin–orbit parameter A was wrongly described as corresponding to a_i in Goudsmit's notation. In fact, in deriving later formulae, factors $\hbar$ and $\hbar/2$ from the angular and spin momentum operators $\mathbf{L}$, $\mathbf{S}$ respectively were absorbed in this parameter A, which therefore corresponds to $a_i/2$. All subsequent formulae are correct but a value of 295 cm^{-1} should be substituted for A instead of 590 cm^{-1}. This also affects the numerical results obtained in Fletcher (1955) on magnetostriction in nickel. The results obtained for the first anisotropy coefficient K_1, the spectroscopic splitting factor g, the gyromagnetic ratio g' and the magnetostriction constants λ_{100}, λ_{111} should therefore read

$$K_1 = -2{\cdot}8 \times 10^6 \,\mathrm{erg\,cm^{-3}}$$

$$g = 2{\cdot}09 \qquad g' = 1{\cdot}92 \text{ to } \mathrm{O}(A)$$

$$g = 2{\cdot}08 \qquad g' = 1{\cdot}92 \text{ to } \mathrm{O}(A^2)$$

$$\lambda_{100} = 46{\cdot}7 \times 10^{-6} \qquad \lambda_{111} = -11{\cdot}1 \times 10^{-6}.$$

REVIEWS OF BOOKS

Proceedings of the Fourth International Conference on Ionization Phenomena in Gases, Vols I and II, edited by N. R. NILSSON. Pp. 1210. (Amsterdam: North-Holland, 1960.) £12 6*s*.

Seven years ago the First International Conference on Ionization Phenomena in Gases was held in Oxford. Since then biennial conferences have been held in Delft, Venice and lastly Uppsala. It is the proceedings of this last meeting which are published in the two huge volumes under review. The growth of the meetings has been almost exponential and has been accompanied by an increasing emphasis on high-temperature plasmas so that almost half the material presented is in or close to this field.

The two hundred and fifty papers read at the conference were presented in four parallel sessions: (i) Fundamental processes in gas discharges, (ii) Different types of discharges and applications, (iii) Theoretical and experimental studies in plasma physics, (iv) Production, confinement and healing of plasmas; and most of them are reproduced in these volumes, sessions (i) and (ii) in volume I and sessions (iii) and (iv) in volume II. Their publication will go far to relieve the grave disadvantages of the parallel session method felt by those who attended the conference, and the division between the volumes will allow groups short of funds to purchase the volume closest to their interest.

It is impossible to give even a bird's eye view of the scope of the conference. It was particularly fortunate in its invited review papers, and the rapid publication will undoubtedly make available many original contributions considerably earlier than would otherwise have been the case.

Few individuals will purchase these proceedings but no research library associated with the field should fail to do so. R. L. F. BOYD.

Nuclear Spectroscopy, edited by FAY AJZENBERG-SELOVE, Part A, Pp. xxi + 622; Part B, Pp. xvi + 525. (New York, London : Academic Press, 1960.) $16.00.

The two books under review together form Volume 9 of a series of monographs in pure and applied physics. The appearance of a new text in nuclear physics immediately invites the questions " What is its scope ? " and " What is the level of its treatment ? " In the present case the title is precise; the books cover the experimental methods of investigating the excitation levels of nuclei and the theoretical interpretation of the results obtained. There is no treatment of the two-body problem, no mention of mass spectroscopy and little reference to high-energy physics. The articles stand generally somewhere between the comprehensive review and the elementary textbook chapter, and are without exception authoritative, informative and readable. They should be particularly useful to those who seek a quick survey of the outstanding features of a particular field of work without having the time available for exhaustive study.

Part A is devoted mainly to experimental methods and results. The main sections are on The spectroscopy of charged particles, Gamma-ray spectra, Neutron spectroscopy and other topics (which includes photonuclear reactions, measurement of short lifetimes and measurement of nuclear moments). Within these divisions there are 23 individual short articles, mainly of about 25 pages length, with some 50 to 100 references and illustrative data tables in many cases. The organization of the available material into articles is logical and satisfactory, although a few overlaps are inevitable in a complex subject, and the twenty-two authors have presented extremely clear accounts of their particular subjects. There is admirable restraint in the amount of detail presented and the brevity of the articles seems to have had a notably beneficial effect on their general clarity. It would be invidious to single out any article for particular mention from a compilation of such excellence; nearly all reduce a large area of experience to a compact and manageable form.

The main divisions of the second book (Part B) are Theoretical analysis of the data, and Nuclear models. The 13 articles are somewhat longer than those in Part A; they deal with nuclear reaction theories and with the interpretation of beta- and gamma-ray transition probabilities as well as with the information on level schemes offered by the independent-particle and collective nuclear models. There seems to be no major omission in coverage as far as nuclear spectroscopy is concerned and all the important techniques of analysis are adequately reviewed. The most successful articles are those which deal with a fairly broad field, such as electromagnetic transitions or collective motion. In other cases a narrower range of subject matter has sometimes resulted in an over-emphasis of detail. The chapter on nuclear coupling schemes, however, is a most useful general account of advances made in the detailed application of the shell-model to the prediction of nuclear spectra. The volume concludes with a table of isotopes, which lists nuclear moments in addition to decay properties.

Taken together, these two books present the nuclear physicist with a valuable and up-to-date account of most of the low-energy aspects of his subjects. Although each article is complete in itself, the editor has succeeded in establishing a general coherence of treatment which is continually helpful to the reader.

W. E. BURCHAM.

Review of Non-linear Wave Mechanics, by L. DE BROGLIE. Pp. xi + 304. (Amsterdam, London, New York, Princeton: Elsevier, 1960.) 57*s*.

This book, a translation from the French, presents a summary of de Broglie's ideas on the interpretation of the quantum theory.

The author begins by describing his point of departure, namely, the idea of the ' double solution ' of the field equations which led him to suggest his wave theory of the electron and the well-known de Broglie relation between the momentum and the wavelength. He then shows how he further developed this point of view, and explains the reasons why he gave it up in 1927, in favour of the usual interpretation of the quantum theory. In doing this, he gives a thorough analysis of both of his original ideas on the quantum theory and those that have come to be accepted since 1927.

He then goes on to describe how he returned to his original ideas in 1950, explaining why he did so, relating his work to that of others in the same field and showing several directions in which ideas similar to his can be developed further.

A brief review of this kind is no place to go into a critical analysis of the contents of this book. However, it can be stated that the book contains material of considerable importance for anyone who is interested, either from a scientific or a philosophical point of view, in understanding the meaning of the quantum theory.

DAVID BOHM.

Laboratory Handbook of Toxic Agents, by C. H. GRAY. Pp. viii + 170. (London: Royal Institute of Chemistry, 1960.) 20*s*.

This book has been prepared by the Royal Institute of Chemistry for easy and ready reference in emergency for those handling toxic materials. It contains a general discussion on the main risks and a note of special precautions, a section on first aid in the laboratory and a central section, printed on coloured paper, listing the various poisonous and corrosive gases, reagents and solvents in alphabetical order with a note of their effects and the first aid to be applied.

Quantum Electronics, edited by C. H. TOWNES. Pp. xviii + 606. (Columbia : University Press, 1960.) £6.

In no field of technical development has physics research had a more immediate and direct impact than in that of microwave radio. Fundamental physics research on stimulated emission of radiation has opened a new era in the design of very-low-noise amplifiers, and has led to the practical development of the MASER. Advances in the physics of semiconductors have reopened the possibilities of parametric amplification at microwave frequencies and, stimulated by healthy competition, those concerned with thermionic valves have been encouraged to new and unforeseen developments.

With such rapid development as has taken place in the last few years, one would expect a symposium attended by many of the leading research workers in the field to be a stimulating and fruitful occasion, especially when organized by Professor C. H. Townes who, for many years, has devoted a large part of his research to microwave physics and who first showed, using ammonia vapour, how stimulated emission could be used to produce microwave amplification.

The present volume gives an account of the papers presented at a symposium held at Shawanga Lodge, New York, 14th–16th September 1959, and also of some of the discussion which took place after the presentation of the papers. This material has been carefully assembled under the editorship of Professor Townes. The field covered is a wide one, including molecular-beam masers, three-level ‘ solid-state ’ masers, atomic frequency standards, optical pumping effects, paramagnetic resonance, spin–lattice relaxation, parametric amplifiers, use of ferrites for amplification and a wide variety of studies of physical phenomena associated with maser action. In addition, a number of articles are included on the use of masers and other low-noise amplifiers in communications, radio astronomy, etc.

The various papers together give a very comprehensive and up-to-date account of this field of research up to September 1959, and in so rapidly advancing a field the inclusion of the discussion is particularly appropriate. The book is certainly not one for a reader who wishes to have a ‘ popular ’ account of the ‘ state of the art ’. It is, however, likely to be found on the desk (rather than on the book shelves) of every active research worker in the field for some time to come. Undoubtedly, the subject matter will become ‘ dated ’ but, for the research man, full value will be had from the book before this is so. There is, at the moment, a dearth of co-ordinated literature (but not of research papers) in this field and this collection of articles is all the more timely. The book is elegantly produced in a handsome format, and Columbia University Press is to be congratulated on its achievement. Not all conference reports are available in such usable form. R. A. SMITH.

Annual Review in Automatic Programming, Vol. 1, edited by R. Goodman. Pp. xi + 300. (Oxford, London, New York, Paris: Pergamon Press, 1960.) 63*s*.

In April 1959 there was held at Brighton a conference whose announced aim was to consider the possibility of standardizing autocoding procedures for digital computers. Naturally, no agreement of a binding kind could result from such a gathering of individuals but several other useful conclusions were reached, one of which was the decision to publish an annual review of automatic programming. The present volume is the first of these reviews and contains the edited version of the papers which were read at Brighton.

The papers may be divided into two classes (apart from the obvious subdivision into good and bad!): general surveys and suggestions for standardizing autocoding methods, and descriptions of specific autocodes already available.

In the first class there are papers on future trends, problems of a universal autocode, formula translation as applied to the automatic coding of differential equations, the 'philosophy' of programming, business applications and, as odd man out, the automatic programming of numerically controlled machine tools.

For specific machines, the systems in use with TREAC, PEGASUS, MERCURY, DEUCE, STANTEC-ZEBRA, the IBM and the Remington Rand machines are discussed.

There are also reprints of A. M. Turing's fundamental papers on the problem of computability.

Naturally, with so many contributions, the quality varies from good to very bad and the presentation from clear to absolutely incomprehensible. Nevertheless, the material is not to be found elsewhere and the editor is to be congratulated upon producing a volume which will be invaluable to all computer users and designers, and it is to be hoped that the next volume will appear in the near future. A. D. BOOTH.

Crystal Growth, Discussions of the Faraday Society, No. 5, 1949. Pp. 366. (London: Butterworth's Scientific Publications, 1959.) 60*s*.

The Discussion of the Faraday Society held at Bristol on 12th–14th April 1949 was memorable for the timeliness of many of the contributions that were made there. The original edition of the *Discussion* has been out of print for some time, and in answer to many requests to the Faraday Society, it has recently been reprinted in entirety.

Probably the most memorable contribution was that by F. C. Frank, for it was here that he first put forward his theory of the part played by screw dislocations in crystal growth from vapour or solution—a theory dramatically confirmed at a subsequent Summer School in Bristol by L. J. Griffin's photographs. On the experimental side, the outstanding contributions came from D. C. Stockbarger; his descriptions of techniques for growing single crystals of lithium and calcium fluorides were most generously supplemented by his personal recounting of the 'tricks of the trade' to those of us who were trying to emulate him.

In his *Treatise on Electricity of Magnetism*, Maxwell said "It is of great advantage to the student of any subject to read the original memoirs on that subject, for science is always most completely assimilated when it is in the nascent state". The reprinting of this Faraday Society Discussion provides just such an opportunity for present-day students of crystal growth. R. V. JONES.

Growth of Crystals. Vol. 1. *Reports at First Conference on Crystal Growth*, held at the Institute of Crystallography, Moscow, March 1956, edited by A. V. SHUBNIKOV and N. N. SHEFTAL. Pp. 294. (New York: Consultants Bureau; London: Chapman and Hall, 1958.) 120*s*. Vol. 2. *Interim Reports between First and Second Conferences of Crystal Growth*, edited by A. V. SHUBNIKOV and N. N. SHEFTAL. Pp. vi + 178. (New York: Consultants Bureau; London: Chapman and Hall, 1959.) 128*s*.

The two volumes provide an interesting survey of some aspects of Russian work on crystal growth in recent years. Volume 1 contains forty-three of the eighty-three reports presented at the 1956 conference, where the main attention was directed towards the growth of single crystals. The papers have a strong practical slant, and there is very little discussion, for example, of such matters as the part played by dislocations in crystal growth. The papers represent mainly an exchange of experiences between experimenters who have been concerned directly with the several techniques of growing single crystals, and they will be of much interest to workers outside Russia who are concerned with similar techniques. In general, the papers at the 1956 conference give the impression that the Russians were trying to catch up on standard techniques, and that there was not a great deal said at the conference that would be new to workers elsewhere. But it must be remembered that one of the editors was a pioneer in the growth of crystals from the melt, and it is therefore not surprising that there are many useful points of experimental detail which make the volume worth reading.

The second volume follows generally the pattern of the first. By far the most substantial of its twenty-five papers is that compiled from the work of the late S. K Popov, summarizing his techniques and experiences of nearly twenty years in the growth of corundum boules and rods. N. N. Sheftal says, of Popov's contribution, " The equipment used in Western Europe would appear to be much more primitive, and the crystals somewhat less good." The reviewer is unable to assess the accuracy of this observation, but it would appear to make the paper worth reading by those concerned with the production of artificial gemstones. There are many interesting points of detail in the other papers. While most of the ways of growing single crystals are treated in one or other of the papers, there is not much work reported on growth from the vapour phase, and there is no mention of work on artificial diamonds.

The high prices of the two volumes, and particularly of the second, will not commend them to the private buyer. Presumably the price is partly determined by the large number of diagrams, some amounting almost to engineering drawings, which add much to the clarity of the text. The first volume is worth buying for the library of any institution concerned with practical crystal growth; the second volume is probably worth acquiring for those institutions concerned particularly with artificial gemstones, on account of the Popov paper. Otherwise, it might be preferable to await the volume which will presumably appear after the Second Conference on Crystal Growth has been held. R. V. JONES.

Encyclopedia of Physics, Vol. IX, *Fluid Dynamics*, Vol. III, edited by S. FLÜGGE. Pp. viii + 814. (Berlin, Göttingen, Heidelberg: Springer, 1960.) DM 198.

This volume on fluid dynamics in the *Handbuch der Physik* contains the following articles: Analytical theory of subsonic and supersonic flows, by M. Schiffer (161 pages); Théorie des ondes de choc, by Henri Cabannes (63 pages); Theory of characteristics of inviscid gas dynamics, by R. E. Meyer (58 pages); Linearized theory of unsteady flow of a compressible fluid, by R. Timman (28 pages); Jets and cavities, by David Gilbarg (135 pages); Surface waves, by John V. Wehausen and Edmund V. Laitone (333 pages).

The subject matter of the volume divides naturally into two parts of approximately equal length. The first five articles are devoted to the mathematical theory of an inviscid perfect gas, and the last two to the motion of an incompressible fluid with a free surface or interface with an immiscible fluid.

To take the articles on gas dynamics first, these are authoritative and on the whole lucid works which will be useful to mathematicians working in the field. However, they tend to be concerned with the fundamental aspects of the mathematical theory and detailed methods of solution, and they cannot be recommended to the physicist and gas dynamicist whose mathematics is at all limited. Very little space is devoted to fitting the mathematical theory into the physical background and discussing the limitations of the inviscid perfect gas approximation. The article on shock waves takes a shock as a surface of discontinuity and pays no attention to the important question of shock structure. Some of the articles are a few years out of date and there is no mention of several recent important developments, the most outstanding omission being hypersonic flow.

To take now the second half of the volume, the article by Gilbarg on jets and cavities, or as it is often called free streamline theory, is excellent and could hardly be bettered. The article discusses the fundamental mathematical theory, but is also concerned with the physical validity and applications of the theory. The author has clearly realised that the applied mathematician should seek to describe and explain natural phenomena. The remaining article on surface or water waves is long and complete, containing an account of almost all the mathematical theory. However, the authors have been reluctant to be critical or selective in their presentation of the material, and the article is more like a catalogue than a critical survey and exposition of the field.

This volume would be a valuable and very worthwhile addition to an Encyclopedia of Mathematics, but is a disappointing addition to an Encyclopedia of Physics, at least according to the reviewer's understanding of the definition of the subject. P. G. SAFFMAN.

The Interpretation of X-ray Diffraction Photographs, 2nd Edn, by N. F. M. HENRY, H. LIPSON and W. A. WOOSTER. Pp. x+282. (London: Macmillan; New York: St. Martin's Press, 1960.) 63*s*.

This book is a teaching manual for students and research workers in X-ray crystallography. It deals with all the principal types of X-ray diffraction photograph in an exceptionally clear and comprehensive way, and gives sufficient of the underlying theory to make the necessary operations intelligible.

A number of useful tables are provided, together with a subject index and many references to original papers. Charts and photographs are reproduced to scale, so that they may be used for practice, and a large number of examples are worked out in detail in the text; these include the more difficult cases, such as triclinic and trigonal crystals, and twins.

The second edition contains many additions and improvements but not, unfortunately, a discussion of anomalous dispersion. This is a topic of increasing practical importance, which can certainly produce appreciable intensity changes on X-ray diffraction photographs, and may also be used for absolute configuration determination and for speeding up certain types of structure analysis. Multiple reflection, which can apparently produce spectra which would otherwise be absent, might also have been mentioned in the section on space-group determination. Also, it seems a pity that in a book in which there are so many really excellent line diagrams, some of the actual X-ray photographs of single crystals are obtained from specimens well below the quality required in these days of accurate data.

Although there is no substitute for personal experience in such work, this book will enable newcomers to each technique to avoid many of the usual mistakes. The minor blemishes mentioned above should not deter any present or future crystallographer from buying this exceedingly useful book.

H. J. MILLEDGE.

Theoretical and Experimental Physics, by H. G. JERRARD and D. B. MCNEILL. Pp. xiv + 624. (London: Chapman and Hall, 1960.) 75*s*.

This book is intended to serve as a manual for a course of degree standard founded on laboratory work and as a reference account of a number of experiments of the measurement kind which are important in many branches of applied physics. The experiments are nearly all ' classical ' in content, though a few measurements of X-ray absorption and critical potentials occur in the electronics section. There are good and stimulating references to books and papers.

Though the book will be useful to aid the memory of university and technical college teachers, it fails in the opinion of the reviewer in its main objects.

The choice of experiments and topics owes too much to the tradition of school and university courses which goes back to the nineteenth century, and the presentation is not critical enough to allow the user to separate the really useful methods from mere laboratory exercises.

The Statistical Properties of Sequences of Stochastic Pulses†

By T. LUKES
Department of Physics, Northampton College of Advanced Technology, London

Communicated by R. Fürth; *M.S. received* 15*th August* 1960,
and in revised form 2*nd January* 1961

Abstract. Two methods are presented for treating sequences of random pulses which are applicable to cases where the distribution of periods, durations or intervals is known. The methods are shown to lead to identical results and enable the correlation functions, after-effect functions and spectra to be calculated. The results are applied to typical sequences; some existing results are shown to be particular cases of the theory presented.

§ 1. Introduction

A large number of physical phenomena may be represented as functions of space or time by a (usually infinite) sequence of irregular pulses. As examples we may take the emission of electrons from a cathode (Rice 1944), or the process of conduction in metals or semiconductors (Machlup 1954).

A number of results relating to particular sequences is available in the literature. Carson (1931) has obtained an expression for the spectrum of a sequence of pulses of fixed shape, the number of pulses in a given interval of time being given by a Poisson distribution. Machlup (1954) has considered the spectrum of a sequence of square pulses with an exponential distribution of intervals and durations, the mean values being different in the two cases. An investigation of the methods used shows that they are limited to the particular cases they consider and do not lend themselves to generalization. A wider approach has been the application of renewal theory to similar problems, particularly in relation to the problem of particle counters (Domb 1947, 1950, Hammersley 1953, Feller 1949, Smith 1957).

R. Fürth has made a general, though more or less qualitative, study of the statistical properties of sequences of random pulses (Fürth 1952) and has shown how the after-effect functions (see § 2) of such a sequence may be used, in certain cases, to determine the average pulse duration and pulse interval. He has been able to apply the theory successfully to the phenomena of star scintillations (Fürth 1955, 1956), and J. Scott has made use of the same method for the analysis of semiconductor noise records (Scott 1960).

The purpose of the present paper is to investigate quantitatively the statistical properties of random pulses under reasonably general conditions.

A pulse is specified for the present purpose as an arbitrary function of time $f(t)$ which is zero outside an interval s, which will be referred to as the pulse duration. The function $y(t)$ given by

$$y(t) = \sum_i f(t - s_i - t_i)$$

---

† This paper forms part of the author's Ph.D. thesis (University of London, 1960), research work for which was carried out at Birkbeck College, University of London, under the supervision of Dr. R. Fürth.

will then be referred to as a sequence of pulses, the variables t_i being the intervals between the pulses and the $q_i = s_i + t_i$ representing the period. In the cases to be considered the values of the variables s_i, t_i, q_i are determined by probability distributions. More specifically, we consider (i) sequences in which all the durations s_i are fixed and equal, the periods q_i being distributed independently of one another; (ii) sequences in which the intervals are distributed independently, the durations again being fixed; (iii) sequences with independent distributions of intervals and durations; (iv) randomized periodic sequences. These need special definition (§ 5).

In § 2, we define the statistical functions of interest and the relationship between them. In § 3, we obtain series expressions for these by direct consideration of the problem in the time domain. In § 4, we consider the problem in the frequency domain and derive expressions for the spectrum; Fourier inversion then leads to results which are identical with those of § 3. In § 5, we consider a further example of a random sequence which does not fall into any of the categories previously considered. In § 6, we apply our results to particular cases and show that existing results emerge as special cases of our general theory. We conclude with § 7, in which we summarize our work.

§ 2.

We shall, for convenience, assume that we are dealing with a function of time only, $y(t)$. The statistical dependence between the values of $y(t)$ at times t, $t+\tau$, is usually measured by the autocovariance $A(\tau)$, which is experimentally obtained as a time average:

$$A(\tau) = \lim_{T\to\infty} \frac{1}{T} \int_{-T/2}^{T/2} y(t)y(t+\tau)\,dt = \overline{y(t)y(t+\tau)}.$$

The 'correlation function' is defined as

$$\rho(\tau) = \frac{A(\tau)}{\overline{y^2(t)}}. \qquad \ldots\ldots(1)$$

For pulse sequences $y(t)$ has, in general, a non-zero mean value and it is then convenient to define the correlation function $r(\tau)$ by

$$r(\tau) = \frac{\overline{[y(t)-\overline{y(t)}][y(t+\tau)-\overline{y(t)}]}}{\overline{[y(t)-\overline{y(t)}]^2}}. \qquad \ldots\ldots(2)$$

The relationship between the two functions is, obviously,

$$r(\tau) = \frac{\rho(\tau)-\rho(\infty)}{\rho(0)-\rho(\infty)}. \qquad \ldots\ldots(3)$$

Another function introduced by Smoluchowski (1914) the importance of which has more recently been emphasized by Fürth (1952) is the after-effect function $\gamma(\tau)$, defined by the equation

$$\gamma(\tau) = \overline{[y(t+\tau)-y(t)]^2}. \qquad \ldots\ldots(4)$$

Corresponding to the correlation function a 'reduced after-effect function' may be defined by the equation

$$d(\tau) = \gamma(\tau)/\gamma(\infty). \qquad \ldots\ldots(5)$$

For a stationary process the following relations obtain:

$$d(\tau) = \frac{1-\rho(\tau)}{1-\rho(\infty)} = 1 - r(\tau), \qquad \gamma(\infty) = 2\sigma^2. \qquad \ldots\ldots(6)$$

In order to compute the autocovariance and other functions, the following procedure will be adopted. A particular record of $y(t)$ of length T, denoted by $y^k(t)$, will be considered, and the corresponding autocovariance $A^k(\tau)$ computed. This will then be a function of some parameters (such as durations, intervals, or periods) which are randomly distributed. The value of $A^k(\tau)$, averaged over these parameters, will be denoted by $\langle A^k(\tau)\rangle$. Since the discussion is confined to ergodic, stationary processes, the limit of $\langle A^k(\tau)\rangle$ as $T\to\infty$, which will be shown to exist in all the cases considered, may be identified with the value of $\overline{y(t)y(t+\tau)}$ obtained over an infinite sequence.

The Fourier transform of $y^k(\tau)$ is defined by

$$Y^k(f)=\int_{-T/2}^{T/2} y^k(t)e^{2\pi ift}\,dt \qquad \ldots\ldots(7)$$

and the power spectrum $G^k(f)$ by

$$G^k(f)=\frac{1}{T}|Y^k(f)|^2. \qquad \ldots\ldots(8)$$

The average value $\langle G^k(f)\rangle$ may again be obtained, and it will be shown that it tends to a finite limit as $T\to\infty$ for all cases considered; this limiting value will be denoted by $G(f)$. The autocovariance may then be expressed in terms of this limiting value by the Wiener–Khinchine relation

$$A(\tau)=\int_{-\infty}^{\infty} G(f)\cos 2\pi f\tau\,df. \qquad \ldots\ldots(9)$$

Eqn (9) assumes that $\overline{y(t)}=0$; if this is not the case a term equal to $\overline{y(t)}^2\delta(f)$ must be added to the spectrum. The correlation function is given by

$$\rho(\tau)=\frac{\int_{-\infty}^{\infty} G(f)\cos 2\pi f\tau\,df}{\int_{-\infty}^{\infty} G(f)\,df}.$$

From Eqn (6) it is then easy to see that the after-effect function can be expressed as

$$d(\tau)=\frac{2\int_{-\infty}^{\infty} G(f)\sin^2 \pi f\tau\,df}{\int_{-\infty}^{\infty} G(f)\,df}. \qquad \ldots\ldots(10)$$

Since the spectrum is an even function of f it follows that the functions $\rho(\tau)$, $r(\tau)$ and $d(\tau)$ must be even in τ. We shall refer to them collectively as 'dependence functions'; they measure the degree of order in the pulse sequence. For highly random systems the dependence functions achieve constant values after small values of τ of the order of the pulse duration or its average. For more ordered sequences the dependence functions have a quasiperiodic character and can even become periodic as $\tau\to\infty$. It is convenient to classify sequences as follows:

(i) Short-range order systems.

(ii) Random systems. $d(\tau)$ is the same function as for a single pulse; in particular, if the pulse duration is constant and equal to s_0, $d(\tau)=1$, $\tau>s_0$. It will be seen that this class is, strictly speaking, included in the first; however, random systems have special properties which justify our including them in a class of their own.

(iii) Long-range order systems. $\lim_{\tau \to \infty} d(\tau) \neq 1$. This includes dependence functions with a periodic component.

§ 3. ANALYSIS OF PULSE SEQUENCES BY A DIRECT METHOD

3.1. *Distribution of Periods*

The method which we shall use consists essentially of the replacement of the experimental time average by a suitable ensemble averaging procedure. Consider a 'snapshot' of a sequence of pulses of distributed period q and fixed duration s_0 (Fig. 1).

We let $q_1, q_2, \ldots q_r$ denote successive periods starting from an arbitrary pulse in the sequence and denote the partial sum of the first n periods by

$$Q_n = \sum_{r=1}^{n} q_r. \qquad \ldots\ldots(11)$$

For the moment we shall assume the sequence occupies a very long period of time T; the extension to sequences of finite length will be made later.

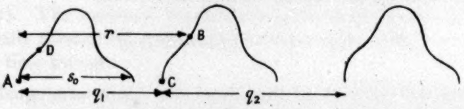

Fig. 1.

We now consider the process by means of which the autocovariance is obtained as a time average over the sequence. Such a time average is clearly a function of the q_r's; if, therefore, we can find an explicit expression for the autocovariance in terms of the q_r's the ensemble average of this expression will be equal to the experimentally determined time average.

Suppose that at some point in the averaging process $y^k(t)$ is at the point A in Fig. 1. We note that if the point $y^k(t+\tau)$ falls between the pulses the contribution to the autocovariance is zero. In general, a non-zero contribution to $y^k(t+\tau)$ can be made by the presence of any one of the other pulses, which may be superimposed and whose contributions can be considered separately. We denote by $A_0(\tau)$ the contribution to the autocovariance due to a single, isolated pulse; we note that this is even in τ and zero for $\tau > s_0$. The contribution of the first pulse to the autocovariance is clearly independent of q_1, and equal to $A_0(\tau)$. Correlation with the second pulse can take place if $\tau > q_1$; the position of $y^k(t+\tau)$ is denoted by B. It is clear that the contribution is unaltered if A is transferred to the point C, in which case the contribution to the autocovariance may be expressed in terms of $A_0(\tau)$, provided that τ is replaced by the stochastic variable $\tau - q_1$. We may therefore write

$$\text{Contribution} = A_0(\tau - q_1). \qquad \ldots\ldots(12)$$

As the point A is moved along the first pulse, a further possibility of correlation with the second pulse occurs if the condition $\tau < q_1 < \tau + s_0$ is satisfied; suppose that, as $y^k(t)$ reaches the point D, $y^k(t+\tau)$ is at C. The same contribution to the autocovariance will be obtained if C is transferred to A, and following the same argument as before all contributions to the autocovariance may be written

$$\text{Contribution} = A_0(|\tau - q_1|).$$

The contributions of other pulses receive similar treatment and we therefore obtain for all contributions arising from the position of $y^k(t)$ on the first pulse

$$A_0(\tau) + A_0(|q_1 - \tau|) + A_0(|q_1 + q_2 - \tau|) + \ldots = \sum_{n=0}^{\infty} A_0(|Q_n - \tau|) \quad \ldots\ldots (13)$$

where $Q_0 = 0$. In order to take the ensemble average over this we need the distribution function for the Q_r's. These can easily be obtained since the periods are independent; denoting the distribution functions for the q_1's by $u_1(q_1)$ we have

$$u_2(Q_2) = \int_0^\infty u_1(Q_2 - q_1) u_1(q_1)\, dq_1$$

$$\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot$$

$$u_n(Q_n) = \int_0^\infty u_{n-1}(Q_n - q_1) u_1(q_1)\, dq_1. \quad \ldots\ldots (14)$$

$$\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot$$

Finally taking the ensemble average over (13) the autocovariance becomes

$$\langle A^k(\tau) \rangle = \sum_{n=0}^{\infty} \int_0^\infty A_0(|Q_n - \tau|) u_n(Q_n)\, dQ_n. \quad \ldots\ldots (15)$$

We now consider the effect of moving $y^k(t)$ in turn over all pulses in the sequence. The contribution from all pulses will clearly be the same, and, assuming there are N pulses occupying an interval T, we obtain for the sequence

$$\begin{aligned} \langle A^k(\tau) \rangle &= \lim_{\substack{T \to \infty \\ N \to \infty}} \frac{1}{T} \left[N \sum_{n=0}^{\infty} \int_0^\infty A_0(|Q_n - \tau|) u_n(Q_n)\, dQ_n \right] \\ &= \frac{1}{q_0} \sum_{n=0}^{\infty} \int_0^\infty A_0(|Q_n - \tau|) u_n(Q_n)\, dQ_n \quad \ldots\ldots (16) \end{aligned}$$

where q_0 is the average period.

3.2. *Distribution of Intervals with Fixed Duration*

We now consider sequences which fall into the group (ii) category. We again denote the fixed duration by s_0 and take as the distributed quantity the intervals t_r. The partial sum of the first n intervals is denoted by

$$T_n = \sum_{r=1}^{n} t_r \quad \ldots\ldots (17)$$

and the interval distribution function by $v_1(t_1)$. The distribution function of the T_n's which we denote by $v_n(T_n)$, can again be obtained by a method identical with that used in obtaining the $u_n(Q_n)$, Eqn (14); the autocovariance becomes, proceeding exactly in as the previous section,

$$\langle A^k(\tau)\rangle = \frac{1}{q_0}A_0(\tau) + \sum_{n=1}^{\infty}\frac{1}{q_0}\left[\int_0^{\tau-(n-1)s_0} A_0[\tau - T_{n-1} - (n-1)s_0]v_{n-1}(T_{n-1})\,dT_{n-1}\right.$$
$$+ \int_{\tau-(n-1)s_0}^{\tau-(n-2)s_0} A_0[(n-1)s_0 + T_{n-1} - \tau]v_{n-1}(T_{n-1})\,dT_{n-1}$$
$$\left. + \int_0^{\tau-(n-1)s_0} A_0[ns_0 + T_n - \tau]v_n(T_n)\,dT_n\right] \qquad \ldots\ldots(18)$$

where $(n-1)s_0 < \tau < ns_0$.

3.3. *Distribution of Intervals and Durations*

We now consider the case in which the durations are allowed to assume randomly distributed values s_r, the intervals t_r also being randomly distributed. The partial sum of the first n durations is denoted by

$$S_n = \sum_{r=1}^{n} s_r$$

and let $w_n(S_n)$ denote the corresponding distribution function; this may be obtained from $w_1(s_1)$ by equations similar to (14). Proceeding as before, we obtain

$$\langle A^k(\tau)\rangle = \sum_{n=0}^{\infty}\frac{1}{q_0}\int_0^{\infty} w(S_n)\left[\int_0^{\infty} A_0(|S_n + T_n - \tau|)v_n(T_n)\,dT_n\right]dS_n. \qquad \ldots\ldots(19)$$

§ 4. THE SPECTRUM OF A SEQUENCE OF STOCHASTIC PULSES

4.1. *Distribution of Period*

As in the direct method we consider a snapshot of the system with periods q_r where the q_r's are distributed independently of one another with distribution $u_1(q_1)$. We let

$$F_0(f) = \int_{-\infty}^{\infty} e^{-2\pi i f t} f_0(t)\,dt$$

be the Fourier transform of the pulse shape, centred at an arbitrary origin. A pulse removed q_1 to the right of the first then has the transform

$$F_1(f) = \exp(-2\pi i f q_1)F_0(f).$$

Considering a train consisting of N pulses we have for the Fourier transform of $y^k(t)$ multiplied by its complex conjugate

$$|Y^k(f)|^2 = |F_0(f)|^2[1 + \exp(-2\pi i f Q_1) + \exp(-2\pi i f Q_2) + \ldots]$$
$$\times [1 + \exp(2\pi i f Q_1) + \exp(2\pi i f Q_2) + \ldots].$$

It will be noted that if all the periods have the same distribution and are distributed independently of one another, the statistical properties of an expression containing as a variable the sum of a number of such periods is determined solely by the number of such periods in the sum; that is, the statistical properties of $q_1 + q_2 + q_3$ (say) are identical with those of $q_2 + q_3 + q_5$.

The power spectrum of a finite sequence of average length T_0 will be defined by the expression

$$G^k(f) = \frac{1}{T_0}|Y^k(f)|^2.$$

In our case $T_0 = Nq_0$. We then obtain

$$\langle G^k(f)\rangle = \frac{1}{Nq_0}|F_0(f)|^2\Bigl[N + \sum_{n=1}^{N}(N-n)\int_0^\infty u_n(Q_n) \times [\exp(2\pi ifQ_n) + \exp(-2\pi ifQ_n)]\,dQ_n\Bigr]. \quad \ldots\ldots(20)$$

In order to evaluate this expression we define the characteristic function of the distribution by

$$U(f) = \int_0^\infty \exp(2\pi ifq_1)u_1(q_1)\,dq_1.$$

Applying the 'faltung theorem' to Eqn (14) we have

$$\int_0^\infty \exp(2\pi ifQ_n)u_n(Q_n)\,dQ_n = U^n(f).$$

Eqn (20) may therefore be written

$$\begin{aligned}\langle G^k(f)\rangle &= \frac{|F_0(f)|^2}{Nq_0}\Bigl[N + \sum_{n=1}^{N}(N-n)(U^n(f) + U^n(f)^*)\Bigr]\\ &= \frac{|F_0(f)|^2}{Nq_0}\Bigl[N + NU(f)\frac{(1-U^N(f))}{1-U(f)} - U(f)\frac{(1-U^N(f))}{(1-U(f)^2)} - \frac{NU^{N+1}(f)}{1-U(f)}\\ &\quad + NU(f)^*\frac{(1-U^N(f)^*)}{1-U(f)^*} - U(f)^*\frac{(1-U^N(f)^*)}{(1-U(f)^*)^2} - \frac{NU^{N+1}(f)^*}{1-U(f)}\Bigr].\end{aligned} \quad \ldots\ldots(21)$$

We emphasize that this is a perfectly general equation for the spectrum of a finite sequence of pulses of arbitrary shape with an arbitrary distribution of intervals. For an infinite sequence the limit of Eqn (21) as $N\to\infty$ has to be considered; for this purpose the behaviour of functions such as $U^N(f)$ as $N\to\infty$ has to be known. We obtain this asymptotic value by applying the central limit theorem which tells us that

$$\lim_{F\to\infty} u_n(Q_n) = \frac{1}{(2\pi N\sigma^2)^{1/2}}\exp\Bigl[-\frac{(Q_n - NM_1)^2}{2N\sigma^2}\Bigr]$$

where $M_1 = \langle q\rangle$ and $\sigma^2 = \langle q^2\rangle - \langle q\rangle^2$. Taking Fourier transforms of both sides we obtain

$$\lim_{N\to\infty} U^N(f) = \exp(2\pi ifNM_1)\exp(-2\pi^2\sigma^2f^2N). \quad \ldots\ldots(22)$$

This shows that expressions multiplied by all such terms in Eqn (21) tend to zero as $N\to\infty$. We finally obtain

$$\lim_{N\to\infty}\langle G^k(f)\rangle = \frac{|F_0(f)|^2}{q_0}\Bigl[1 + \frac{U(f)}{1-U(f)} + \frac{U(f)^*}{1-U(f)^*}\Bigr]. \quad \ldots\ldots(23)$$

4.2. *Distribution of Intervals with Fixed Duration*

Following the same procedure as in the previous section we obtain for the transform of the $(n+1)$th pulse

$$F_{n+1}(f) = \exp[-2\pi if(ns_0 + T_n)]F_0(f).$$

Denoting the characteristic function of the interval distribution by $V(f)$ we obtain $V^n(f)$ for the characteristic function of the distribution $v_n(T_n)$. The spectrum then becomes

$$\langle G^k(f)\rangle = \frac{1}{Nq_0}|F_0(f)|^2\Big[N+\sum_{n=1}^{N}(N-n)$$
$$\times\{\exp(2\pi ifns_0)V^n(f)+\exp(-2\pi ifns_0)V^n(f)^*\}\Big]. \quad\ldots\ldots(24)$$

As before, the series can be summed to give

$$\langle G^k(f)\rangle = \frac{1}{Nq_0}|F_0(f)|^2\Big[N+N\exp(2\pi ifs_0)\frac{V(f)[1-\exp(2\pi ifNs_0)V^N(f)]}{1-\exp(2\pi ifs_0)V(f)}$$
$$-\exp(2\pi ifs_0)\frac{V(f)[1-\exp(2\pi ifNs_0)V^N(f)]}{[1-\exp(2\pi ifs_0)V(f)]^2}$$
$$-\frac{N\exp[2\pi if(N+1)s_0]\,V^{N+1}(f)}{1-\exp(2\pi ifs_0)V(f)}$$
$$+N\exp(-2\pi ifs_0)\frac{V^*(f)[1-\exp(-2\pi ifNs_0)V^N(f)^*]}{1-\exp(-2\pi ifs_0)V(f)^*}$$
$$-\exp(-2\pi ifs_0)\frac{V(f)^*[1-\exp(-2\pi ifNs_0)V(f)^*]}{[1-\exp(-2\pi ifs_0)V(f)^*]^2}$$
$$-\frac{N\exp(-2\pi if(N+1)s_0)V^{N+1}(f)^*}{1-\exp(-2\pi ifs_0)V(f)^*}\Big]. \quad\ldots\ldots(25)$$

For the spectrum of an infinite sequence the limit of this expression as $N\to\infty$ must again be considered. The remarks in § 4.1 relating to the central limit theorem again apply and we obtain

$$\lim_{N\to\infty}\langle G^k(f)\rangle = \frac{|F_0(f)|^2}{q_0}\Big[1+\frac{\exp(2\pi ifs_0)V(f)}{1-\exp(2\pi ifs_0)V(f)}$$
$$+\frac{\exp(-2\pi ifs_0)V(f)^*}{1-\exp(-2\pi ifs_0)V(f)^*}\Big]. \quad\ldots\ldots(26)$$

4.3. *Distribution of Intervals and Durations*

We denote the (distributed) duration of the first pulse by s. The averaging procedure can now only be carried out over the intervals, since the transform of the pulse shape now depends on the duration. We then obtain

$$\langle G^k(f)\rangle = \frac{1}{Nq_0}\int_0^\infty |F_0(f,s)|^2\Big[N+\sum_{n=1}^{N}(N-n)[\exp(2\pi ifS_n)V^n(f)$$
$$+\exp(-2\pi ifS_n)V^n(f)^*]\Big]w(S_n)\,dS_n. \quad\ldots\ldots(27)$$

The expression cannot be further simplified without making further assumptions as to the form of $F_0(f,s)$; an example where this is done is considered in § 6.4.

4.4. *Discussion of Results Obtained for the Spectrum*

The results of §§ 4.1–4.3 enable the spectrum to be calculated if either the distribution of periods, or the distribution of intervals and durations, is known.

By the inversion theorems, Eqns (9) and (10), the dependence functions can be calculated from the spectrum and for infinite sequences the results obtained should agree with those obtained by the direct method, §3. We first show that this is indeed the case, and then proceed to consider what deductions can be made from the spectrum about the form of the dependence functions.

Considering first the case of a distribution of period, Eqn (23) may be written in the form

$$\langle G^k(f)\rangle = \frac{|F_0(f)|^2}{q_0}\left[1+\sum_{n=1}^{\infty}[U^n(f)+U^n(f)^*]\right].$$

We note that

$$\int_{-\infty}^{\infty}|F_0(f)|^2\cos 2\pi f\tau\, df = A_0(\tau),$$

$$\int_{-\infty}^{\infty}[U^n(f)+U^n(f)^*]\cos 2\pi f\tau\, df = u_n(\tau).$$

Applying the faltung theorem to the inversion of the product we immediately obtain

$$\frac{1}{q_0}\int_{-\infty}^{\infty}\cos 2\pi f\tau|F_0(f)|^2[U^n(f)+U^n(f)^*]\, df = \frac{1}{q_0}\int_{0}^{\infty}A_0|Q_n-\tau|u_n(Q_n)\, dQ_n.$$

When both sides are summed over n this is in exact agreement with Eqn (16). Consideration of the case of group (ii) and group (iii) sequences proceeds similarly and there is, therefore, exact agreement between the results for the dependence functions obtained by both methods.

Recalling the classification of pulse systems (§2) it is clear that the presence of long-range order in a sequence is determined by periodic terms in the dependence functions. Such periodic terms in turn correspond to delta function terms of the form $\delta(f-f_0)$ in the spectrum. We therefore consider whether it is possible for such terms to be present in the spectra of any of the systems hitherto examined. Consideration of Eqn (25) shows that factors of the type $\exp(2\pi ifNM_1)$ are indeed present in the spectrum; as $N\rightarrow\infty$ such terms show delta function behaviour. However, our application of the central limit theorem shows that as $N\rightarrow\infty$ all such terms are multiplied by factors which go to zero as e^{-N} and therefore remove the rapidly oscillating terms from the spectrum. Similar considerations apply to group (ii) systems. Any system which has a distribution of durations as well is less ordered than a system with fixed durations and we can therefore say quite generally that a system with a distribution of periods, or of intervals and durations, of any kind whatever cannot give rise to long-range order.

Considering next the more general question of the degree of dependence between the pulses it is clear that if the system is to be random the spectrum must have the same shape as that of a single pulse. The probability factor must therefore be equal to a constant; this leads to the equation

$$\frac{U(f)}{1-U(f)}+\frac{U(f)^*}{1-U(f)^*}=\text{constant} \qquad \ldots\ldots(28)$$

for the case of a distribution of periods and to the equation

$$\frac{\exp(2\pi ifs_0)V(f)}{1-\exp(2\pi ifs_0)V(f)}+\frac{\exp(-2\pi ifs_0)V(f)^*}{1-\exp(-2\pi ifs_0)V(f)^*}=\text{constant} \qquad \ldots\ldots(29)$$

for the case of a group (ii) sequence. We shall show in the next section that Eqn (28) is satisfied for the particular case of an exponential distribution of periods, the value of the constant being in this case zero, so that our method yields Carson's theorem as a particular case. However, the general character of Eqns (28) and (29) shows that a spectrum of the form predicted by Carson's theorem by no means implies that the distribution of periods is exponential; on the contrary, there is an infinity of distributions which satisfy Eqns (28) and (29) all of which give rise to the same spectrum.

Considering next the more general case in which the probability factor is a function of the frequency, inspection of the effect of Fourier inversion shows that such spectra give rise to non-random short-range order systems, that is, the dependence functions show variation with τ for $\tau > s_0$. Further prediction of the shape of the dependence functions is not easy and in some cases at least these are determined by the values of the parameters used in the distribution functions as well as by the distribution functions themselves.

§ 5. RANDOMIZED PERIODIC SYSTEMS

We define a randomized periodic system to be one which can be represented by an ensemble of systems such that each member of the ensemble is periodic. It will be assumed that the distribution of periods is known.

If the kth member of the ensemble has period q_k that particular member can be represented by a Fourier series

$$y^k(t) = \sum_{n=-\infty}^{\infty} a_{kn} \exp\left(\frac{2\pi i n t}{q_k}\right)$$

where

$$a_{kn} = \frac{1}{q_k}\int_0^{q_k} f_0(t) \exp\left(-\frac{2\pi i n t}{q_k}\right) dt. \qquad \ldots\ldots(30)$$

Each pulse clearly contributes equally to the dependence functions so that

$$A^k(\tau) = \lim_{T\to\infty} \frac{1}{T}\int_0^T y^k(t) y^k(t+\tau)\, dt = \frac{1}{q_k}\int_0^{q_k} y^k(t) y^k(t+\tau)\, dt.$$

All other averages are similarly modified by being taken over one period. The autocovariance becomes

$$A^k(\tau) = \frac{1}{q_k}\int_0^{q_k} \sum_{n=-\infty}^{\infty}\sum_{m=-\infty}^{\infty} a_{kn} a_{km} \exp\left(\frac{2\pi i (n+m) t}{q_k}\right) \exp\left(\frac{2\pi i n \tau}{q_k}\right) dt.$$

The integrals have the value zero unless $n = -m$, in which case they take the value $a_{nk} a_{-nk} \exp(2\pi i n \tau / q_k)$. We thus obtain

$$A^k(\tau) = \sum_{-\infty}^{\infty} a_{nk} a_{-nk} \exp\left(\frac{2\pi i n \tau}{q_k}\right) = |a_0|^2 + 2\sum_{1}^{\infty} |a_{nk}|^2 \cos\left(\frac{2\pi n \tau}{q_k}\right). \qquad \ldots\ldots(31)$$

For the correlation function we have

$$\rho^k(\tau) = \frac{|a_0|^2 + 2\sum_1^{\infty} |a_{nk}|^2 \cos 2\pi n \tau / q_k}{|a_0|^2 + \sum_1^{\infty} |a_{nk}|^2} \qquad \ldots\ldots(32)$$

and for the after-effect function, using Eqn (6)

$$d^k(\tau) = \frac{2\sum_1^{\infty} |a_{nk}|^2 \sin^2 \pi n \tau / q_k}{\sum_1^{\infty} |a_{nk}|^2}. \qquad \ldots\ldots(33)$$

These equations may be used as they stand for periodic systems, the suffix k being in this case of course unnecessary. For randomized periodic systems the average over the period q_k has to be taken, so that we obtain for the autocovariance

$$\langle A^k(\tau)\rangle = \int_0^\infty \left[|a_0|^2 + 2\sum_1^\infty |a_{nk}|^2 \cos\frac{2\pi n\tau}{q_k}\right] u(q_k)\, dq_k$$

with similar expressions for the other functions.

§ 6. CONSIDERATION OF PARTICULAR CASES

We now consider the application of the general equations of the previous sections to the computation of the dependence functions of some typical systems. For the sake of uniformity the after-effect function has been plotted in all cases and the square pulse has been used as the pulse shape throughout; further, the discussion is confined to infinite sequences.

6.1. *Random Systems*

As has been mentioned in § 1, Carson has considered the spectrum of an infinite sequence of pulses of fixed shape, the number of pulses in a given interval of time being given by a Poisson distribution. This corresponds to a distribution of periods which is exponential,

$$u(q) = \frac{1}{q_0}\exp\left(-\frac{q}{q_0}\right). \qquad \ldots\ldots(34)$$

Eqn (23) should therefore yield Carson's theorem as a particular case. The characteristic function of the distribution is given by

$$U(f) = \int_{-\infty}^{\infty} (1/q_0)\exp\left(-\frac{q}{q_0}\right)\exp(2\pi i f q)\, dq = \frac{\beta}{\beta - 2\pi i f} \qquad \ldots\ldots(35)$$

where $\beta = q_0^{-1}$. Substituting into Eqn (22) we have

$$\langle G^k(f)\rangle = \frac{|F_0(f)|^2}{q_0}\left[1 + 2\mathscr{R}\left(-\frac{\beta}{2\pi i f}\right)\right] = \frac{|F_0(f)|^2}{q_0} \qquad \ldots\ldots(36)$$

which is just Carson's result. More specifically, we now take for $f_0(t)$ the square pulse defined by

$$\begin{aligned} f_0(t) &= h \qquad |t| < \tfrac{1}{2}s_0 \\ &= 0 \qquad |t| > \tfrac{1}{2}s_0. \end{aligned} \qquad \ldots\ldots(37)$$

Then

$$\begin{aligned} F_0(f) &= \int_{-\infty}^{\infty} f_0(t)\exp(2\pi i f t)\, dt \\ &= \frac{h \sin \pi f s_0}{\pi f} \end{aligned}$$

and

$$\langle G^k(f)\rangle = \frac{h^2}{q_0}\,\frac{\sin^2 \pi f s_0}{\pi^2 f^2}.$$

Substituting into Eqn (10) we obtain for the after-effect function

$$\begin{aligned} d(\tau) &= \frac{\tau}{s_0} \qquad \tau < s_0 \\ &= 1 \qquad \tau > s_0. \end{aligned}$$

In this and in all other cases, the other dependence function can be obtained from Eqn (6). This example illustrates very simply the fact that the shape of the dependence functions is determined solely by that of the isolated pulse and that for $\tau > s_0$ they assume their final, constant, values.

6.2. *Gamma Distribution of Order* 2

It was shown in § 6.1 that an exponential distribution of periods yields a probability factor of unity. We now consider a related distribution of periods designed to give a frequency dependent probability factor.

The 'gamma distribution of order n' is defined by

$$u(q, u) = \frac{\beta^n q^{n-1}}{n!} e^{-\beta q}.$$

The characteristic function is given by

$$U(n, f) = \int_0^\infty \exp(2\pi i f q) \frac{\beta^n q^{n-1}}{n!} e^{-\beta q} \, dq = \frac{\beta^n}{(\beta - 2\pi i f)^n}.$$

The average period q_0 is given by

$$\lim_{f \to 0} \frac{1}{2\pi i} \frac{d}{df} \left[\frac{\beta^n}{(\beta - 2\pi i f)^n} \right] = n\beta^{-1}.$$

For the case of an infinite sequence we obtain for the spectrum, using Eqn (23)

$$\langle G^k(f) \rangle = \frac{\beta}{n} |F_0(f)|^2 \left[1 + \frac{\beta^n}{(\beta - 2\pi i f)^n} \left(\frac{1}{1 - \beta^n/(\beta - 2\pi i f)^n} \right) + \frac{\beta^n}{(\beta + 2\pi i f)^n} \left(\frac{1}{1 - \beta^n/(\beta + 2\pi i f)^n} \right) \right]. \qquad \ldots\ldots (38)$$

For the particular case of $n = 1$ we again obtain the exponential distribution of the previous chapter. In order to obtain a probability factor which is frequency dependent we now choose $n = 2$ and for the pulse shape again take the square pulse defined by Eqn (37). We obtain

$$\langle G^k(f) \rangle = \frac{h^2 \beta}{2} \frac{\sin^2 \pi f s_0}{\pi^2 f^2} \left[1 - \frac{2\beta^2}{4\pi^2 f^2 + (2\beta)^2} \right]. \qquad \ldots\ldots (39)$$

Using Eqn (10) we obtain for the after-effect function

$$\begin{aligned} d(\tau) &= \frac{1 - \exp(-2\beta s_0) + 2\beta\tau - \exp(-2\beta\tau) + \exp(-2\beta s_0) \cosh 2\beta\tau}{1 - \exp(-2\beta s_0) + 2\beta s_0} & \tau < s_0, \\ &= \frac{1 - \exp(-2\beta s_0) + 2\beta s_0 - \exp(-2\beta\tau) + \exp(-2\beta\tau) \cosh 2\beta s_0}{1 - \exp(-2\beta s_0) + 2\beta s_0} & \tau > s_0. \end{aligned}$$
$$\ldots\ldots (40)$$

General points which may be noted about these results are that the shape of the dependence functions for $\tau < s_0$ is not determined solely by the pulse shape (cf. the results of § 6.1) and that the dependence functions vary monotonically for $\tau > s_0$. The after-effect function is plotted in Fig. 2 according to Eqn (40) for various values of the parameter 2β.

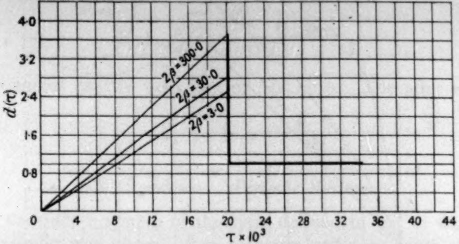

Fig. 2. The after-effect function plotted according to Eqn (40). $s_0 = 0{\cdot}02$.

6.3. *Fixed Duration and Random Distribution of Intervals*

The spectrum of a sequence consisting of pulses of fixed duration and arbitrary distribution of intervals is given by Eqn (26). For the interval distribution we again take the exponential distribution of Eqn (24) with characteristic function given by Eqn (35). We obtain, after some reduction,

$$\langle G^k(f)\rangle = \frac{|F_0(f)|^2}{q_0}\left[1+\frac{\beta\cos 2\pi f s_0 - 2\pi f\sin 2\pi f s_0 - \beta}{\beta + 2\pi^2 f^2\beta^{-1} - \beta\cos 2\pi f s_0 + 2\pi f \sin 2\pi f s_0}\right]. \quad \ldots\ldots (41)$$

Inversion of this expression is not particularly easy. This is due to the fact that a given value of τ automatically sets a limit to the number of pulses which can contribute to the dependence functions; thus for $0 < \tau < s_0$ only two pulses need be considered. Since the particular point of the spectrum method is that it gives in closed form the contribution of all the pulses it is apparent that the advantage of using the spectral method is lost in the present example. We therefore turn our attention to the direct method. The autocovariance for the case we are considering is given by Eqn (18), where

$$\begin{aligned} A_0(\tau) &= h(s_0-\tau) \qquad \tau < s_0 \\ &= 0 \qquad \tau > s_0 \end{aligned}$$

$$u_n(T_n) = \frac{\beta^n T_n{}^{n-1}}{(n-1)!}\exp(-\beta T_n).$$

Substituting into Eqn (18) and using Eqn (6) we obtain

$$\begin{aligned} d(\tau) &= \frac{s_0+\beta^{-1}}{s_0}(1-\mathrm{e}^{-\beta\tau}) \qquad 0<\tau<s_0 \\ &= \frac{s_0+\beta^{-1}}{s_0}(1-\mathrm{e}^{-\beta\tau}) - \frac{(s_0+\beta^{-1})}{s_0\beta^{-1}}(\tau-s_0)\exp[-\beta(\tau-s_0)] \qquad s_0<\tau<2s_0. \end{aligned} \quad \ldots\ldots (42)$$

This function is plotted in Fig. 3. Unlike the cases considered, these do indeed show a quasiperiodic character. The extent to which this quasiperiodic character is maintained clearly depends on the value of $s_0\beta$. If this is large, only a small contribution comes from the random part of the sequence. Curve (1) illustrates this case for the value $\beta s_0 = 10$. Curve (3) illustrates the opposite case where the ratio βs_0 is small (equal to $0{\cdot}1$) so that the after-effect function has a highly random character. Finally, curve (2) represents the intermediate case in which the value of βs_0 is of the order of unity.

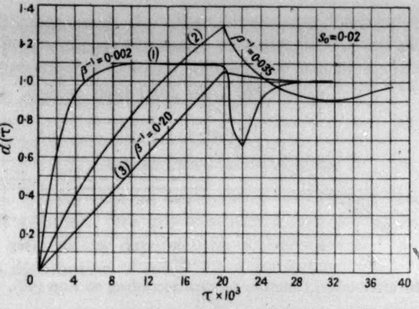

Fig. 3. The after-effect function plotted according to Eqn (42). $s_0 = 0{\cdot}02$.

6.4. *Distribution of Intervals and Durations*

As a final example of distribution of intervals and durations we take the case considered by Machlup (1954): Machlup considers the fluctuations of current in a semiconductor due to trapping and suggests that the current can, under certain conditions, be considered to consist of a sequence of square pulses of random interval and duration, the distribution of durations and intervals being given by the exponential distribution of Eqn (34) with mean values q_0 which are the mean lifetimes of the respective states. For the particular pulse shape and distribution considered it is then possible to write an equation for the number of pulses per unit time from which the autocovariance and spectrum can be derived. Although our method is perfectly general we consider the same problem for comparison.

We take

$$v(t_1) = \beta \exp(-\beta t_1), \qquad w(s_1) = \gamma \exp(-\gamma s_1).$$

Substituting into Eqn (26) we then have for the spectrum

$$\langle G^k(f)\rangle = \frac{h^2}{q_0}\int_0^\infty \frac{\sin^2 \pi f s}{\pi^2 f^2}\left[1 + \sum_1^\infty \left(\frac{\beta^n \exp(2\pi i f S_n)}{(\beta - 2\pi i f)^n} + \frac{\beta^n \exp(-2\pi i f S_n)}{(\beta + 2\pi i f)^n}\right)\right] w(S_n)\, dS_n. \qquad \ldots\ldots (43)$$

Writing the pulse shape in terms of exponentials allows the integrations to be carried out and the resulting series may then be summed. We then obtain

$$\langle G^k(f)\rangle = \frac{h^2}{q_0}\int_0^\infty \frac{\sin^2 \pi f s}{\pi^2 f^2}\gamma e^{-\gamma s}\, ds + \frac{h^2}{2\pi^2 f^2 q_0}\left[-\frac{4\pi^2 f^2 \beta}{2\gamma(\gamma - 2\pi i f)(2\pi i f[\beta+\gamma] + 4\pi^2 f^2)} + \frac{4\pi^2 f^2 \beta}{2\gamma(\gamma + 2\pi i f)(+2\pi i f[\beta+\gamma] - 4\pi^2 f^2)}\right].$$

Finally the spectrum becomes

$$\langle G^k(f)\rangle = \frac{2h^2}{q_0}\left[\frac{1}{(\beta+\gamma)^2 + 4\pi^2 f^2}\right]; \qquad \ldots\ldots (44)$$

q_0 is given by

$$q_0 = \lim_{f\to 0} \frac{1}{2\pi i}\left(\frac{\beta}{\beta + 2\pi i f}\right)\left(\frac{\gamma}{\gamma + 2\pi i f}\right) = \beta^{-1} + \gamma^{-1}.$$

From Eqn (9) we then obtain for the autocovariance

$$A(\tau)=\frac{\gamma^{-1}\beta^{-1}}{(\gamma^{-1}+\beta^{-1})^2}\,e^{-(\beta+\gamma)\tau} \qquad \ldots\ldots(45)$$

a result which agrees exactly with that of Machlup. The after-effect function is given by

$$d(\tau)=1-e^{-(\beta+\gamma)\tau}. \qquad \ldots\ldots(46)$$

6.5. *Randomized Periodic Systems*

We finally consider a system of the type defined in §5, to which the name randomized periodic was given. For a square pulse we obtain, substituting into Eqn (30)

$$a_{kn}=\frac{h}{\pi n}\,\frac{\sin \pi n s_0}{\pi f}.$$

As an example we take the distribution of periods given by Eqn (34). In averaging over Eqn (31) there occur integrals of the type

$$\int_0^\infty \beta \exp(-\beta q_k)\cos\frac{(2\pi n s_0)}{q_k}\,dq_k.$$

Putting $g=q_k{}^{-1}$ we obtain

$$\int_0^\infty \beta \exp(-\beta q_k)\cos\left(\frac{2\pi n s_0}{q_k}\right)dq_k=\int_0^\infty \beta e^{-\beta/g}\cos(2\pi g n s_0)\frac{dg}{g^2}$$
$$=\left(\frac{2\pi n s_0}{q_0}\right)^{1/2}\left[i^{1/2}K_1\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}+i^{-1/2}K_1\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}\right]$$

where $\beta^{-1}=q_0$ and $K_1(x)$ is the modified Bessel function of the second kind. Introducing the Kelvin functions $\mathrm{ker}_1(x)$ and $\mathrm{kei}_1(x)$ the right-hand side may be written

$$-\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}\mathrm{ker}_0'\left(\frac{8\pi n s_0}{q_0}\right)^{1/2} \quad \text{where} \quad \mathrm{ker}_0'(x)=\frac{d}{dx}[\mathrm{ker}_0(x)].$$

Finally we substitute into Eqn (33) and obtain

$$d(\tau)=\sum_1^\infty \frac{2h^2}{\pi^2 n^2}\left\{1+\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}\mathrm{ker}_0'\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}+\left(\frac{8\pi n \tau}{q_0}\right)^{1/2}\mathrm{ker}_0'\left(\frac{8\pi n \tau}{q_0}\right)^{1/2}\right.$$
$$\left.-\tfrac{1}{2}\left[\frac{8\pi n}{q_0}(s_0+\tau)\right]^{1/2}\mathrm{ker}_0'\left[\frac{8\pi n}{q_0}(s_0+\tau)\right]-\tfrac{1}{2}\left[\frac{8\pi n}{q_0}|s_0-\tau|\right]^{1/2}\mathrm{ker}_0'\left[\frac{8\pi n}{q_0}|s-\tau|\right]^{1/2}\right\}$$
$$\times\left\{\sum_1^\infty \frac{2h^2}{\pi^2 n^2}\left[1+\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}\mathrm{ker}_0'\left(\frac{8\pi n s_0}{q_0}\right)^{1/2}\right]\right\}^{-1}. \qquad \ldots\ldots(47)$$

Examination of the order of magnitude of the various terms for different values of n shows that owing to the factor of n^{-2} terms for $n>1$ make very small contributions. We therefore obtain a good approximation by taking only the first term of the series in the numerator and denominator of Eqn (47). The results for various values of the parameter s_0/q_0 are plotted in Fig. 4. As might be expected, the curves have a quasiperiodic character, the pulse duration being given by the first maximum of the curves.

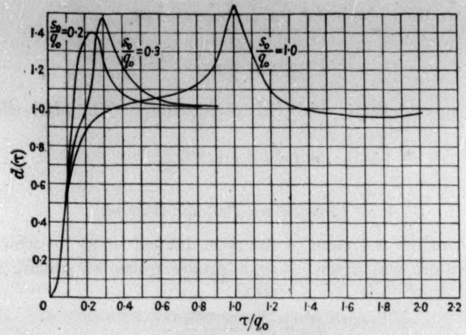

Fig. 4. The after-effect function plotted according to Eqn (47).

§ 7. CONCLUSION

Our results show that it is possible to derive the statistical properties of pulse sequences under a considerably wider range of conditions than those which have hitherto been considered. As far as the computation of the dependence functions is concerned the direct method and the spectrum method give identical results, the use of either being a matter of convenience. The most general conclusion which may be found from these results is that it is impossible for any of the pulse sequences considered to exhibit long-range order.

ACKNOWLEDGMENTS

I wish to thank Dr. R. Fürth for his interest and encouragement during the course of this work. I am indebted to the Mathematics Department, Northampton College of Advanced Technology, London, for the use of a Pegasus Computer.

Elastic Recovery of Conical Indentations

By N. A. STILWELL and D. TABOR
Physics and Chemistry of Solids, Cavendish Laboratory, Cambridge

MS. received 16*th February* 1961

Abstract. This paper discusses the changes in shape which occur when a hard conical indenter is pressed into a metal (to form a plastic indentation) and then withdrawn. It is shown that there is little change in the diameter of the indentation during withdrawal but a decrease in its depth. This may be expressed analytically in terms of the elastic constants of the metal and there is reasonable agreement between the theoretical and observed changes in depth. The elastic energy released when the indenter is withdrawn may be calculated and it is shown that this accounts quantitatively for the elastic rebound observed when a conical indenter strikes an elasto-plastic metal. The analysis is also applied to the experimental results given by Davis and Hunter in 1959.

§ 1. INTRODUCTION

In an earlier paper it was shown that when a spherical indenter is pressed into a plastic material to form an indentation and the load then removed, elastic recovery of the indentation and the indenter occur. The changes in shape could be described in terms of Hertz's equation for the elastic deformation of spherical surfaces. Further it was shown in impact experiments that the energy involved in this elastic recovery could account quantitatively for the observed rebound. The present paper describes a similar investigation using conical indenters.

§ 2. STATIC INDENTATION AND ELASTIC RECOVERY

2.1. *Materials*

Two cones were kindly lent to us by Dr. C. D. Davies of Fort Halstead. They were of tungsten carbide of semi-apical angle 68° and 45° and had a small curved tip. In the experiments to be described the indentations were always made large compared with the dimensions of the tip.

Experiments were carried out with various metals in the form of parallel-sided blocks. The faces to be indented were finely abraded and the specimens and the indenter incorporated in a Hounsfield tensometer modified to operate in compression. After a specified load had been applied the load was reduced in decrements. A sensitive dial gauge was attached to the indenter and arranged so that its sensory end rested on the free surface of the specimen a short distance from the indentation. In this way the total elastic recovery of the indentation and indenter was determined as the load was removed. The parasitic elastic distortions in the dial gauge were estimated to be about $0{\cdot}4 \times 10^{-3}$ cm. This is between 3 and 6% of the total recovery observed.

2.2. *The Change in Shape*

Davis and Hunter have suggested that when a hard conical indenter is withdrawn from a plastically formed indentation the elastic recovery is as shown in Fig. 1, i.e. the indentation retains its geometric shape and contracts both in depth and in diameter. Thus if the depth recovery is Y the diameter diminishes by an amount $2Y \cot \phi$ where ϕ is the semi-angle of the cone.

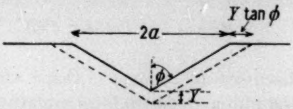

Fig. 1. Elastic recovery of a conical indentation if it retains its geometric shape. If the decrease in depth is Y the diminution in diameter is $2Y \cot \phi$.

To test the validity of this assumption two simple measurements were made: (*a*) the depth recovery was measured as described above, (*b*) the change in diameter was determined as follows. A thin layer of soot was deposited on the cone and slightly wetted with a mineral oil. This gives it a fine coherent texture (Eldredge 1950). When the indenter is pressed into the metal the soot is heavily compressed, wherever it comes in contact with the indentation. On removing the indenter a clearly marked line of demarcation is visible between the disturbed and undisturbed soot. The diameter is a reasonably reliable measure of the size of the indentation as it was formed. The recovered diameter $2a$ is measured directly. The results obtained are given in Table 1.

Table 1. Changes in Depth Y and in Chordal Diameters of Indentations

(1)	(2)	(3)	(4)
68° cone			
Dural	11·3	56·1	2·0
Mild steel	6·8	33·7	2·0
Roller steel	11·3	56·1	0
45° cone			
Dural	12·2	24·4	2·0
Mild steel	8·15	16·3	3·0
Roller steel	12·2	24·4	0
Magnesium	13·2	26·4	4·0

(1) Metal specimen; (2) height of elastic recovery observed $Y(10^{-3}$ cm); (3), (4) contraction of diameter of indentation (10^{-3} cm): (3) according to Davis and Hunter, $2Y \cot \phi$, (4) observed.

It is seen that although there is an appreciable recovery in depth there is practically *no* change in diameter of the indentation. This was also found in the earlier work with spherical indenters. Fig. 2 (Plate) shows a cross section of a recovered indentation with the indenter lying within it. It is seen that the recovered indentation is conical with an almost straight boundary: its apical angle is slightly greater than that of the indenter.

2.3. *Cyclic Loading Experiments*

Experiments were carried out in which after the main load was applied the load was reduced and increased cyclically from its original value to zero. The total elastic recovery is plotted in Fig. 3 for the 68° cone on a Dural alloy. It is seen that there is a difference in the increasing and decreasing part of the cycle. This is due to slight creep during the repeated application of the load. After several cycles the loop becomes very narrow and the curves are very close. It is evident that, at this stage, the deformation on loading and unloading is essentially elastic. It is also seen that the variation of depth Y with load W is roughly parabolic.

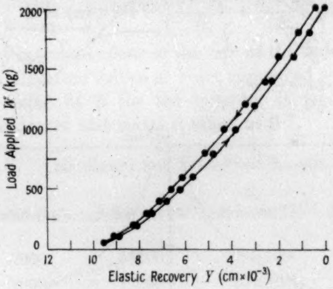

Fig. 3. Conical indenter on duralumin. Change in depth Y as load W is removed and then re-applied. Maximum load 2000 kg; semi-apical angle of cone 68°. After a few cycles the loop becomes very narrow and variation of Y with W is roughly parabolic.

2.4. *Calculation of Elastic Recovery*

It is simplest to consider the elastic deformation of the recovered indentation when the load is re-applied. We assume that the recovered indentation is a right circular cone as shown in Fig. 4 (*a*) and that the free surface of the specimen is flat. We assume that the pressure distribution is such that when the conical indentation is deformed by the conical indenter the resulting contour is also conical with the same apical angle as the cone. We do not need to derive an original solution of this problem since we may use Boussinesq's solution (see Love 1939) for the deformation of a flat surface by a rigid cone of apical angle 2ϕ, see Fig. 4 (*b*).

The pressure distribution over the contact region is not uniform; indeed at the centre, for a geometrically perfect cone it approaches infinity (see Fig. 4 (*c*)). However the mean pressure p over the contact region has a finite value and is given by

$$p = \frac{E_1 \cot \phi}{2(1-\nu_1^2)} \qquad \ldots\ldots (1)$$

where E_1, ν_1 are Young's modulus and Poisson's ratio respectively of the specimen. It should be noticed that p depends only on ϕ and not on the size of the indentation. Thus as the cone is loaded on to the specimen the average value of p remains constant. Fig. 4 (*c*) shows the pressure distribution and it is seen that except for the central region the pressure lies between 0 and about $2p$. The dotted curve represents the probable pressure distribution under conditions of *plastic* deformation. Except over the central region the distributions are not widely

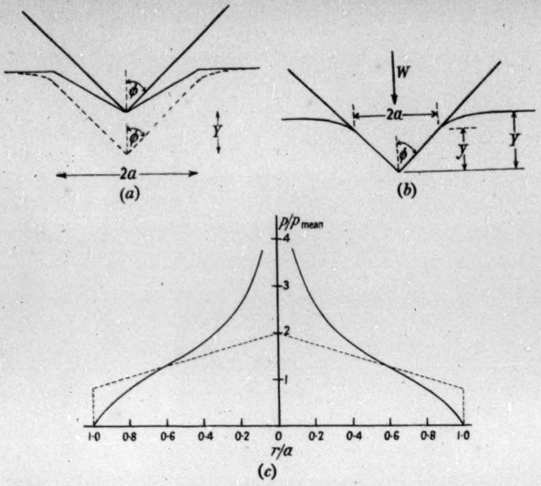

Fig. 4. (*a*) Assumed changes in shape of a conical identation formed by a rigid indenter of semi-apical angle ϕ. The indentation diameter remains constant but the depth diminishes by an amount Y; the recovered indentation is assumed to be a cone of semi-apical angle slightly greater than ϕ. (*b*) Deformation of an elastic solid by a rigid conical indenter according to Boussinesq (see Love 1939). (*c*) Pressure distribution over circle of contact between a rigid cone and an elastically deformed specimen. Pressure expressed as fraction of mean pressure; abscissa as fraction of radius of circle of contact. Broken line: approximate pressure distribution for *plastic* deformation by a hard cone.

different. Thus it is reasonable to assume that, on removing the load from a plastically formed indentation, the change in shape will not be greatly different from that used in the present elastic theory.

The depth of the elastic indentation (see Fig. 4 (*b*)) is

$$y = a \cot \phi \qquad \ldots\ldots (2)$$

where $2a$ is the chordal diameter of the indentation.

Hence

$$y = 2pa\frac{(1-\nu_1^2)}{E_1}. \qquad \ldots\ldots (3)$$

The total distance Y moved down by the indenter is, according to Love's analysis, greater than this by the ratio $\pi/2$.

Hence

$$Y = \frac{\pi}{2}y = \frac{\pi pa(1-\nu_1^2)}{E_1}. \qquad \ldots\ldots (4)$$

It is seen that Y is independent of the angle of the cone. This implies that the same result will apply if a conical indentation is deformed by a conical indenter.

Further it implies that the indenter itself will also yield elastically by an analogous quantity. Consequently the total elastic recovery becomes

$$Y = Y_1 + Y_2 = \pi p a \left[\frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}\right] \qquad \ldots\ldots(5)$$

where E_2, ν_2 are the corresponding elastic constants of the indenter. If the load is W, the corresponding value of a is $(W/\pi p)^{1/2}$ so that

$$Y = (\pi p)^{1/2} W^{1/2} \left[\frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}\right]. \qquad \ldots\ldots(6)$$

It is seen that since p is independent of the size of the indentation Y varies parabolically with W. Calculated values of Y are compared with the observed values in Table 2. The value of E for the indenter is taken as 70×10^{12} g cm^{-1}. Poisson's ratio for indenter and metal is taken as 0·3.

Table 2. Calculated and Observed Elastic Recovery

Material	Load (kg)	p (kg cm^{-2})	E_1 (dyn cm^{-2})	Y_{calc} (10^{-3} cm)	Y_{obs} (10^{-3} cm)
Aluminium alloy	2000	15000	$7{\cdot}5 \times 10^{11}$	13	12·2
Mild steel	2000	17000	20×10^{11}	6	6·85
Roller steel	2000	67500	20×10^{11}	11	11·7
Magnesium alloy	2000	3600	$4{\cdot}5 \times 10^{11}$	10	10·2

In Fig. 5 a series of results are given for the 68° and 45° cones. The theoretical curves are drawn as a continuous line. Two features are at once clear. The general trend and the actual values agree with the predicted values. Secondly the recovery does not depend on the angle of the conical indenter.

2.5. *Limitations*

The treatment here assumes that the recovered indentation is a right circular cone bounded by a flat undisturbed surface. In practice the free surface will

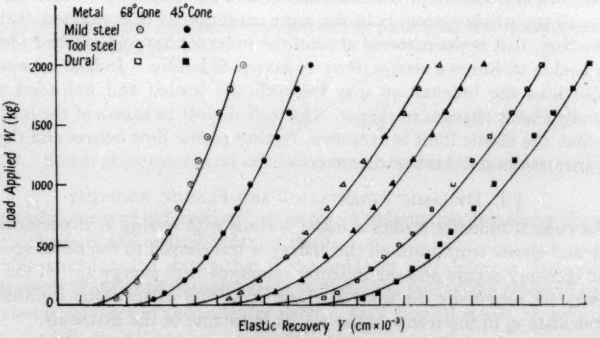

Fig. 5. Change in depth Y as load is removed for tungsten carbide cones of semi-apical angle 45° (open symbols) and 68° (closed symbols) on various metals. The theoretical curves are drawn as continuous lines.

rarely be flat. If the metal is highly work-hardened it will tend to pile up towards the edge of the indentations (Fig. 6 (*a*)). If it is heavily annealed it will tend to sink-in near the indentation as shown in Fig. 6 (*b*). These changes in the shape cannot however seriously affect the elastic analysis. A more serious limitation arises from the assumption that the recovered indentation has straight sides. When the recovery is large this is not so. Fig. 7 (Plate) shows a section made across the indentation formed in a block of polymer. It is seen that the walls of the indentation are markedly curved. This means that the pressure distribution and the deformation are not accurately accounted for by the simple theory we have described here. However, as Fig. 2 (Plate) shows, the recovery with metals is small and the walls appear to be reasonably straight.

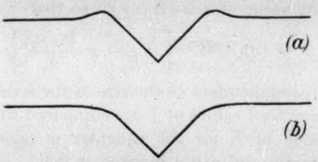

Fig. 6. Shape of indentation (*a*) with ' piling-up ', (*b*) with ' sinking-in '.

2.6. *Plastic and Elastic Deformation*

It is clear that when a conical indenter is pressed into a metal, plastic flow occurs for the smallest loads and, on account of geometric similarity, the mean pressure will be constant whatever the size of the indentation. The pressure distribution is not known analytically; probably it is roughly uniform but is highest in the centre and falls off rapidly near the edge of the indentation. When the indenter is withdrawn elastic recovery occurs. As the pressure distribution (except near the centre) is probably not widely different from that which occurs in the elastic deformation of cones, the change in shape is such that a cone changes into a cone of slightly different apical angle. There is no appreciable change in the basal diameter of the indentation but a diminution in its depth. If this load is re-applied the surface of the indentation (and the indenter) will deform elastically until the whole system is in the same condition as that attained during the first loading, that is the material around the indenter has just reached plasticity. If the load is withdrawn elastic recovery occurs as before. Indeed between zero and full load the indentation may be cyclically loaded and unloaded to give essentially elastic changes in shape. If a load slightly in excess of the initial load is applied, the elastic limit is exceeded, further plastic flow occurs and there is a slight increase in indentation diameter.

§ 3. DYNAMIC INDENTATION AND ELASTIC RECOVERY

If a conical indenter strikes a metal surface with energy ϵ_1 it performs both plastic and elastic work until all the energy is transferred to the metal specimen. Elastic recovery occurs and the indenter rebounds with energy ϵ_2. If the elastic processes are essentially the same as those occurring under static conditions we may calculate ϵ_2 in the terms of the elastic constants of the materials.

For simplicity we first assume that the indenter is perfectly rigid and has a semi-apical angle ϕ. We assume that the mean pressure is constant throughout the indentation process though it need not necessarily be the same as that involved under static conditions.

The total elastic recovery of the indentation as we saw in Eqn (4) is

$$Y = \frac{\pi}{2}y = \pi p a\left[\frac{1-\nu_1^2}{E_1}\right] \qquad \ldots\ldots(7)$$

where $2a$ is the diameter of the permanent indentation formed (see Fig. 8). The elastic work released by the indentation as it recovers is

$$\epsilon_2 = \int p\pi a^2 dY = \int_0^a p\pi a^2 . \pi p\left(\frac{1-\nu_1^2}{E_1}\right)da = p\frac{\pi a^2}{3}Y. \qquad \ldots\ldots(8)$$

We now consider the permanent plastic work done on the metal

$$\epsilon_1 - \epsilon_2 = p \times (\text{volume of recovered indentation}). \qquad \ldots\ldots(9)$$

The height of the initial indentation (see Fig. 8) is

$$h = a\cot\phi.$$

The diminution in height due to elastic recovery is simply

$$y = \frac{2}{\pi}Y. \qquad \ldots\ldots(10)$$

The height of the recovered indentation is then

$$h_1 = h - y = h - \frac{2}{\pi}Y$$

so that the volume of the permanent indentation left after elastic recovery is $\pi a^2/3$ times this.

Then from Eqn (9) we have

$$\epsilon_1 - \epsilon_2 = p\frac{\pi a^2}{3}\left(h - \frac{2}{\pi}Y\right) \qquad \ldots\ldots(11)$$

$$= p\frac{\pi a^2}{3}h - p\frac{\pi a^2}{3}\frac{2}{\pi}Y. \qquad \ldots\ldots(12)$$

It is seen from Eqn (8) that the last term on the right is equal to $(2/\pi)\epsilon_2$. Hence

$$\epsilon_1 - \left(1 - \frac{2}{\pi}\right)\epsilon_2 = p \times (\text{nominal volume of indentation}). \qquad \ldots\ldots(13)$$

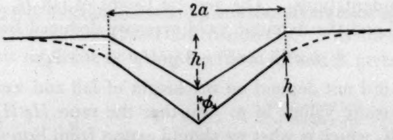

Fig. 8. Sketch of indentation for calculating energy involved in elastic recovery.

By 'nominal volume of indentation' we imply an indentation possessing the same geometric shape as the conical indenter itself.

Careful consideration shows that if the indenter also deforms elastically an identical result is obtained though here ϵ_2 includes the part of the rebound energy due to elastic recovery of the indenter itself. As a general result, therefore, we have

$$\text{Impact energy} - 0{\cdot}363\ (\text{rebound energy})$$
$$= p \times (\text{nominal volume of indentation}). \qquad \ldots\ldots(13a)$$

It is interesting to note that in the analysis of impact by a spherical indenter (Tabor 1948, 1951) a very similar relation is obtained except that the numerical factor in front of ϵ_2 is 3/8 instead of 0·363.

3.1. *Ratio of Rebound to Impact Energy*

In any impact experiment the simplest quantities to measure are the energy of impact ϵ_1 and the energy of rebound ϵ_2. We now show that there is a very simple analytic relation for the ratio between them.

The impact energy from Eqn (13) is

$$\epsilon_1 = p\frac{\pi a^2}{3}h + \left(1 - \frac{2}{\pi}\right)\epsilon_2. \qquad \ldots\ldots(14)$$

The rebound energy is obtained from Eqn (8) and equals $\pi p a^2 Y/3$. Then

$$\frac{\epsilon_1}{\epsilon_2} = \frac{h}{Y} + \left(1 - \frac{2}{\pi}\right) = \frac{h}{Y} + 0{\cdot}363. \qquad \ldots\ldots(15)$$

In general for all but the hardest metals ϵ_1/ϵ_2 is of the order of 20 or more. Consequently the last term in Eqn (15) may be neglected without introducing an error of more than a few per cent. Noting that $h = a\cot\phi$ and that, if we include the elastic recovery of the indenter as well as the indentation, Y is given by Eqn (5), we obtain

$$\frac{\epsilon_2}{\epsilon_1} = \pi p \tan\phi\left[\frac{1-\nu_1{}^2}{E_1} + \frac{1-\nu_2{}^2}{E_2}\right] \qquad \ldots\ldots(16)$$

or assuming $\nu_1 = \nu_2 = 0{\cdot}3$

$$\frac{\epsilon_2}{\epsilon_1} = 2{\cdot}85\, p\tan\phi\left[\frac{1}{E_1} + \frac{1}{E_2}\right]. \qquad \ldots\ldots(17)$$

3.2. *Impact Experiments*

Some simple experiments were carried out with the 45° cone mounted on a horizontal bar of total mass M supported on a pendulum of length 1 metre. The metal specimens were attached to a massive anvil and impacts were carried out by drawing the cone to one side by a certain distance and allowing it to strike the specimen. The distance of rebound was measured and also the diameter $2a$ of the permanent indentations. The vertical height of fall H_1 and of rebound H_2 were determined and the dynamic yield pressure deduced from the relation

$$\tfrac{1}{3}\, p\pi a^2(a\cot\phi) = Mg(H_1 - 0{\cdot}363H_2).$$

The values of p did not depend on the height of fall and were generally a little bigger than the static values of p. Further the ratio H_2/H_1 was more or less independent of H_1 which is what we should expect from Eqn (17). In effect this conclusion must be true on grounds of geometric similarity. In Table 3 we give three specific calculations for three different metals and in the last two columns compare the ratio $H_2/H_1(=\epsilon_2/\epsilon_1)$ as deduced from Eqn (17) with the observed ratio. It is seen that the agreement is reasonably good.

3.3. *Experimental Data of Davis and Hunter*

We see from Eqn (17) that if impact experiments are carried out with indenters of semi-apical angles ϕ_1 and ϕ_2 we should obtain

$$\frac{(\epsilon_2/\epsilon_1)_1}{(\epsilon_2/\epsilon_1)_2} = \frac{p_1\tan\phi_1}{p_2\tan\phi_2}.$$

In the experiments of Davis and Hunter (1959) the ratio of impact and rebound velocities V_1 and V_2 was measured. Two indenters of semi-apical angle 68° and 45° were used. Consequently we should expect to find

$$\frac{(V_2/V_1)_1}{(V_2/V_1)_2} = \left(\frac{p_1 \tan 68°}{p_2 \tan 45°}\right)^{1/2} = \left(\frac{p_1}{p_2}\right)^{1/2} 1{\cdot}57.$$

Table 3

Metal (cm)	E (dyn cm^{-2})	H_1 (cm)	H_2 (cm)	$2a$ (cm)	p_{calc} (kg mm^{-2})	$(H_2/H_1)_{\text{calc}}$	$(H_2/H_1)_{\text{obs}}$
Tool steel	20×10^{11}	1·165	0·106	0·0323	510	0·094	0·091
Al alloy	$7{\cdot}5 \times 10^{11}$	0·523	0·033	0·0378	145	0·061	0·063
Mg alloy	$4{\cdot}5 \times 10^{11}$	0·523	0·017	0·046	80	0·034	0·033

Using their published results and some additional data kindly provided privately we may compare their results with the calculated one. We have

$$\left(\frac{p_2}{p_1}\right)^{1/2} \frac{(V_2/V_1)_1}{(V_2/V_1)_2} = 1{\cdot}57.$$

It is seen in Fig. 8 that the experimental ratios lie fairly well distributed about the theoretical ratio.

Finally we may make a general comparison between the calculated ratio ϵ_2/ϵ_1 and the observed ratio $(V_2/V_1)^2$. The experiments were carried out with cones of semi-apical angle 45° and 68° so that the theoretical values are

$$2{\cdot}85p\left[\frac{1}{E_1} + \frac{1}{E_2}\right] \quad \text{and} \quad 7p\left[\frac{1}{E_1} + \frac{1}{E_2}\right] \quad \text{respectively.}$$

All the results are plotted in Fig. 9. It is seen that there is fair agreement with the theoretical relation considering the very wide range of conditions and materials. Those points which lie off the theoretical line (materials 8, 9, 10, 13) do so consistently for both indenters. Thus the divergence is not due to friction (which we have ignored throughout this treatment). It is due either to a mistaken value of the elastic modulus or to some error in $2a$ which gives too low a value to

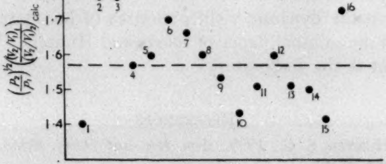

Fig. 9. Experimental data of Davis and Hunter (1959) comparing the ratio of rebound velocity V_2 to impact velocity V_1 for cones of semi-apical angles 45° and 68°. According to the theoretical prediction $(p_2/p_1)^{1/2}(V_2/V_1)_1/(V_2/V_1)_2$ should be equal to 1·57. (For code see Appendix.)

the dynamic yield pressure. It may also be noted that of these materials 8, 9 and 10 have free graphite in them whilst 13 is an austenitic steel so that their physical properties may be anomalous.

The assumptions made in this paper are clearly over-simplifications. This particularly applies to the assumption that the pressure distribution over the contact region leads to a change in shape of the conical indentation given by Love's analysis of the elastic deformation of cones. Nevertheless the broad agreement obtained between experiments and the theoretical predictions suggest that the basic model is reasonably valid and that it may be applied satisfactorily to both static and dynamic indentations.

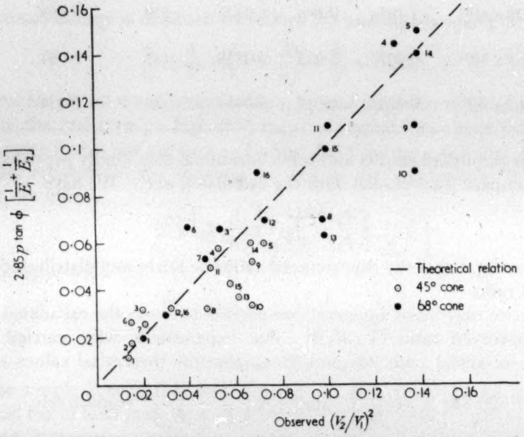

Fig. 10. Experimental data of Davis and Hunter comparing observed rebound energy $(V_2/V_1)^2$ with the predicted value $2{\cdot}85p \tan\phi[1/E_1+1/E_2]$. Open circles 45° cone; closed circles 68° cone. The materials 8, 9, 10 give poor agreement; they all contain free graphite. Material 13 is an austenitic steel. (For code see Appendix.)

ACKNOWLEDGMENTS

We wish to express our thanks to Mr. E. L. Morris for completing some of the experimental measurements and for checking the calculations. We particularly wish to thank Dr. C. D. Davis of Fort Halstead for the loan of the indenters and for further data on the dynamic yield pressures of his materials: this was not given explicitly in the original paper of Davis and Hunter. We thank Vauxhall Motors for a grant to the Laboratory.

Spin–Lattice Relaxation Time Measurements in Dilute Potassium Ferricyanide

By D. H. PAXMAN

Mullard Research Laboratories, Salfords, Nr. Redhill, Surrey

MS. received 14*th November* 1960, *in revised form* 30*th January* 1961

Abstract. Measurements of the spin–lattice relaxation time T_1 of $K_3Fe(CN)_6$ diluted with $K_3Co(CN)_6$ have been made in the temperature range 4·2° to 1·6°K in the X-band (9375 Mc/s). The results are compared with existing theories, and it is suggested that the results are not inconsistent with the theory proposed by Van Vleck.

---

§ 1. Introduction

At present most measurements of the spin–lattice relaxation time T_1 have been made on systems having more than two energy levels. The interpretation of the results of such experiments is difficult since in general all the levels present contribute to the relaxation of the pair under observation. Under these conditions there are added complications due to the possible occurrence of cross relaxation phenomena (Bloembergen *et al.* 1959).

In view of this difficulty a system having only two energy levels was chosen for measurement: in this case $K_3Fe(CN)_6$ diluted by the addition of $K_3Co(CN)_6$.

This material has been investigated in some detail, paramagnetic resonance data being given by Baker, Bleaney and Bowers (1956), and the theoretical interpretation of these results by Bleaney and O'Brien (1956).

§ 2. Apparatus and Experimental Technique

A pulse saturation technique similar to that described by Davis, Strandberg and Kyhl (1958) has been used in the present work; the recovery of the paramagnetic absorption to its equilibrium value, after saturation by a 'heater' pulse, being observed on a superheterodyne X-band paramagnetic resonance spectrometer. An accuracy to about 10% was obtained for T_1 with this technique.

The specimen temperature was determined using a resistance thermometer ($\frac{1}{4}$ w, 56 Ω, Allen Bradley carbon resistor), this having been calibrated using a helium vapour pressure thermometer which was constructed round the cavity. The results fitted a resistance temperature relation of the form

$$\frac{1}{T_R} = \frac{a^2}{\log R} + b^2 \log R + 2ab$$

and the temperature T_R was calculated from the thermometer resistance R using

$$\frac{1}{T_R} = \frac{1{\cdot}024028}{\log R} + 0{\cdot}39125 \log R - 1{\cdot}26595.$$

§ 3. CRYSTALS

The crystals used were grown by the method of slow evaporation at a constant temperature. Chemical analysis of the batch was used to determine the impurity contents of the crystals. The crystals used were D, C, E, containing 6·6%, 3·2%, 1·7% $K_3Fe(CN)_6$ respectively, all containing less than 0·001% of the elements Ti, V, Cr, Mn, Ni, Cu.

The resonance data given by Baker *et al.* show that the paramagnetic ions form two similar, but differently oriented, magnetic complexes. The crystal is pseudo-orthorhombic, and the spectra of the two ions are identical if the steady magnetic field H_0 lies in the *ac* and *bc* planes of the crystal. The present measurements were made with H_0 along the *b* axis of the crystal.

§ 4. RESULTS

The results are shown in Fig. 1, in which T_1 (msec) is plotted as a function of temperature on a logarithmic scale. All the specimens investigated show similar behaviour.

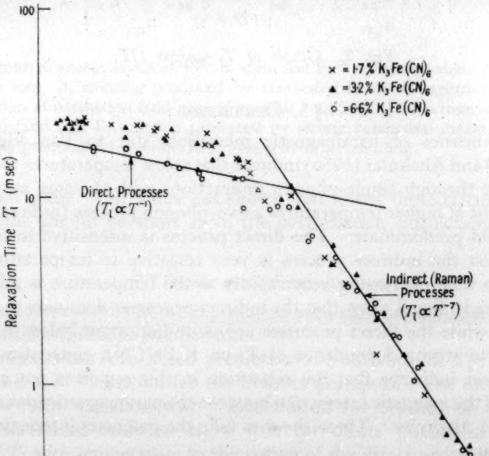

Fig. 1. Graph of log T_1 (msec) against log T(°K).

Above 2·8°K T_1 is a rapidly varying function of the temperature (approximately $T_1 \propto T^{-7}$), whilst below 2·8°K this relation no longer applies, the relaxation time becoming approximately inversely proportional to temperature below 2·4°K. The results obtained below this temperature are replotted in Fig. 2 in which T_1 is displayed as a function of $1/T$. This demonstrates that in this region the relaxation time T_1 is increasing slightly with decreasing $K_3Fe(CN)_6$ concentration, though the experimental data are not sufficiently accurate to make any quantitative formulation of the variation of T_1 with concentration.

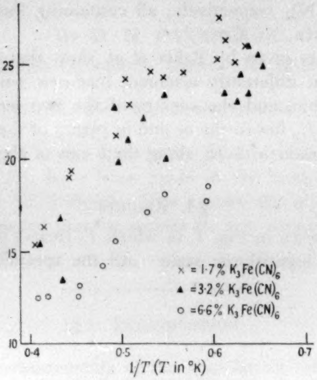

Fig. 2. Graph of T_1 against $1/T$.

§ 5. DISCUSSION

Existing theories of paramagnetic relaxation, due to Van Vleck (1940), Waller (1932) and Altshuler (1956) indicate that at low temperatures the relaxation occurs mainly through single-phonon interactions with the spin system (direct process), whilst at higher temperatures a two-phonon process (indirect or Raman process) would predominate. The direct process is insensitive to temperature changes, whilst the indirect process is very sensitive to temperature changes, the relaxation time decreasing very rapidly as the temperature is raised.

The results in Fig. 1 show that the indirect processes dominate the relaxation above 2·8°K, while the direct processes are more important below 2·4°K.

The lack of strong dependence of T_1 on $K_3Fe(CN)_6$ concentration for the direct processes indicates that the relaxation in this region is not caused by a modulation of the magnetic interaction between the paramagnetic ions as proposed by Waller and Altshuler. These theories take the magnetic interaction between the ions as being

$$U_{\text{int}} = g^2\beta^2 \left\{ \frac{S_1 S_2}{r_{12}^{\;3}} - 3\frac{(S_1 r_{12})(S_2 r_{12})}{r_{12}^{\;5}} \right\}$$

where r_{12} is the distance between ions 1 and 2, $S_{1,2}$ the spins of ions 1 and 2, g the g factor, and β the Bohr magneton. The relaxation process is therefore a very sensitive function of r_{12} and hence sensitive to concentration.

Detailed comparison with the calculations of Van Vleck which are for titanium and chromium alum is difficult since in the ferricyanide there is a very strong crystalline field acting and there is considerable covalent bonding. There are, however, strong similarities between the cases of titanium alum and ferricyanide since both have a series of low lying orbital levels within a few hundred cm^{-1}

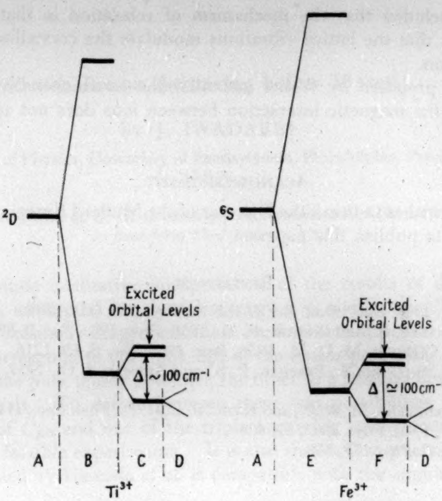

Fig. 3. Diagram of energy levels of Ti^{3+} in alum and Fe^{3+} in ferricyanide: A, ground state of free ion; B, splitting produced by octahedral field; C, splitting produced by distortion of octahedral field plus spin–orbit coupling; D, Zeeman splitting due to applied field H_0; E, splitting produced by strong octahedral crystalline field; F, splitting produced by rhombic field plus spin–orbit coupling.

of the ground state. Van Vleck has shown that under these circumstances the relaxation time should be short as in the perturbation calculations the energy difference:

$$\Delta = E_{\text{ground state}} - E_{\text{next orbital level}}$$

occurs in the denominators of the expressions used and therefore the perturbation due to the lattice vibrations will be large.

For titanium alum Van Vleck predicts a T^{-1} variation of T_1 for the direct processes, and a T^{-9} variation for the indirect processes. The direct processes should show little variation with concentration for crystals of this dilution.

The observations reported show that for dilute potassium ferricyanide variation of T_1 with temperature in the region of the direct processes is as would be expected on the Van Vleck model. The variation of T_1 with temperature in the region of Raman processes is not as rapid as suggested by Van Vleck, but this may be due to the fact that the observations are being made close to the region in which the relaxation mechanism is changing. Van Vleck's theory predicts a strong frequency dependence of T_1 ($T_1 \propto f^{-4}$); it would therefore be of considerable interest to measure the relaxation time at other frequencies.

§ 6. CONCLUSION

The measured relaxation times in $K_3Fe(CN)_6$ show close similarities to the behaviour expected on the basis of the theory of Van Vleck. It is therefore tentatively concluded that the mechanism of relaxation is that suggested by Van Vleck, i.e. that the lattice vibrations modulate the crystalline electric field acting on the ion.

The model proposed by Waller and Altshuler in which relaxation is due to modulation of the magnetic interaction between ions does not appear to apply here.

ACKNOWLEDGMENT

The author wishes to thank the Director of the Mullard Research Laboratories for permission to publish this paper.

Proton–Proton Scattering below 50 MeV

By J. IWADARE[†]

Department of Physics, University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A.

Communicated by E. H. S. Burhop; MS. received 27th June 1960, in final form 23rd January 1961

Abstract. A simple qualitative interpretation of the results of detailed phase shift analyses is attempted for the low energy p–p scattering. The following conclusions are obtained: In general, there are four sets of phase shift solutions, two of which correspond to the right sign of the tensor potential. One of them corresponds to the pure tensor potential, the other to a mixture of the tensor and the **L.S** potentials. To decide between these two possibilities the combined measurements of C_{nn} and one of the triple scattering parameters are the most convenient and feasible experiments. It is also shown that a version of the pion potential proposed by Hamada *et al.* is compatible with the angular distribution below 5 MeV.

§ 1. INTRODUCTION AND SUMMARY

THERE are several accurate measurements of the proton–proton scattering angular distribution at various energies. Detailed phase shift analyses of these data in the low energy region have been performed by MacGregor and others (Noyes and MacGregor 1958, MacGregor 1959, and MacGregor, Moravcsik and Noyes 1960). At energies lower than 40 MeV one usually finds four sets of phase shifts which fit the angular distribution equally well, for any pair of the $^1S_0$ and $^1D_2$ phase shifts which lies in the so-called solution region (MacGregor 1959, Clementel and Villi 1955). Some of these possible sets will be eliminated either by the measurement of triple scattering parameters or by some argument based on the pion theory of nuclear forces (Iwadare *et al.* 1956). Combining these two arguments gives another experimental check of the theory.

In this paper we consider the inter-relations among these four solutions and then compare them with the predictions based on the pion theoretical potential. The potential predicts a phase shift set similar to that in groups I and II of MacGregor (1959). In order to eliminate the ambiguity in the phase shift analysis it is proposed to fix the value of the $^1S_0$ phase shift by a spin correlation measurement and then to distinguish different sets by a triple scattering measurement of $R(\theta)$ or $A(\theta)$. Finally the results of the phase shift analyses at energies lower than 5 MeV are compared with the predictions based on the pion potential. It is concluded that the version of Hamada *et al.* (1960) of the pion potential can fit most of the existing data in this energy region. For a crucial test against the purely static potentials (central plus tensor potentials) we have to wait until the results of triple scattering measurements are available.

§ 2. PHASE SHIFT ANALYSIS OF THE p–p ANGULAR DISTRIBUTION DATA

2.1. *The Characteristic Features of the Observed Angular Distribution*

The angular distribution of the p–p scattering consists of three parts, that is, the pure Coulomb (σ_C), the Coulomb–nuclear interference (σ_{CN}), and the pure nuclear (σ_N) parts:

$$\sigma(\theta)=\sigma_C(\theta)+\sigma_{CN}(\theta)+\sigma_N(\theta). \qquad \ldots\ldots(1)$$

Except for very small angles the Coulomb–nuclear interference term can be written as

$$k^2\sigma_{CN}(\theta)\simeq-\tfrac{1}{4}\eta\operatorname{cosec}^2\tfrac{1}{2}\theta\cos(2\eta\log\sin\tfrac{1}{2}\theta)$$
$$\times(A+B\cos\theta+C\cos^2\theta+\ldots),$$

where $\eta=e^2/\hbar v$

$$A=\sin 2\delta_0+(1-\cos 2\delta_0)-\frac{5}{2}\sin 2\delta_2+\ldots,$$
$$B=\sin 2\delta_{P_0}+3\sin 2\delta_{P_1}+5\sin 2\delta_{P_2}+\ldots.,$$
$$C=\frac{15}{2}\sin 2\delta_2+\ldots.. \quad . \qquad \ldots\ldots(2)$$

The nuclear part is simply expressed as a power series of $\cos^2\theta$

$$k^2\sigma_N(\theta)\simeq a+b\cos^2\theta+c\cos^4\theta+\ldots.,$$

$$a+\frac{b}{3}+\frac{c}{5}+\ldots=\sin^2\delta_0+5\sin^2\delta_2$$
$$+\sin^2\delta_{P_0}+3\sin^2\delta_{P_1}+5\sin^2\delta_{P_2}+(1-2\cos 2\epsilon_2)\cos^2\delta_{P_2}+\ldots,$$
$$b=15\sin\delta_0\sin\delta_2\cos(\delta_0-\delta_2)-\frac{75}{2}\sin^2\delta_2$$
$$+\frac{9}{4}\sin^2\delta_{P_1}+\frac{21}{4}\sin^2\delta_{P_2}+6\sin\delta_{P_0}\sin\delta_{P_2}\cos(\delta_{P_0}-\delta_{P_2})$$
$$+\frac{27}{2}\sin\delta_{P_1}\sin\delta_{P_2}\cos(\delta_{P_1}-\delta_{P_2})+\frac{6\sqrt{6}}{4}\sin 2\delta_{P_0}\sin 2\epsilon_2\cos(\delta_{P_0}-\delta_{P_2})$$
$$-\frac{9\sqrt{6}}{4}\sin 2\delta_{P_1}\sin 2\epsilon_2\cos(\delta_{P_1}-\delta_{P_2})+\frac{3\sqrt{6}}{4}\sin 2\delta_{P_2}\sin 2\epsilon_2$$
$$-\frac{51}{4}\sin^2 2\epsilon_2+\ldots,$$
$$c=\frac{225}{4}\sin^2\delta_2+\frac{75}{4}\sin^2 2\epsilon_2+\ldots.$$

In the above we have neglected the small Coulomb phase shifts and the nuclear phase shifts higher than D-waves. We use the following notation, for nuclear *bar* phase shifts of Stapp, Ypsilantis and Metropolis (1957).

δ_L = the singlet even phase shifts

δ_{P_J} = the triplet P_J-wave phase shifts

ϵ_2 = the mixing parameter of $J=2$ waves.

Since we are dealing with the low energy scattering, we shall expand all the expressions in terms of the phase shifts except for δ_0, which simplifies the formulae a great deal and allows us a simple interpretation of the results.

The most remarkable point in the observed angular distribution of p–p scattering is the small value of B, the coefficient of the $\cos\theta$ interference term:

$$B \simeq 2(\delta_{P_0} + 3\delta_{P_1} + 5\delta_{P_2}) \equiv 18\Delta \ll 1. \qquad \ldots\ldots(4)$$

This means that the three triplet P phase shifts cancel each other to give a small effective phase shift Δ. The magnitudes of Δ obtained by MacGregor (1959) in his analyses of the experimental data are shown in Table 1. The effective phase shift is less than 10% of the individual ones except at 40 MeV, where it amounts to about 30% of the smallest one, i.e. δ_{P_2}. As is seen in the original paper (MacGregor 1959) the value of Δ is not determined uniquely except at very low energies, since the Coulomb–^{1}D ($\cos^2\theta$) term and the Coulomb–^{1}S(1) term cannot be completely separated from the Coulomb–^{3}P ($\cos\theta$) term.

Table 1. Parameters of the Angular Distribution of the p–p Scattering

E (MeV)	a	b	c	Δ (deg)
4·203	0·655	—	—	−0·2 — 0
9·73	0·68	0·013	0·0002	−0·35 — −0·10
19·8	0·62	0·026	0·0027	−0·2 — +0·2
39·4	0·55	−0·017	0·124	+1 — +1·5

Other interesting features of the data are the small values of the two anisotropy coefficients b and c (See Table 1). These, together with the former remark, might be interpreted as indicating that the scattering is mainly in the ^{1}S state in the energy region of interest. This, however, does not seem to be the case from the point of view of the pion theory. The strong tensor potential in ^{3}P states which originates from the one-pion exchange process predicts a large ^{3}P scattering with small B and b. This point can be decided easily by measuring the spin correlation parameter $C_{nn}(90^\circ)$ which serves to separate the singlet scattering from the triplet scattering (§ 3.2).

2.2. *S, P, D Fit to the Angular Distribution*

We now try to fit the observed angular distribution with S-, P- and D-wave phase shifts. In the first approximation we neglect the mixing parameter ϵ_2. Using the relation (4) to eliminate δ_{P_2}, we obtain

$$a + \frac{b}{3} + \frac{c}{5} \sim \sin^2\delta_0 + 5\delta_2^2 + 1{\cdot}2\{(\delta_{P_0} - \Delta) + 0{\cdot}5(\delta_{P_1} - \Delta)\}^2 + 4{\cdot}5(\delta_{P_1} - \Delta)^2 + 9\Delta^2, \qquad \ldots\ldots(5)$$

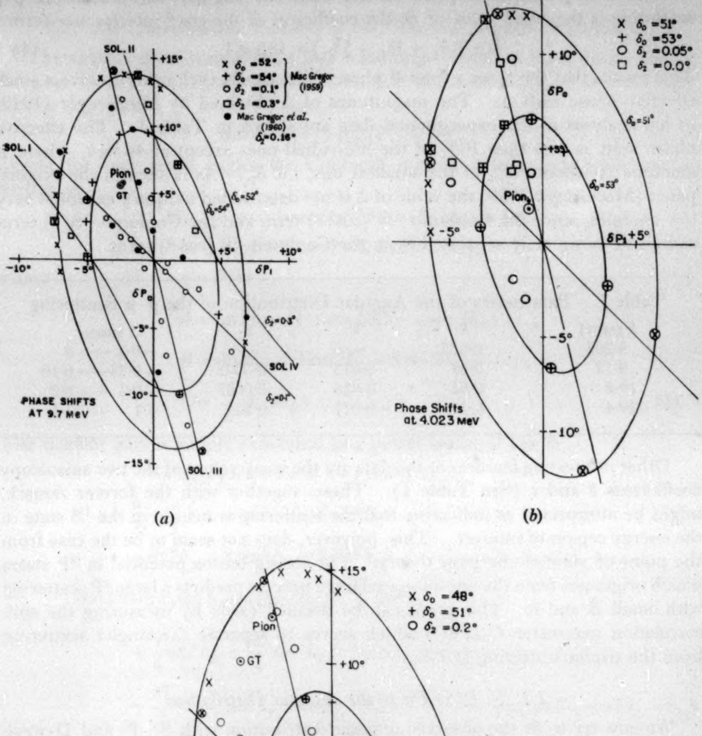
$$b \sim 7{\cdot}5 \sin 2\delta_0\,\delta_2 - 37{\cdot}5\delta_2^2 - 3{\cdot}96\{(\delta_{P_0} - \Delta) - 2{\cdot}54(\delta_{P_1} - \Delta)\}^2 + 9{\cdot}82(\delta_{P_1} - \Delta)^2 + 27\Delta^2. \qquad \ldots\ldots(6)$$

If we fix the values of δ_0 and δ_2, (5) represents an ellipse on the $\delta_{P_0} - \delta_{P_1}$ plane with centre (Δ, Δ) eccentricity 0·88 and two principal axes

$$\delta_{P_1} - \Delta = -0{\cdot}16\,(\delta_{P_0} - \Delta),$$
$$\delta_{P_1} - \Delta = 6{\cdot}2(\delta_{P_0} - \Delta). \qquad \ldots\ldots(7)$$

(6) in its turn represents a hyperbola with the same centre and two asymptotic lines

$$\delta_{P_1} - \Delta = -0{\cdot}24\,(\delta_{P_0} - \Delta),$$
$$\delta_{P_1} - \Delta = -1{\cdot}03\,(\delta_{P_0} - \Delta). \qquad \ldots\ldots(8)$$



(*a*) (*b*)

(*c*)

Fig. 1. Phase shift solutions plotted on the $\delta_{P_0} - \delta_{P_1}$ plane. (*a*) p–p scattering at 9·7 MeV, (*b*) p–p scattering at 4·2 MeV, (*c*) p–p scattering at 19·8 MeV.

The size of the ellipse is mainly determined by δ_0 and that of the hyperbola by δ_2 (since $\sin 2\delta_0 \sim 1$).

The intersections of the ellipse and the hyperbola give the possible phase shift solutions. In Fig. 1 (*a*) we have shown a plot in the δ_{P_0}–δ_{P_1} plane of MacGregor's solutions at 9·7 MeV (MacGregor 1959). MacGregor has tried to get an overall fit to the data fixing the values of δ_0 and δ_2 as parameters and varying δ_{P_J}'s. For further details of his method readers are referred to the original paper. Fig. 1 (*a*) shows MacGregor's solutions for $\delta_0 = 52°$ and $54°$ with various δ_2 and for $\delta_2 = 0{\cdot}1°$ and $0{\cdot}3°$ with various δ_0. Ellipses correspond to our approximations for $\delta_0 = 52°$ and $54°$, hyperbola to that for $\delta_2 = 0{\cdot}3°$ (both for $\Delta = 0$). Two asymptotic lines correspond to $\delta_2 \sim 0{\cdot}1°$. We used parameter values given by MacGregor (1959) (see our Table 1). One can see that the simple calculations reproduce the results of the detailed phase shift analysis very closely. The same, of course, applies to any energy value provided that the values of the individual phase shifts are small enough.

It is seen that there are four sets of the phase shift solutions in general which fit the experimental data equally well. Thanks to the small values for Δ, two of them are obtained from the other two just by changing the signs of the ^3P_J phase shifts. The four solutions are called I, II, III, and IV by MacGregor (1959). They correspond to each branch of the hyperbola (Fig. 1 (*a*)).

At low energies the phase shifts given by any non-central potential (properly defined as a tensor product in the spin and coordinate space) will give vanishing contributions to the effective ^3P phase shift Δ. The observed small Coulomb–^3P interference suggests that the central potential in the triplet odd state is rather weak. Roughly speaking, the solutions which appear in the second or the fourth quadrant correspond to positive or negative tensor potentials, respectively, and those in the first or the third quadrant to positive or negative $\mathbf{L}.\mathbf{S}$ potentials. Since it is not very probable that the ^1D phase shift is as large as $0{\cdot}4°$ at 9·4 MeV, the sensible solutions with reasonable values for δ_0 are expected to appear in the second and fourth quadrants, and we can reject the possibility of the dominating $\mathbf{L}.\mathbf{S}$ potential in the ^3P states. Similar plots for the phase shift solutions at 4·2 MeV and 19·8 MeV are shown in Figs 1 (*b*) and (*c*).

The solution regions in the $\delta_0 - \delta_2$ plane as shown in Fig. 1 of MacGregor's paper (1959) are obtained as the regions where the intersections of the ellipse and the hyperbola exist.

2.3. *Effects of Inclusion of the Higher Waves*

As one of the results of their detailed phase shift analysis, Noyes and MacGregor (1958) concluded that one has to take account of the mixing parameter ϵ_2 of $J = 2$ states in order to obtain a good fit to the angular distribution at 40 MeV, if one wants to avoid unreasonable values for both ^1S and ^1D phase shifts. Their argument can be summarized in the following way. If one ascribes the observed value of $c(c = 0{\cdot}124)$ entirely to the ^1D scattering, then one has to have a large $\delta_2(\delta_2 \sim 3°)$ and this gives rise to a large contribution to b. To compensate the contribution it is necessary to introduce a very large ^3P scattering. This in its turn reduces the ^1S scattering appreciably ($\delta_0 < 33°$). These values of δ_0 and δ_2, however, are not compatible with the predictions based on the pion potential. Furthermore these solutions usually lead to an appreciable polarization of scattered protons which seems to be rejected by observation (Noyes and MacGregor 1958).

Now that the importance of the long-tailed one-pion exchange potential in the nuclear force phenomena is firmly established both at low energies (Iwadare *et al.* 1956), and at high energies (Cziffra *et al.* 1959, and MacGregor, Moravcsik and Stapp 1959), and the potential predicts a strong tensor potential in the triplet odd state, it is very interesting to examine the effects of higher waves, particularly that of the mixing parameter ϵ_2 of $J=2$ states.

MacGregor, Moravcsik and Noyes (1960) have performed a modified phase shift analysis at various energies below 40 MeV, taking into account the scattering of higher waves by the one-pion exchange process. The phase shifts thus obtained at 9·7 MeV are plotted in Fig. 1 (*a*). The direction of the correction will be easily seen from (3). In general, the effects can be described as follows. For fixed values of δ_0, δ_2 and ϵ_2, the condition for $a+\frac{1}{3}b+\frac{1}{5}c$, the nuclear total cross section, again gives an ellipse in the plane with a centre (Δ, Δ) and a little smaller in size than before. The condition for b gives a hyperbola with the centre $(\Delta-5\sqrt{6}\epsilon_2/2, \Delta+5\sqrt{6}\epsilon_2/4)$ and a corresponding change in size.

At an energy as high as 40 MeV the term $\cos^4\theta$ is no longer negligible and gives a relation between δ_2 and ϵ_2

$$c \sim \frac{75}{4}(3\delta_2^2+4\epsilon_2^2). \qquad \ldots\ldots(9)$$

We have two values for ϵ_2 with opposite signs for given values of c and δ_2. For a definite sign of ϵ_2 we no longer have the symmetry between the solutions I and IV or II and III. The shift of the centre of the hyperbola destroys it. We have, however, another kind of symmetry. Let us call the solutions with a negative ϵ_2 I, II, III and IV and those with a positive ϵ_2 I′, II′, III′ and IV′. Since Δ is still fairly small we get the solutions I′, II′, III′ and IV′ from IV, III, II and I by changing the signs of δ_{P_J} and ϵ_2. When the value of δ_0 increases the solutions I and III (with IV′ and II′) disappear first and then II and IV (with III′ and I′).

The solutions I and II ($\delta_{P_0}>0$, $\delta_{P_1}<0$, $\epsilon_2<0$) correspond to the positive tensor potential and III′ and IV′ to the negative one. The other four solutions do not have counter parts in the simple potential description.

§ 3. POLARIZATION AND SPIN CORRELATION MEASUREMENTS AT LOW ENERGIES

3.1. *Polarization Measurements* (*Double Scattering*)

In order to resolve the degeneracy in the phase shift solutions, the double scattering measurements for vector polarization have been proposed. Unfortunately the expected polarization is very small at low energies. The vector polarization caused by a single scattering of the unpolarized beam is proportional to the imaginary part of the product of two R-matrices, i.e. $\mathscr{I}(R^*_1R_2)$ (Goldfarb 1958), and thus is of the order of $\delta_{P_J}^3$. Of course there is no polarization effect from the singlet scattering. The double scattering measurements, therefore, are not very helpful in resolving the degeneracy in the energy region concerned. Any sensible measurement must be able to detect a polarization of about 1%. (For n–p polarization, see note added during revision, p. 195.)

3.2. *Spin Correlation Measurements*

The spin correlation parameters are expressed by the real part of the product of two R-matrices. There is no interference between the singlet scattering and the triplet one, since the incident beam is unpolarized. Therefore, the results are invariant for the transformation $\delta_{P_J} \to -\delta_{P_J}$, $\epsilon_2 \to -\epsilon_2$, or in their first approximation they are the same for the solutions I and IV′ (IV and I′) or II and III′ (III and II′).

The correlation parameter C_{nn} defined in the single scattering plane is the easiest to measure and will provide very valuable information. Particularly a measurement at 90°(c.m.) is dependent only on the singlet and triplet cross sections at that angle, and, when combined with the unpolarized cross section data at the same angle, it serves to separate the singlet scattering from the triplet one. The expression for this parameter is as follows:

$$\sigma C_{nn}(90^\circ) = {}^3\sigma(90^\circ) - {}^1\sigma(90^\circ) = \sigma(90^\circ) - 2\,{}^1\sigma(90^\circ) = 2\,{}^3\sigma(90^\circ) - \sigma(90^\circ),$$

$$\sigma(C_{nn}(90^\circ) - 1) \sim -\frac{1}{2k^2}\left(\sin^2\delta_0 + \frac{25}{4}\sin^2\delta_2 - 5\sin\delta_0\sin\delta_2\cos(\delta_0 - \delta_2)\right).$$

C_{nn} (90°) starts from -1 at zero energy and reaches $+1$ at some energy around 150 MeV. Since the magnitude of the ^{1}D phase shift can be inferred from the outer property of the pion potential, the measurement gives useful information concerning the ^{1}S phase shift and enables us to infer the properties of the inner potential in the singlet even state. The angular variation of C_{nn} at low energies will not be of much use. The energy variation of C_{nn} (90°) is far more valuable. To give an idea of the magnitudes of the parameter, predicted values for $C_{nn}(90^\circ)$ are shown in Fig. 2 as functions of energy for the pion potential of Hamada *et al.* (1960) and the potential of Gammel and Thaler (1957). The numerical values of the predictions should not be taken too seriously, because they are subject to change due to small modifications in the inner potentials of both the singlet and triplet states. The determination is indispensable for the further search for the genuine phase shift solution. An accuracy to better than 10% is desirable.

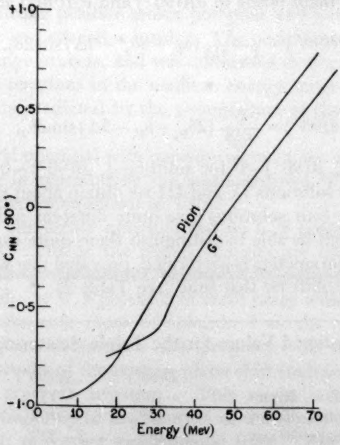


Fig. 2. Predicted values for $C_{nn}(90^\circ)$. Pion, Hamada *et al.* pion potential; GT, Gammel–Thaler potential.

Another simple correlation parameter is C_{kp}. This is given as

$$\sigma C_{\mathrm{kp}}(\theta) \sim \frac{\sin\theta}{k^2}\left\{\frac{3}{100}(\delta_{\mathrm{P}_0}+8\delta_{\mathrm{P}_1}-9\Delta)^2-\frac{9}{50}(2\delta_{\mathrm{P}_0}+\delta_{\mathrm{P}_1}-3\Delta)^2\right\},$$

$$\begin{aligned} C_{\mathrm{kp}} &> 0 \quad \text{for the solutions I and IV,} \\ &< 0 \quad \text{for the solutions II and III.} \end{aligned} \qquad \ldots\ldots(11)$$

This parameter is of the order of magnitude $\delta_{\mathrm{P}_J}{}^2$ ($\lesssim 20\%$ at 40 MEV) and must be measured to approximately 5%. The angular dependence is of $\sin\theta$ form and probably of little interest. Various modifications of the pion potential give diverse predictions for the parameter.

3.3. *Triple Scattering Parameters*

The best way of distinguishing the four possible solutions is to measure the triple scattering parameters. For the second scattering we use an incident beam with spin polarization, i.e. a beam with a definite phase relation between the singlet and triplet waves. Thus we can detect the interference of the singlet and triplet scatterings by measuring the polarization of the beam after scattering. Since the singlet scattering is of known sign and very large at low energies, the triple scattering parameters are, in general, rather large and their signs are determined by those of the $^3\mathrm{P}_J$ phase shifts. For this reason they are very useful in distinguishing between the four possible solutions.

For example, the main terms in $\sigma R(90°)$ and $\sigma A(90°)$ are given as

$$\sigma R(90°) \sim \frac{3}{5\sqrt{2}k^2}(\delta_{\mathrm{P}_0}+8\delta_{\mathrm{P}_1}-9\Delta)\sin 2\delta_0, \qquad \ldots\ldots(12)$$

and

$$\sigma A(90°) \sim \frac{3\sqrt{2}}{5k^2}(2\delta_{\mathrm{P}_0}+\delta_{\mathrm{P}_1}-3\Delta)\sin 2\delta_0. \qquad \ldots\ldots(13)$$

Thus $R(90°) \ll 0$ and $A(90°) \sim 0$ for solution I, $R(90°) \sim 0$ and $A(90°) \gg 0$ for solution II. For the solutions IV and III we obtain about the same figures with opposite signs. The four solutions give quite different predictions for the two parameters and we shall be able to distinguish them quite easily when a measurement of one of these parameters is performed, provided that we know the probable value of the ^{1}S phase shift by that time (see Table 2).

Table 2. Predicted Values for the Triple Scattering Parameters

			$D(60°)$	$R(90°)$	$A(90°)$
(*a*)	Hamada *et al.* pion potential	20 MEV	−15%	−15%	+30%
		40 MEV	−33%	−30%	+56%
	Gammel–Thaler potential	20 MEV	−14%	−22%	+21%
		40 MEV	−18%	−42%	+27%
		Solution	$D(60°)$	$R(75°)$	$A(75°)$
(*b*)	MacGregor	I	−10%	−25%	+ 4%
	18·2 MEV	II	−11%	− 9%	+32%
	$\delta_0 = 50°$	III	+ 6%	+ 9%	−21%
	$\delta_2 = 0{\cdot}4°$	IV	+ 7%	+31%	0

For the depolarization parameter $D(\theta)$ the situation is slightly different. The $^1\mathrm{S}$–$^3\mathrm{P}_J$ interference vanishes at 90°, where the leading term is of the order of magnitude $\delta_{P_J}{}^2$. However, at angles around 60°, the $\cos\theta$ term becomes dominant and has different values for the four solutions.

$$\sigma D(\theta) \sim \frac{3}{5k^2}\cos\theta(-\delta_{P_0}+2\delta_{P_1}+\Delta)\sin 2\delta_0. \qquad \ldots\ldots (14)$$

The predicted values based on Hamada *et al.* pion potential and the Gammel–Thaler potential at 20 and 40 MeV are shown in Table 2 with some predictions by MacGregor at 18 MeV. For the fuller tabulation of MacGregor's predictions readers are referred to the original paper (MacGregor 1959). It is confirmed that a very rough measurement of $R(90°)$ or $A(90°)$ will suffice to resolve the ambiguity in the phase shift analysis. The best way is first to measure $C_{nn}(90°)$ to pin down the value of the ^{1}S phase shift and then to perform one measurement of $R(90°)$ or $A(90°)$ at the same energy. An accuracy to about 5% will be enough for the triple scattering measurement.

§ 4. THE PREDICTIONS BASED ON THE PION THEORETICAL POTENTIAL†

4.1. *p–p Scattering above* 5 MeV

Recently it has been shown that the pion theoretical potential supplemented with a kind of phenomenological potential in the inner region (the so-called Hamada *et al.* pion potential) can reproduce very well the p–p angular distribution below 70 MeV (Hamada *et al.* 1960). The potential in the triplet odd state consists of a strong positive tensor potential and a central potential which is repulsive outside and attractive inside. The positive tensor potential is due to the one-pion exchange process, and was confirmed in the analysis of the angular distribution in γ–d reactions in the medium energy range (Iwadare *et al.* 1956). The ^3P_J phase shifts predicted by the potential are of the same type as those in solutions I and II.

The weak central potential with opposite signs in the outer and inner regions is very satisfactory in reproducing the small effective ^{3}P phase shift Δ and its peculiar energy dependence shown in Table 1.

If there is only the tensor potential and no **L . S** potential in the triplet odd state, the ^3P_J phase shifts at the higher energies are more similar to those of solution II than to those of solution I, because of the enhancement of the attractive force. If there is also an **L . S** potential of short range with negative sign then the phase shifts will approach those of solution I as the energy increases. The Gammel–Thaler phase shifts show this property. At high energies of a few hundred MeV, the results of the existing phase shift analyses suggest that the signs of the δ_{P_0} and δ_{P_1} are both negative. This might indicate that the genuine solution would fit smoothly to the solution of the type I at low energies. This point should be left to further experimental tests. The predicted phase shifts for the Hamada *et al.* pion potential and the Gammel–Thaler potential are shown in Fig. 1 where they are available.

The ^{1}D wave phase shift is determined by the outer part of the singlet even potential and is evaluated fairly accurately in the energy range under consideration.

---

† Similar considerations were reported by Hamada, Otsuki, Tamagaki and Watari at the nuclear force seminar which was held in Tokyo in 1959. Some figures used in this paragraph were taken from the unpublished results by Hamada, Otsuki, Tamagaki and Watari. The author would like to express his sincere thanks to Drs. Hamada, Otsuki, Tamagaki and Watari for making their results available prior to publication.

Predicted values are plotted in Fig. 3. This information can be used to deduce the value of the ^{1}S phase shifts from the experimental value of $C_{\mathrm{nn}}(90°)$.

4.2. *p–p Scattering below* 5 MeV

For some years it has been believed that the angular distribution of the p–p scattering below 5 MeV provides direct evidence for the presence of the one-pion exchange potential in the ^{3}P state (Otsuki and Tamagaki 1954, 1955). Recently, however, it has been recognized that there are a few corrections to be made on the experimental data before they can be compared with the predictions of a nuclear potential (Erikson, Foldy and Rarita 1956, Ohmura, report at 1958 Tokyo Nuclear Seminar, Durrand 1957). These corrections reduce the magnitude of the effective ^{3}P nuclear phase shift Δ to some extent. Thus it is necessary to re-examine the experimental data in the light of this new development. (The figures at 4·2 MeV in Table 1 are already corrected for the effect.)

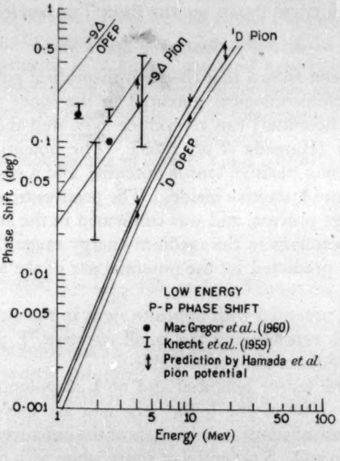

Fig. 3. p–p scattering phase shifts at low energies. Pion, Hamada *et al.* pion potential; OPEP, one-pion exchange potential.

Knecht *et al.* (1959) remeasured the p–p angular distribution and analysed the results in terms of the ^{1}S and effective ^{3}P phase shifts after correcting them for the vacuum polarization effect. MacGregor, Moravcsik and Noyes (1960) re-analysed the same data taking proper account of the higher wave scattering by the one-pion exchange potential. MacGregor (1959) also performed a conventional phase shift analysis of Worthington's old data at 4·2 MeV in terms of the ^{1}S, ^{1}D and ${}^3P_J$ phase shifts. Their results are shown in Fig. 3. The resulting ^{3}P phase shifts at 4·2, 2·4 and 1·85 MeV show $E^{3/2}$ energy dependence as expected. The point at 1·4 MeV is far higher than that obtained from the extrapolation of the other values. This seems to be due to experimental uncertainty, exaggerated by a method of phase shift analysis that was too rigid. If this peculiar energy dependence should turn out to be real, there must be some other effects, which have so far been overlooked, to be taken into account.

The calculation with the Hamada *et al.* pion potential at 4 MeV predicts an effective ^{3}P phase shift of $-0{\cdot}02°$ to $-0{\cdot}035°$. The extrapolation of this value to the low energy side just covers the phenomenological values at 2·4 and 1·85 MeV. In the course of their analysis MacGregor, Moravcsik and Noyes (1960) note that the one-pion exchange contribution to the ^{3}P scattering destroys the fit to the observed angular distribution even at 1·85 MeV. This is expected from the shape of the actual potential. The unperturbed wave for the P state has a radial dependence of kr for $kr \ll 1$. If the potential is rather singular and, in the calculation of the Born phase shift, the contribution to the integral

$$\int_0^\infty r^2 V(r) dr$$

from the inner region (due to the two-pion exchange) is comparable with that from the outer region (due to the one-pion exchange), then one is not justified in using the one-pion exchange approximation even when the impact parameter is much larger than unity. This is by no means an objection against the presence of the one-pion exchange potential in the outer region. The predicted values for the effective ^{3}P phase shift Δ based on the Hamada *et al.* pion potential and the one-pion exchange potential shown in Fig. 3 illustrate this point quite clearly.

Note added during revision:

Recently there has been a new contribution on this subject. Dr. R. J. N. Phillips has looked into the n–p polarization at low energies. He found that the sign and the magnitude of the polarization are essentially determined by $^3S_0$ and ^3P_J phase shifts. Assuming a reasonable value for the former phase shift, which is insensitive to the answer, he concluded that the preliminary data exclude solutions II and IV, thus leaving only solution I as the physically acceptable one.

ACKNOWLEDGMENTS

The author's appreciations are due to Drs. T. Hamada, S. Otsuki, R. Tamagaki and W. Watari for their comments and for making their unpublished results available to him. He is very grateful to Prof. A. Klein for his hospitality at the Physics Department of the University of Pennsylvania. A part of this work was performed during the author's stay at the Physics Department of the University College London, as a visiting fellow of the Department of Scientific and Industrial Research. He would like to express his thanks to the Department of Scientific and Industrial Research for the fellowship, and to Professor Sir Harrie Massey, for his hospitality. He thanks Dr. E. H. S. Burhop and Dr. T. C. Griffith for their interest in and stimulating discussions on this work. The work was supported in part by the United States Atomic Energy Commission.

The Band Spectrum of a CuAg Molecule in the Visible Region

By K. C. JOSHI† and K. MAJUMDAR
Physics Department, Allahabad University, India

MS. received 15*th February* 1961

Abstract. The emission spectrum of a CuAg molecule in the visible region has been investigated in thermal emission at 1800°c in a vacuum graphite furnace. Bands have been observed in the region λλ4090–3790. All these bands are degraded to red and have been classified in one band system ascribed as A–X. The bands can be represented by the equation

$$\nu_{v'v''}=25\,851{\cdot}6+178{\cdot}5(v'+\tfrac{1}{2})-0{\cdot}50(v'+\tfrac{1}{2})^2-231{\cdot}8(v''+\tfrac{1}{2})+0{\cdot}80(v''+\tfrac{1}{2})^2.$$

§ 1. Introduction

The study of spectra of molecules in thermal emission is full of possibilities, though not much work has been done in this direction. The process of emission is very simple as there is no electrical stimulus or chemical reaction as in other modes of excitation. The intensities of bands and band lines are expected to be governed by Maxwellian distribution. Ruamps (1954), Kleman *et al.* (1951) and Kleman and Lindkvist (1954, 1955) investigated the spectra of Ib–Ib molecules, viz. Cu_2, Au_2, CuAu and Ag_2 in thermal emission. Although there is not much regularity in the spectroscopic behaviour of these molecules, one can expect the formation of similar molecules, e.g. CuAg and AgAu. It was with a view to studying the spectra of such molecules that this investigation was undertaken. The present communication is concerned with the study of the spectrum of CuAg.

§ 2. Experimental

A high temperature vacuum graphite furnace, capable of attaining temperatures of the order of 2300°c was used during this investigation (see Figure). Its main features are the outer covering, ABC and the furnace tube FF made of graphite. The covering and the electrodes EE are kept cool by a continuous flow of water. The tube is clamped to the electrodes with the help of graphite blocks GG and is thus kept in a horizontal position in line with the quartz windows QQ. The tube is heated by passing through it a large current from a 10 kw step down transformer. To reduce the loss of heat from the furnace tube by radiation and thus to enable higher temperatures to be attained, the tube is surrounded by a cylindrical mantle M of iron kept at some distance from it.

Spectroscopically pure samples of copper and silver from Messrs. Johnson Matthey, London, were inserted into the graphite tube of the furnace which was 8 cm long and had an inner diameter of 0·5 cm. The tube was placed inside the vacuum furnace. After evacuation of air, nitrogen gas at a pressure of about 50 cm Hg was introduced into the furnace. This was done in order to reduce effusion of the vapours from the graphite tube. The sample was then heated by passing an electric current through the tube and observations were made at various temperatures ranging from 600°c to 2300°c. The spectrograph was pointed towards the tube of the furnace so as to receive the radiations emitted by the hot vapours. Care was taken to prevent radiations from the sides of the furnace tube from reaching the spectrograph. Well-defined bands in the region λλ 4090–3790 were obtained at a temperature of about 1800°c. A Hilger E492 large quartz spectrograph was used with an average reciprocal dispersion of 11 Å mm^{-1} in this region. Kodak 103-F spectroscopic plates and Ilford R.40 plates were used for recording the spectrum. The optimum exposure time was from 5 to 10 minutes. A copper arc was used for obtaining a comparison spectrum.

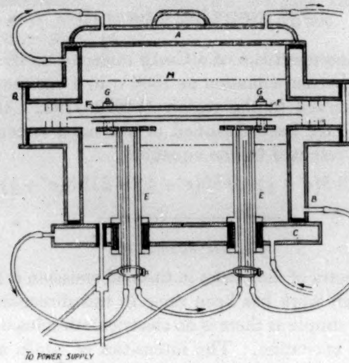
† Now at Air Force Cambridge Research Laboratories, Bedford, Massachusetts, U.S.A.



Vacuum graphite furnace.

§ 3. RESULTS

About 40 bands, all degraded to the red, were observed. Table 1 gives the wavelengths of the band heads, their visual relative intensities and the corresponding wave numbers in cm^{-1}. It also gives the wave numbers calculated by using the proposed formula and the vibrational assignment of each band. All these bands can be fitted in a Deslandres scheme shown in Table 2. Table 3 gives the distribution of band intensities. The most intense bands lie on a Condon parabola. The spectrogram for the bands of the molecule shows that the heads of the bands can be represented by the following equation derived from the experimental data:

$$\nu_{v'v''}=25\,851{\cdot}6+178{\cdot}5(v'+\tfrac{1}{2})-0{\cdot}50(v'+\tfrac{1}{2})^2-231{\cdot}8(v''+\tfrac{1}{2})+0{\cdot}80(v''+\tfrac{1}{2})^2.$$

§ 4. DISCUSSION

The bands which are obtained by heating a mixture of copper and silver appear in the region λλ 4090–3790, where no bands due to the molecules Cu$_2$ or Ag$_2$ are known to be present. When either copper or silver alone was put in the experimental tube these bands did not make their appearance, showing thereby

that the bands are not due to either of the molecules Cu_2 or Ag_2. Some observations were also made without introducing nitrogen gas into the chamber when the tube containing the mixture of copper and silver was heated. The bands appeared in this case also, but with slightly diminished intensity. On heating the graphite tube alone, there was no trace of any bands. These experimental facts suggest that the bands observed have nothing to do with the nitrogen introduced into the furnace chamber or the carbon of the graphite tube. They also indicate that for the production of these bands copper and silver are the two necessary elements.

Now, in view of the fact that these bands appear in thermal emission—a process of low energy excitation—the electronic states involved in their emission must be low-lying states, A and X, of which the lower state X is, in all probability, the ground state of the molecule. The value for the vibrational frequency of the lower state of the molecule has been found to be $231{\cdot}8\ \text{cm}^{-1}$. This value lies between the values of the ground state vibration frequencies for Cu_2 and Ag_2 which are $266{\cdot}1\ \text{cm}^{-1}$ and $192{\cdot}4\ \text{cm}^{-1}$ respectively. This fact suggests that the molecule is heavier than the Cu_2 and lighter than the Ag_2 molecule. It is, therefore, not unreasonable to consider the molecule CuAg as the emitter of these bands.

The low values of the vibrational frequencies of the two states suggest that the molecule under consideration should not be confused with a hydride, a carbide, a nitride or an oxide of copper or of silver. In all such cases the molecules are comparatively much too light and are not expected to have frequencies of the order of 200 to $300\ \text{cm}^{-1}$.

Further, the vibrational analysis of the bands from experimental data gives a value for the frequency of the lower (ground) state of the molecule which agrees with the values that can be predicted for the frequency of the diatomic molecule CuAg from other empirical considerations. If we take the value for the ground state frequency of Cu_2 molecule as $266{\cdot}1\ \text{cm}^{-1}$ and that of Ag_2 molecule as $192{\cdot}4\ \text{cm}^{-1}$ and apply the empirical formula proposed by Majumdar and Varshni (1954), we find that the value for the ground state frequency for the CuAg molecule comes out to be $228{\cdot}2\ \text{cm}^{-1}$, which is almost the same as the experimental value $231{\cdot}8\ \text{cm}^{-1}$.

The association of the system with the ground state was shown by the self-absorption of some of the most intense bands. The low dispersion of the spectrograph did not permit of a study of the isotopic effect in the system.

Lines of the N v Spectrum in the Visible and Near Ultra-violet Wavelength Regions

By R. HALLIN† and T. P. HUGHES‡

† Department of Physics, University of Uppsala, Uppsala, Sweden
‡ Research Laboratory, Associated Electrical Industries, Aldermaston Court, Aldermaston, Berkshire

Communicated by D. R. Chick; MS. received 14th March 1961

Abstract. Measured wavelengths of several N v lines emitted from the toroidal gas discharge apparatus SCEPTRE III are given. For hydrogenic transitions they agree closely with the predictions of a polarization formula due to Edlén. Observations of 6–7 transitions are compared with those reported by Lukianov and Sinitsyn which, being made at higher pressures, were probably more strongly influenced by the Stark effect. The possibility of using the Stark effect in high quantum number transitions in Li sequence atoms such as C IV, N V or O VI for density measurements is discussed briefly.

SOME broad lines emitted in the visible and near ultra-violet wavelength regions from the toroidal high current gas discharge apparatus SCEPTRE III (Allen *et al.* 1958) have been identified as belonging to the N v spectrum. In this note, measured wavelengths are presented which agree closely with the predictions of a polarization formula given by Edlén.

The discharge conditions required to excite the lines were not critical. We used an initial axial magnetic field (B_{ϕ_0}) of 500 G, and discharged a 150 μF condenser bank at 20 kV into an 8-turn primary winding, thus producing a gas current of about 10^5 A. The duration of each discharge was about 750 μsec, and 1000 discharges were required for each exposure.

The lines were recorded using a Hilger medium spectrograph with interchangeable glass and quartz optics. The discharge was viewed radially so as to avoid errors due to Doppler displacement of the wavelengths (Hughes and Kaufman 1959). Identification of the lines was facilitated by comparing the spectra obtained with a fixed initial pressure of deuterium (1·8 mtorr) in the torus when different proportions of nitrogen (0, 5, 10, 20, 50, 100% of deuterium pressure) were added. The N v lines were strongest with 20% of added nitrogen. Additional evidence was obtained from the breadths of the lines (Kaufman, Hughes and Williams 1960), and from a comparison with Bockasten's (1956) observations on the isoelectronic C IV spectrum.

Cu II and Cu I lines excited in the discharge itself were used as wavelength standards. The measured wavelengths of the N v lines are shown in the second column of the Table. The uncertainty is ±0·05 Å except for two blended lines for which it is about ±0·2 Å.

Hydrogen-like term values T were calculated from the following polarization formula given by Edlén (1961)

$$T = T_H + \Delta p,$$

where T_H is the hydrogenic term value including the Sommerfeld relativistic correction and the polarization energy is

$$\Delta p = 2{\cdot}887R\phi(n, l)\left[1+2{\cdot}982\,\frac{\psi(n, l)}{\phi(n, l)}\right].$$

Here R is the Rydberg constant and the functions $\phi(n, l)$, $\psi(n, l)$ have been tabulated by Bockasten (1956). Wavelengths obtained from these term values are given in the third column of the Table. We were unable to resolve the components of the fundamental bands (Edlén 1956) of the transition groups 5–6, 6–7, 6–8 and 7–9. The centroids of the strongest components of each unresolved band were therefore calculated from hydrogen-like relative intensities obtained using recent values (Herdan and Hughes 1961) of Gordon's expression for the radial integral $R^{n', l-1}_{n, l}$. Both statistical and dynamical excitation (Bethe and Salpeter 1957) were considered, and the corresponding centroids S and D are given in columns 4 and 5 of the Table. Dynamical excitation is probably the better approximation for these levels in the SCEPTRE discharge, although cascade processes are neglected. As may be seen from the table, the observed wavelengths and the theoretical centroids are in good agreement.

Wavelengths of N V Lines

Intensity	λ(air)$_{obs}$ (Å)	λ(air)$_{calc}$ (Å)	Calc. centroid (Å) D	S	Transition
4	4944·53	4944·72 4944·48 4943·59	4944·54	4944·45	6h–7i 6g–7h 6f–7g
2 bl. N II	4619·9				$3s^2S_{1/2}$–$3p^2P_{1/2}$
3	4603·83				$3s^2S_{1/2}$–$3p^2P_{3/2}$
1 bl. N III	4519·9	4519·87 4519·81 4519·66 4519·15	4519·77	4519·68	7i–9k 7h–9i 7g–9h 7f–9g
3	2998·45	2998·55 2998·45 2998·09	2998·44	2998·39	6h–8i 6g–8h 6f–8g
6	2981·24	2981·36 2980·81	2981·21	2981·17	5g–6h 5f–6g
4	2974·38	2974·21			5d–6f

Lukianov and Sinitsyn (1958) added small quantities of nitrogen to hydrogen in a fast linear pinched discharge device, and identified broad lines at 4943 Å and 4945 Å as being N V (6f–7g) and N V (6g–7h). These lines appeared close to the instant of maximum contraction, when the ion density was about 10^{17} cm^{-3}, and in Fig. 5 of the paper referred to they are separated by about 2·4 Å. In SCEPTRE, where the maximum ion density was about 5×10^{14} cm^{-3}, we have found that the wavelength difference between (6f–7g) and (6g, h–7h, i) must be smaller than 1·2 Å. It seems probable from a consideration of Bockasten's (1956) perturbation calculations for the isoelectronic C IV atom that the difference between these results is due to the greater Stark effect at higher density.

We observe the transition $3^2S_{1/2}$–$3^2P_{3/2}$ to be stronger than $3^2S_{1/2}$–$3^2P_{1/2}$, as might be expected. Lukianov and Sinitsyn report only the latter component.

The possibility of using the Stark effect in lines corresponding to high quantum number transitions in atoms of the Li isoelectronic sequence for measuring plasma density is attractive. C IV, N V and O VI have convenient excitation potentials, and CO_2 and N_2, for example, are easily introduced into the discharge space. The lines will be influenced also by the Doppler effect, but fortunately this may be determined independently from observations on the 3s–3p transitions, which are virtually free from Stark effect. A convolution calculation would then give the true Stark effect. In this respect, Li sequence atoms have a distinct advantage over those of the H sequence. Accurate theoretical calculation of the Stark effect is a formidable task, and in the absence of some empirical calibration the method might be limited initially to applications such as the estimation of density variations during a discharge from time-resolved spectrograms.

ACKNOWLEDGMENTS

We are indebted to Professor B. Edlén of the University of Lund for his interest in the work, and especially for providing us with the polarization formula quoted above in advance of publication. We are grateful to Professor K. Siegbahn and Dr. K. Bockasten of the University of Uppsala for their encouragement and advice, and to Mr. R. F. Hemmings, Mr. J. E. Read and others responsible for the operation and maintenance of SCEPTRE III for their assistance. The work was supported in part by a contract from the Atomic Energy Research Establishment, Harwell. The visit of R. Hallin to England was sponsored by the United States Air Force, Air Research and Development Command, through its European Office. This paper is published with the permission of Dr. T. E. Allibone, Director of the Research Laboratory, Associated Electrical Industries, Aldermaston Court.

The Phonon-assisted Auger Effect in Semiconductors

By D. M. EAGLES

Services Electronics Research Laboratory, Baldock, Herts.

MS. received 22nd August 1960, *in revised form* 19th *December* 1960

Abstract. Some calculations on the effect of phonons on Auger recombination and impact ionization in semiconductors with simple bands are presented. It is shown that phonon-assisted Auger recombination will dominate the direct Auger process at low temperatures, and that in highly doped specimens the recombination rate due to the phonon-assisted Auger effect can be comparable with rates generally expected from other mechanisms. At low carrier temperatures the rate of phonon-assisted impact ionization will be greater than the direct impact ionization rate. However, phonon-assisted impact ionization may be difficult to detect because of other complications.

§ 1. Introduction

One of the most important parameters determining the usefulness of semiconductors for devices is the lifetime of excess carriers injected into the material. In nearly all semiconductor specimens so far produced the lifetime is determined by recombination through impurities or other defects; however the experimental results on lifetime in InSb at high temperatures can be fitted to a theory of Beattie and Landsberg (1958) involving transitions in which an electron and a hole recombine directly, giving up their energy to a third free-carrier. This type of recombination is known as Auger recombination because of its analogy to the recombination occurring in the Auger effect in atoms.

Beattie and Landsberg's treatment of the problem is based on the assumption that the conduction and valence bands of a semiconductor are simple. The recombination probabilities are calculated by using first order, time-dependent perturbation theory, with a screened Coulomb interaction between the electrons as the perturbation. A factor which reduces the importance of the effect is that transitions from states in which the initial particles have small crystal momentum are not possible, since both energy and momentum conservation conditions have to be satisfied in a transition. However, this conservation difficulty can be overcome if a phonon is emitted or absorbed in the process, the phonon having large momentum but not much energy. Some calculations on this phonon-assisted Auger effect are given in this paper, with the principal aim of seeing whether the advantage of transitions from lower energy states being allowed can more than counter-balance the decrease in transition probabilities when phonons are involved. The paper also contains a discussion of the inverse process of impact ionization. Here again the emission or absorption of a phonon can be of assistance in that it lowers the threshold energy above which ionization can occur. This may be of importance in theories of carrier multiplication and avalanche breakdown.

In § 2 we make approximate calculations of transition probabilities, using second order, time-dependent perturbation theory, with the Coulomb interaction between the electrons plus the electron–phonon interaction as the perturbation. These results are used in § 3 to calculate the lifetime that would occur in a semiconductor with simple bands if the phonon-assisted Auger process were the dominant recombination mechanism. In § 4 a consideration of impact ionization rates is given, and § 5 contains a discussion of the results of the previous sections.

§ 2. TRANSITION PROBABILITIES

The four basic types of Auger transition in which we are interested are represented in Fig. 1 (which is reproduced from Beattie and Landsberg's article). Two of these ((*a*) and (*c*) in the Figure) show recombination processes in which the energy released by the destruction of an electron–hole pair is given up either to an electron or to a hole; the other two ((*b*) and (*d*)) represent the impact ionization transitions which are the inverses of (*a*) and (*c*).

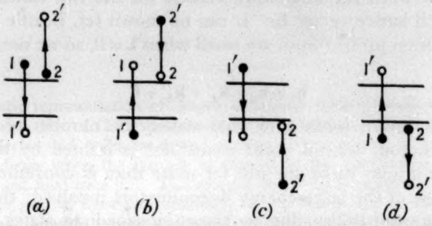

Fig. 1. Auger effects leading to the creation and destruction of an electron–hole pair in a semiconductor. (*a*) Destruction of a pair by electron–electron collision, (*b*) creation of a pair by the reverse effect, (*c*) destruction of a pair by hole–hole collision, (*d*) creation of a pair by the reverse effect. (This figure is reproduced from Beattie and Landsberg 1958.)

In this section we shall attempt to calculate the probabilities for the occurrence of transitions of type (*a*) for the case where a phonon is emitted or absorbed while the electronic transitions are taking place. We shall treat the problem by using second order, time-dependent perturbation theory, assuming that the one-electron wave functions for the conduction and valence bands of the crystal are known, and finding approximate matrix elements for the transitions in terms of integrals involving these functions. The perturbing Hamiltonian H' will be taken as

$$H' = H^{\mathrm{c}} + H^{\mathrm{e-p}} \qquad \ldots\ldots (2.1)$$

where H^{c} is the difference, due to the Coulomb interaction of electrons, between the complete Hamiltonian for the crystal and the Hamiltonian which is used in the one-electron approximation, and $H^{\mathrm{e-p}}$ denotes that part of the Hamiltonian involving the electron–phonon interaction.

Let us now consider a particular transition of type (*a*). Suppose that two electrons of wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ in the conduction band and a hole of wave vector $(-\mathbf{k}_1')$ in the valence band† are destroyed and are replaced by a single, high-energy electron of wave vector $\mathbf{k}_2'$ in the conduction band, a phonon of wave vector $\mathbf{f}$ being emitted during the process. Various cases arise because of the different possible spin states of the particles involved, but there are only two essentially different types of spin configurations for which transitions are allowed. Typical states for the two cases may be represented as follows:

---

† If there is an electron missing from a state in the valence band with wave vector $\mathbf{k}$ and spin $(+)$ then we say the band contains a hole with wave vector $(-\mathbf{k})$ and spin $(-)$.

$$\begin{array}{lll}\text{Case (i)} & \text{initial state} & |\mathrm{a}\rangle=|\mathbf{k}_1+,\ 1\mathrm{e};\ \mathbf{k}_2+,\ 1\mathrm{e};-\mathbf{k}_1'-,\ 1\mathrm{h};\ \mathbf{f},N\rangle \\ & \text{final state} & |\mathrm{f}\rangle=|\mathbf{k}_2'+,\ 1\mathrm{e};\ \mathbf{f},\ N+1\rangle \\ \text{Case (ii)} & \text{initial state} & |\mathrm{a}\rangle=|\mathbf{k}_1+,\ 1\mathrm{e};\ \mathbf{k}_2-,\ 1\mathrm{e};\ -\mathbf{k}_1'-,\ 1\mathrm{h};\ \mathbf{f},N\rangle \\ & \text{final state} & |\mathrm{f}\rangle=|\mathbf{k}_2'-,\ 1\mathrm{e};\ \mathbf{f},\ N+1\rangle. \end{array} \qquad \ldots\ldots(2.2)$$

Here a symbol such as $|\mathbf{k}_1+,\ 1\mathrm{e};\ \mathbf{k}_2+,\ 1\mathrm{e};\ -\mathbf{k}_1'-,\ 1\mathrm{h};\ \mathbf{f},\ N\rangle$ indicates a state containing electrons of wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ and spin (+) in the conduction band, a hole of wave vector $(-\mathbf{k}_1')$ and spin (−) in the valence band, and N phonons of wave vector $\mathbf{f}$ in the branch of the phonon spectrum being considered.

Transitions between the above initial and final states will only be possible if the difference between the total wave vectors for the two states is equal to 2π times a reciprocal lattice vector $\mathbf{L}$. It can be shown (cf. Beattie and Landsberg 1958) that transition probabilities are small when $\mathbf{L}\neq 0$, so we need only consider cases where

$$\mathbf{k}_1+\mathbf{k}_2=\mathbf{k}_1'+\mathbf{k}_2'+\mathbf{f}. \qquad \ldots\ldots(2.3)$$

Although, for given initial and final states, the number of possible intermediate states for our second order transitions is limited by the wave vector conservation condition, there are still far more than is convenient to consider. However, because of the large energy denominators involved, the contribution to the transition probability due to those intermediate states which require creation and destruction of electrons in bands above the conduction band or holes in bands below the valence band is likely to be small. If these intermediate states are ignored the number to be considered is reduced to seven.

The seven intermediate states for our two cases (spin directions for case (ii) being put in brackets) are:

$$\left.\begin{array}{l} |1\rangle=|\mathbf{k}_1-\mathbf{f}+(+),\ 1\mathrm{e};\ \mathbf{k}_2+(-),\ 1\mathrm{e};\ -\mathbf{k}_1'-(-),\ 1\mathrm{h};\ \mathbf{f},\ N+1\rangle \\ |2\rangle=|\mathbf{k}_1+(+),\ 1\mathrm{e};\ \mathbf{k}_2-\mathbf{f}+(-),\ 1\mathrm{e};\ -\mathbf{k}_1'-(-),\ 1\mathrm{h};\ \mathbf{f},\ N+1\rangle \\ |3\rangle=|\mathbf{k}_1+(+),\ 1\mathrm{e};\ \mathbf{k}_2+(-),\ 1\mathrm{e};\ -\mathbf{k}_1'-\mathbf{f}-(-),\ 1\mathrm{h};\ \mathbf{f},\ N+1\rangle \\ |4\rangle=|\mathbf{k}_1+(+),\ 1\mathrm{e};\ \mathbf{k}_2'+(-),\ 1\mathrm{e};\ -\mathbf{k}_1+\mathbf{f}-(-),\ 1\mathrm{h};\ \mathbf{f},\ N\rangle \\ |5\rangle=|\mathbf{k}_2'+(-),\ 1\mathrm{e};\ \mathbf{k}_2+(-),\ 1\mathrm{e};\ -\mathbf{k}_2+\mathbf{f}-(+),\ 1\mathrm{h};\ \mathbf{f},\ N\rangle \\ |6\rangle=|\mathbf{k}_2'+(-),\ 1\mathrm{e};\ \mathbf{k}_1'+\mathbf{f}+(+),\ 1\mathrm{e};\ -\mathbf{k}_1'-(-),\ 1\mathrm{h};\ \mathbf{f},\ N\rangle \\ |7\rangle=|\mathbf{k}_2'+\mathbf{f}+(-),\ 1\mathrm{e};\ \mathbf{f},\ N\rangle. \end{array}\right\}\ldots\ldots(2.4)$$

For transitions through states $|1\rangle$ to $|3\rangle$ a phonon is emitted first and then the Auger mechanism takes over, while for states $|4\rangle$ to $|7\rangle$ this order is reversed. As an example transitions via intermediate state $|3\rangle$ are represented schematically in Fig. 2 for a semiconductor with simple bands, the initial wave vectors $\mathbf{k}_1$, $\mathbf{k}_2$ and $-\mathbf{k}_1'$ having been taken to be small.

Before proceeding further in the calculations it is necessary to choose explicit forms for H^{c} and $H^{\mathrm{e-p}}$.

We shall assume that H^{c}, the difference due to Coulomb interactions between the complete Hamiltonian and that of the one-electron approximation is given by

$$H^{\mathrm{c}}\equiv \tfrac{1}{2}\sum_{i,j}\frac{e^2}{\epsilon r_{ij}}\exp(-\lambda r_{ij}). \qquad \ldots\ldots(2.5)$$

Here $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$, where $\mathbf{r}_i$ and $\mathbf{r}_j$ are the position vectors of the ith and jth electrons, ϵ is an effective dielectric constant to be used in our problem† and the summation is over all pairs of electrons.

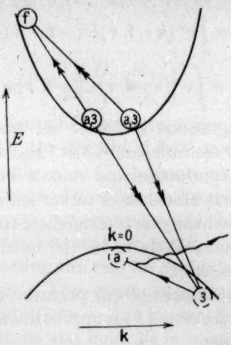

Fig. 2. Schematic representation of Auger transitions with phonon emission via intermediate state $|3\rangle$ of (2.4) shown on an E–$\mathbf{k}$ diagram. Electrons are represented by full circles and holes by dotted circles. The symbols a, 3 and f inside the circles indicate when the particle is present in the initial state $|a\rangle$, intermediate state $|3\rangle$ and final state $|f\rangle$. The straight lines denote electronic transitions; single arrows are put on lines corresponding to transitions due to the electron–phonon interaction; double arrows indicate Coulomb-induced transitions. A wavy line leaving a straight line indicates the emission of a phonon.

The part $H^{e-p'}$ of the electron–phonon interaction due to the branch of the phonon spectrum being considered will be written in the form

$$H^{e-p'} \equiv \frac{1}{(N')^{1/2}} \sum_{\mathbf{f}, i} a(\mathbf{f}) U(\mathbf{f}, \mathbf{r}_i) \exp(i\mathbf{f} \,.\, \mathbf{r}_i) \qquad \ldots\ldots (2.6)$$

where N' is the number of unit cells in the crystal, $a(\mathbf{f})$ is the normal coordinate of the mode of wave vector $\mathbf{f}$, U is a periodic function with the dimensions of energy divided by length, and the summation is over all wave vectors $\mathbf{f}$ and all electron coordinates $\mathbf{r}_i$. This form of $H^{e-p'}$ is likely to be a good approximation provided that the displacements of atoms from their equilibrium positions are small.

Having chosen forms for H^c and $H^{e-p'}$ it is fairly straightforward to work out the matrix elements required for second order transitions between the initial and final states of (2.2). The Coulomb matrix elements will involve integrals over the crystal of the periodic parts $u(\mathbf{k}, \mathbf{r})$ and $v(\mathbf{k}, \mathbf{r})$ of the electronic wave functions for the conduction and valence bands; we define these integrals by

$$\left.\begin{aligned} I_{cc}(\mathbf{k}, \mathbf{k}') &\equiv \int u^*(\mathbf{k}, \mathbf{r}) u(\mathbf{k}', \mathbf{r}) d\tau \\ I_{cv}(\mathbf{k}, \mathbf{k}') &\equiv \int u^*(\mathbf{k}, \mathbf{r}) v(\mathbf{k}', \mathbf{r}) d\tau \\ I_{vc}(\mathbf{k}, \mathbf{k}') &\equiv \int v^*(\mathbf{k}, \mathbf{r}) u(\mathbf{k}', \mathbf{r}) d\tau \\ I_{vv}(\mathbf{k}, \mathbf{k}') &\equiv \int v^*(\mathbf{k}, \mathbf{r}) v(\mathbf{k}', \mathbf{r}) d\tau. \end{aligned}\right\} \qquad \ldots\ldots (2.7)$$

---

† See the discussion in § 5.

The electron–phonon matrix elements will contain functions C, D, E defined by

$$\left.\begin{aligned} f\,C(\mathbf{k},\mathbf{f}) &\equiv \int u^*(\mathbf{k}-\mathbf{f},\mathbf{r})U(-\mathbf{f},\mathbf{r})u(\mathbf{k},\mathbf{r})d\tau \\ f\,D(\mathbf{k},\mathbf{f}) &\equiv \int v^*(\mathbf{k}-\mathbf{f},\mathbf{r})U(-\mathbf{f},\mathbf{r})v(\mathbf{k},\mathbf{r})d\tau \\ f\,E(\mathbf{k},\mathbf{f}) &\equiv \int v^*(\mathbf{k}-\mathbf{f},\mathbf{r})U(-\mathbf{f},\mathbf{r})u(\mathbf{k},\mathbf{r})d\tau \end{aligned}\right\} . \qquad \ldots\ldots (2.8)$$

Here $f=|\mathbf{f}|$, and the integrations are over all space. For long-wavelength acoustical phonons C and D are independent of $\mathbf{f}$ and are equal to the deformation potential constants for the conduction and valence bands respectively.

As the form of the matrix elements is rather similar for all the intermediate states we shall write them down only for intermediate state $|3\rangle$. This intermediate state is the one which appears likely to be the most important in determining lifetimes (see the following section).

We find that the matrix element of our perturbing Hamiltonian between the final state $|\mathrm{f}\rangle$ and intermediate state $|3\rangle$ is approximately given by

$$\begin{aligned} H_{\mathrm{f}3}' = H_{\mathrm{f}3}{}^{\mathrm{c}} = \frac{4\pi e^2}{\epsilon V}\left\{\frac{\Delta}{\lambda^2+(\mathbf{k}_2'-\mathbf{k}_1)^2} I_{\mathrm{cc}}(\mathbf{k}_2',\mathbf{k}_1)\,I_{\mathrm{vc}}(\mathbf{k}_1'+\mathbf{f},\mathbf{k}_2)\right. \\ \left. -\frac{1}{\lambda^2+(\mathbf{k}_2'-\mathbf{k}_2)^2} I_{\mathrm{cc}}(\mathbf{k}_2',\mathbf{k}_2)\,I_{\mathrm{vc}}(\mathbf{k}_1'+\mathbf{f},\mathbf{k}_1)\right\} \qquad \ldots\ldots (2.9)\end{aligned}$$

provided that λ and the wave vector changes are small compared with any non-zero reciprocal lattice vector.

In (2.9) V is the volume of the crystal and Δ is unity for case (i) of (2.2) and zero for case (ii).

For the matrix element between the initial state $|\mathbf{a}\rangle$ and intermediate state $|3\rangle$ we have

$$H_{3\mathrm{a}}' = H_{3\mathrm{a}}{}^{\mathrm{e-p}} = f\left(\frac{\hbar}{2MN'\omega(\mathbf{f})}\right)^{1/2}(N(\mathbf{f})+1)^{1/2}D(\mathbf{k}_1'+\mathbf{f},\mathbf{f}). \qquad \ldots\ldots (2.10)$$

Here M is the mass in a unit cell and $\omega(\mathbf{f})$ is the angular frequency of the phonon $\mathbf{f}$.

The energy denominator occurring in the transition probability is given by

$$E_{\mathrm{a}} - E_3 = E_{\mathrm{V}}(\mathbf{k}_1') - E_{\mathrm{V}}(\mathbf{k}_1'+\mathbf{f}) - \hbar\omega(\mathbf{f}) \qquad \ldots\ldots (2.11)$$

where $E_{\mathrm{V}}(\mathbf{k})$ denotes the energy below the maximum for the band of an electron of wave vector $\mathbf{k}$ in the valence band of the semiconductor.

Having found expressions (2.9), (2.10) and (2.11) and similar ones for the other six intermediate states we are now in a position to write down second-order transition probabilities between given initial and final states. The probabilities for the corresponding hole process ((*c*) in Fig. 1) may be obtained by making the appropriate interchange between conduction and valence band parameters, while for the inverse processes (*b*) and (*d*) they will be identical with those for (*a*) and (*c*).

§ 3. LIFETIME

In this section we shall make use of the results of § 2 to obtain an approximate expression for the mean probability of recombination of an electron in the conduction band of a non-degenerate semiconductor with simple bands due to the phonon-assisted Auger mechanism, and shall make a comparison with the corresponding expression for the simple Auger process given by Beattie and Landsberg.

The transition probability per unit time W due to our perturbation H' from an initial state with wave vectors as in (2.2) is given by

$$W=\frac{2\pi}{\hbar}\langle U^2\rangle_\alpha(\mathbf{k}_1,\ \mathbf{k}_2,\ \mathbf{k}_1')\rho(E_f)_{E_f=E_a} \qquad \ldots\ldots(3.1)$$

where we have defined U^2 by

$$U^2=\left|\sum_i\frac{H_{fi}'\,H_{ia}'}{E_a-E_i}\right|^2 \qquad \ldots\ldots(3.2)$$

(H_{lm}' denotes the matrix element of H' between states l and m and E_l denotes the energy of state l), and $\rho(E_f)$ is the density of final states with respect to energy. The angular brackets (with suffix α) in (3.1) denote an average over possible spin configurations and over directions of possible final wave vectors $\mathbf{k}_2'$.

To find the lifetime of excess carriers we have to obtain the net recombination rate by integrating over the wave vectors $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k}_1'$ for a non-equilibrium distribution of carriers and subtracting the rate for the equilibrium distribution as in Beattie and Landsberg's paper. The excess concentrations of electrons and holes over the equilibrium concentrations n_0 and p_0 are denoted by δn and δp, and it is supposed that the electrons and holes lie in quasi-Fermi distributions with quasi-Fermi levels displaced from the equilibrium Fermi level.

If these quasi-Fermi levels are well inside the band gap then the occupation probability function reduces to a simple Boltzmann factor. Assuming this exponential factor varies much more quickly with energy than the transition probabilities we can perform the integrals over $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k}_1'$ fairly easily, and it only remains to find the value of $\langle U^2\rangle_\alpha(\mathbf{0},\mathbf{0},\mathbf{0})$.

Now, if we work out the matrix elements and energy denominators for all our seven intermediate states (2.4) and put $\mathbf{k}_1=\mathbf{k}_2=\mathbf{k}_1'=0$ we can show that:

(i) For case (i) of (2.2) (that with initial electron spins parallel) $U^2=0$.

(ii) For case (ii) of (2.2) (electron spins anti-parallel), if m_c and m_v are the effective masses of electrons in the conduction band and holes in the valence band and E_G is the energy gap, the matrix elements and energy denominators for the seven intermediate states are approximately as in Table 1, provided that phonon energies can be ignored. Hence, assuming that C and E are not much greater than D at the wave vectors considered, and that $m_c \ll m_v$, it should be a fair approximation to ignore all intermediate states except $|3\rangle$ in calculating U^2.

Table 1

Intermediate state	$\lvert H_{fi}'H_{ia}'\rvert$	$\lvert E_a-E_i\rvert$
$\lvert 1\rangle$	$\gamma\lvert C\rvert$	E_G
$\lvert 2\rangle$	0	E_G
$\lvert 3\rangle$	$\gamma\lvert D\rvert$	μE_G
$\lvert 4\rangle$	$\gamma'\lvert E\rvert$	$(1+\mu)E_G$
$\lvert 5\rangle$	0	$(1+\mu)E_G$
$\lvert 6\rangle$	$\gamma''\lvert E\rvert$	$2E_G$
$\lvert 7\rangle$	0	E_G

γ, γ' and γ'' are constants with the dimension of energy, and are likely to be of the same order of magnitude. $\mu=(m_c/m_v)$.

Making this approximation, and remembering that for only two of the eight possible initial spin configurations will transitions of type (ii) to a final state of given spin be allowed, we find that, for acoustical phonons,

$$\langle U^2\rangle_\alpha(\mathbf{O},\mathbf{O},\mathbf{O}) = \frac{2\pi^2 e^4 kT}{\epsilon^2 M s^2 N' V^2(\lambda^2+f_0{}^2)^2}\left(\frac{m_{\rm v}}{m_{\rm c}}\right)^2 \times \frac{\overline{|D(\mathbf{f}_0,\mathbf{f}_0)|^2}}{E_{\rm G}{}^2}\,\overline{|I_{\rm cc}(-\mathbf{f}_0,\mathbf{O})\,I_{\rm vc}(\mathbf{f}_0,\mathbf{O})|^2}. \qquad \ldots\ldots(3.3)$$

Here $\mathbf{f}_0$ is a wave vector such that

$$\frac{\hbar^2}{2m_{\rm c}}\mathbf{f}_0{}^2 = E_{\rm G} \qquad \ldots\ldots(3.4)$$

and the bars on the right-hand side denote averages over all directions of $\mathbf{f}_0$. We have assumed that for acoustical phonons

$$\omega(\mathbf{f}_0) = sf_0 \qquad \ldots\ldots(3.5)$$

and

$$N(\mathbf{f}_0)+1 \simeq (kT/\hbar s f_0) \qquad \ldots\ldots(3.6)$$

where s is the velocity of sound in the material.

If we now put in the correct density of states function in (3.1), integrate as indicated above and use (3.3), we find that the part $(1/\tau')_{\rm a}$ of the reciprocal of the electron lifetime which arises from the above acoustical phonon-assisted Auger mechanism satisfies

$$\left(\frac{1}{\tau'}\right)_{\rm a} = 3\left(\frac{e^4 m_{\rm c}}{\epsilon^2\hbar^3}\right)\left(\frac{kT}{E_{\rm G}}\right)^4\left(\frac{\overline{|D|^2}}{E_{\rm G}{}^2}\right)\left(\frac{E_{\rm G}}{Ms^2}\right)\left(\frac{m_{\rm v}}{m_{\rm c}}\right)^{7/2}\left(\frac{f_0}{f_{\max}}\right)^3 \times \frac{1}{\{1+(\lambda^2/f_0{}^2)\}^2}\,\overline{|I_{\rm cc}I_{\rm vc}|^2}\left\{1+\frac{(\delta p/\delta n)n_0}{p_0}\right\}\exp\left(-\frac{E_{\rm G}}{kT}\right) \qquad \ldots\ldots(3.7)$$

provided that $\delta n \ll n_0$. Here we have defined $f_{\max}$ by

$$4\pi\,(f_{\max}/2\pi)^3/3 = N'/V. \qquad \ldots\ldots(3.8)$$

In calculating (3.7) we have used the fact that in the approximations made here the probabilities of transitions with the absorption of an acoustical phonon are just the same as those for emission.

This result is to be compared with the corresponding reciprocal time (which we shall call $(1/\tau)_{\rm a}$) for the no-phonon case. If we neglect screening, from (5.13), (4.9), (4.10) and (4.11) of Beattie and Landsberg's article (ignoring the second term in the first square bracket in (5.13) as it is due to processes (*c*) and (*d*)) this can be shown to be given by

$$\left(\frac{1}{\tau}\right)_{\rm a} = \frac{8}{[2\pi(1+\mu)]^{1/2}(1+2\mu)}\left(\frac{e^4 m_{\rm c}}{\epsilon^2\hbar^3}\right)\left(\frac{kT}{E_{\rm G}}\right)^{3/2}|I_{\rm cc}(\mu k_{10}{}', \overline{2\mu+1}\,k_{10}{}')\,I_{\rm cv}(\mu k_{10}{}', k_{10}{}')|^2 \times\left\{1+\frac{(\delta p/\delta n)n_0}{p_0}\right\}\exp\left(-\frac{2\mu+1}{\mu+1}\frac{E_{\rm G}}{kT}\right). \qquad \ldots\ldots(3.9)$$

Here $\mu = m_{\rm c}/m_{\rm v}$ and $k_{10}{}'$ satisfies

$$\frac{\hbar^2}{2m_{\rm c}}(1+\mu)(1+2\mu)(k_{10}{}')^2 = E_{\rm G} \qquad \ldots\ldots(3.10)$$

(Beattie and Landsberg implicitly assume that variations of the integrals I with direction of the wave vectors can be neglected, and hence write the integrals as functions of the magnitudes of the wave vectors only).

Hence, from (3.7) and (3.9) the ratio $(\tau/\tau')_{\rm a}$ for negligible screening satisfies

$$\left(\frac{\tau}{\tau'}\right)_{\rm a} \sim \frac{\overline{|D|^2}}{E_{\rm G}{}^2}\left(\frac{kT}{E_{\rm G}}\right)^{5/2}\left(\frac{E_{\rm G}}{Ms^2}\right)\left(\frac{f_0}{f_{\max}}\right)^3\left(\frac{m_{\rm v}}{m_{\rm c}}\right)^{7/2}\exp\left(\frac{\mu}{1+\mu}\frac{E_{\rm G}}{kT}\right) \qquad \ldots\ldots(3.11)$$

provided that the products of I's for the two cases are of the same order of magnitude.

Similar results may be obtained for transitions involving optical phonons by using (3.6) and obtaining $\overline{U^2}$ from § 2. However, the electron–phonon matrix elements were written in the form (2.10) for convenience in dealing with acoustical modes, and it must be remembered that C and D may be sharply varying functions of wave vector for optical phonons, being in fact proportional to $(1/f^2)$ for long-wavelength polar modes.

§ 4. IMPACT IONIZATION

In this section we shall calculate the rate of impact ionization due to phonon-assisted Auger processes of type (*b*) in Fig. 1, for a semiconductor with simple bands. Just as the assistance of phonons enables low energy electrons and holes to take part in recombination, so does the threshold energy for impact ionization become lowered when phonons are used for momentum conservation.

We are now interested in transitions where the initial and final states of (2.2) are interchanged. Using perturbation theory we find that the average probability per unit time $Q_{\mathrm{e}}'(k_2')$ that an electron with wave vector of magnitude k_2' will form an electron–hole pair with simultaneous emission of a phonon is given by

$$Q_{\mathrm{e}}'(k_2') = \frac{2\pi}{\hbar} \langle U^2 \rangle_\beta (k_2') \rho(E_{\mathrm{f}})_{E_{\mathrm{f}}=E_{\mathrm{a}}} \qquad \ldots\ldots\ldots (4.1)$$

where U^2 is defined by (3.2), and the angular brackets with suffix β denote averages over the values of $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k}_1'$ for which the energy conservation conditions are satisfied, over possible final spin configurations and over directions of $\mathbf{k}_2'$. The density of final states $\rho(E_{\mathrm{f}})$ may be obtained by integrations over $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k}_1'$ space and it can be shown that

$$\rho(E_{\mathrm{f}}) = \frac{2\pi}{105} \left(\frac{V}{2\pi^2}\right)^3 \left(\frac{2m_{\mathrm{c}}}{\hbar^2}\right)^3 \left(\frac{2m_{\mathrm{v}}}{\hbar^2}\right)^{3/2} (E_{\mathrm{f}} - E_{\mathrm{G}})^{7/2}. \qquad \ldots\ldots (4.2)$$

If the energy of the initial electron above the bottom of the band is only slightly greater than the energy gap, then the possible values of $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k}_1'$ are all fairly small, and so it should be a fair approximation to write

$$\langle U^2 \rangle_\beta (k_2') \simeq \langle U^2 \rangle_\alpha (\mathbf{O}, \mathbf{O}, \mathbf{O}) \qquad \ldots\ldots (4.3)$$

($\langle U^2 \rangle_\alpha (\mathbf{O}, \mathbf{O}, \mathbf{O})$ is defined in § 3).

The probability per unit time for impact ionization with absorption of an acoustical phonon will be the same as that for emission in our approximation. Hence, from (4.1), (4.2), (4.3), (3.3), (3.4) and (3.8) we find that the total probability $Q'(k_2')$ for acoustical phonon-assisted impact ionization is given by

$$Q'(k_2') = \frac{8}{35} \left(\frac{e^4 m_{\mathrm{c}}}{\epsilon^2 \hbar^3}\right) \left(\frac{kT}{Ms^2}\right) \frac{\overline{|D(\mathbf{f}_0, \mathbf{f}_0)|^2}}{E_{\mathrm{G}}^2} \left(\frac{m_{\mathrm{v}}}{m_{\mathrm{c}}}\right)^{7/2} \left(\frac{f_0}{f_{\mathrm{max}}}\right)^3$$
$$\times \frac{1}{\{1 + (\lambda^2/f_0^2)\}^2} \overline{|I_{\mathrm{cc}}(-\mathbf{f}_0, \mathbf{O}) I_{\mathrm{vc}}(\mathbf{f}_0, \mathbf{O})|^2} \left(\frac{E_{\mathrm{c}k_2}'}{E_{\mathrm{G}}} - 1\right)^{7/2} \qquad \ldots\ldots (4.4)$$

where

$$E_{\mathrm{c}k_2}' = (\hbar^2/2m_{\mathrm{c}}) k_2'^2. \qquad \ldots\ldots (4.5)$$

The other symbols in (4.4) are defined in § 3, the bars denoting averages over directions of $\mathbf{f}_0$.

To obtain the corresponding ionization probability $Q(k_2')$ in the no-phonon case it would be necessary to integrate the transition probability given in (2.11) of Beattie and Landsberg's paper over $\mathbf{k}_1$, $\mathbf{k}_2$ and $\mathbf{k}_1'$, to average over directions of $\mathbf{k}_2'$ and to sum over possible spin configurations. In general this would be rather difficult, but if k_2' is such that $E_{\mathrm{c}k_2'}$ is not much above the threshold E_{A} above which ionization is possible, then we can make the simplifying assumptions that the matrix elements and wave vector changes involved do not vary much over the regions of $\mathbf{k}$-space considered. We then obtain the result that, if screening is neglected,

$$Q(k_2') = \frac{(2\mu+1)^{1/2}}{(\mu+1)^2}\left(\frac{e^4 m_{\mathrm{c}}}{\epsilon^2\hbar^3}\right)|I_{\mathrm{cc}}(\mu k_{10}', \overline{2\mu+1}\,k_{10}')I_{\mathrm{cv}}(\mu k_{10}', k_{10}')|^2\left(\frac{E_{\mathrm{c}k_2'}}{E_{\mathrm{A}}}-1\right)^2 \qquad \ldots\ldots(4.6)$$

where

$$E_{\mathrm{A}} = \frac{2\mu+1}{\mu+1}E_{\mathrm{G}} \qquad \ldots\ldots(4.7)$$

and k_{10}' is defined by (3.10). There is a slight discrepancy between this result and one quoted by Franz (1958), who quotes work by Tewordt (1954), but the quadratic dependence on the energy and the order of magnitude are the same for the two expressions.

If we assume a Maxwellian distribution for the electrons with temperature T_{e} (T_{e} not necessarily equal to the lattice temperature T), then by integration of Q' and Q over energy we may obtain the total ionization rates S' and S for the acoustical phonon-assisted and no-phonon processes respectively. The result is that if $\lambda \ll f_0$, the ratio S'/S satisfies

$$\frac{S'}{S} \sim \left(\frac{kT_{\mathrm{e}}}{E_{\mathrm{G}}}\right)^{3/2}\left(\frac{kT}{Ms^2}\right)\left(\frac{\overline{|D|^2}}{E_{\mathrm{G}}^2}\right)\left(\frac{m_{\mathrm{v}}}{m_{\mathrm{c}}}\right)^{7/2}\left(\frac{f_0}{f_{\max}}\right)^3\exp\left(\frac{\mu}{1+\mu}\frac{E_{\mathrm{G}}}{kT_{\mathrm{e}}}\right) \qquad \ldots\ldots(4.8)$$

provided as before that the products $I_{\mathrm{cc}}I_{\mathrm{cv}}$ are of the same order of magnitude in the two cases.

§ 5. DISCUSSION

5.1. *General*

In the last two sections we have given expressions for acoustical phonon-assisted Auger lifetimes and impact ionization probabilities in semiconductors with simple bands. The calculations for optical phonons would be very similar, but rough estimates indicate that in the III–V compounds the matrix elements of the polar interaction with optical modes for the transitions of interest will be rather smaller than the corresponding ones for acoustical modes.

Before numerical values can be obtained for the theoretical expressions for Auger lifetimes and ionization probabilities it is necessary to know what value to take for the 'effective dielectric constant' ϵ occurring in the expression for H^{c}. We expect the Coulomb interaction to change from an e^2/r law at small distances through an $e^2/\epsilon_\infty r$ law at intermediate distances (where ϵ_∞ is the high-frequency dielectric constant) to an $e^2/\epsilon_{\mathrm{s}} r$ law at large distances (where ϵ_{s} is the static dielectric constant). The distance at which the transition from $\epsilon = 1$ to $\epsilon = \epsilon_\infty$ will occur will probably be of the order of an atomic spacing, while the transition from $\epsilon = \epsilon_\infty$ to $\epsilon = \epsilon_{\mathrm{s}}$ will take place at distances of the order of v/ω, where v is the velocity of the electrons involved and ω is the frequency of the optical modes of the lattice. As we are dealing with high energy electrons this distance is likely to be quite large, of the order of 10^{-6} cm. Since it would be difficult to solve our perturbation problem with anything but a simple Coulomb law we content ourselves with taking an effective dielectric constant corresponding to that which is applicable at the distances where most of the interaction occurs. This distance will be of the order of the reciprocal of the wave vector change occurring in the transitions and this roughly equals $1/f_0$ for the transitions of importance.

In this discussion we shall give numerical results for the two III–Vcompounds InSb and GaAs using the values given in Table 2 for the parameters concerned. For InSb we find that $1/f_0 \simeq 3 \times 10^{-7}$ cm and for GaAs $1/f_0 \simeq 6 \times 10^{-8}$ cm, so for both these substances it appears that $\epsilon = \epsilon_\infty$ is the best choice to make.

5.2. *Lifetime*

From (3.11) we can see that the main temperature dependence of the ratio of the Auger lifetimes associated with processes (*a*) and (*b*) in Fig. 1 without and with the assistance of acoustical phonons is contained in the function

$$g(x) \equiv x^{5/2} \exp(1/x), \quad \text{where} \quad x = \{(1+\mu)/\mu\}(kT/E_G).$$

The function $g(x)$ is plotted in Fig. 3. It can be seen that the function becomes very large at low temperatures (because of the exponential term) and also at very high temperatures (because of the $T^{5/2}$ term).

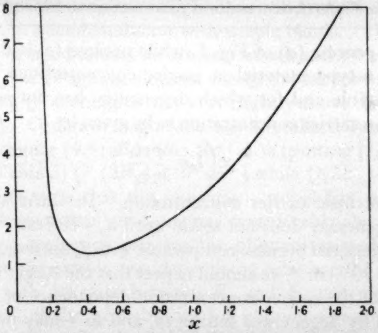

Fig. 3. Plot of the function $g(x) \equiv x^{5/2} \exp(1/x)$ against x. With suitable scaling this is equivalent to a plot of the ratio of the direct to acoustical phonon-assisted Auger lifetimes against temperature in a semiconductor with simple bands.

To obtain an idea of orders of magnitude we have calculated the value of the ratio $(\tau/\tau')_a$ of (3.11) for InSb and GaAs at room temperature. For InSb at room temperature we find $(\tau/\tau')_a \sim 10^{-3}$ while for GaAs $(\tau/\tau')_a \sim 10^{-2}$. Room temperature is above the minimum in InSb but well below it for GaAs; if we go slightly below room temperature we should expect $(1/\tau')_a$ to become greater than $(1/\tau)_a$ in GaAs.

Under the assumption that $|I_{cc} I_{cv}|^2 \sim 10^{-2}$, Beattie and Landsberg calculate the direct Auger lifetime in intrinsic InSb to be of the order of 10^{-7} sec at room temperature; with the same value for $|I_{cc} I_{cv}|^2$, using the values of parameters given in Table 2, we find a direct Auger lifetime for intrinsic GaAs of the order of 10^{19} sec, which is rather too long to be of practical importance!

However, a log–log plot of Auger lifetime against carrier concentration looks schematically as shown in Fig. 4. On the right-hand half of the curve the lifetime

Table 2

Quantity	Values taken for InSb	Values taken for GaAs
m_C	$0{\cdot}03m$†	$0{\cdot}08m$
m_V	$0{\cdot}2m$	$0{\cdot}5m$
D (ev)	2‡	2‡
E_G(ev)	0·18	1·4
M (a.m.u.)	237	145
s (cm sec^{-1})	4×10^5	5×10^5
$f_{\max}$ (cm^{-1})	$9{\cdot}5\times10^7$	$1{\cdot}1\times10^8$
ϵ_∞	16	11
	Deduced values	
μ	0·15	0·16
f_0 (cm^{-1})	$3{\cdot}8\times10^6$	$1{\cdot}7\times10^7$
Ms^2 (ev)	39	38
E_G/kT (at room temperature)	7·2	56

† There is no point in taking the effective mass at the bottom of the band ($0{\cdot}013m$) as we are dealing with high energy electrons and the effective mass increases quite rapidly as we move away from the band minimum.

‡ These values are guesses. All we know is that, at zero wave vector, $C-D\sim7$ ev both for InSb and for GaAs (from results of measurements of energy gap against pressure).

is determined by process (*a*) of Fig. 1, while process (*c*) is dominant on the left-hand side. For n-type material at carrier concentrations low enough so that screening is negligible and for which degeneracy has not set in, we expect the dependence of τ on carrier concentration to be given by

$$\frac{1}{\tau}\propto\left(1+\frac{\delta p}{\delta n}\frac{n_0^2}{n_i^2}\right) \qquad \ldots\ldots(5.1)$$

where n_i is the intrinsic carrier concentration. In GaAs at room temperature $n_i\sim10^6\,\text{cm}^{-3}$, degeneracy does not set in until $n_0\sim10^{17}\,\text{cm}^{-3}$, and the reciprocal screening length does not become comparable with f_0 until $n_0\gtrsim10^{19}\,\text{cm}^{-3}$. Hence, if $\delta p=\delta n$ and $n_0\sim10^{17}\,\text{cm}^{-3}$ we should expect that the Auger lifetime $\tau\sim10^{-3}$ sec. It seems likely that the carrier-concentration dependence of the lifetime will not be greatly altered by degeneracy setting in, and so τ may be reduced by several

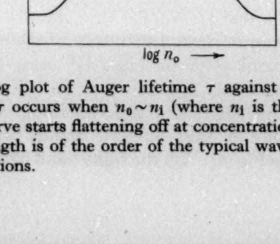

Fig. 4. Schematic log–log plot of Auger lifetime τ against electron concentration n_0. The maximum in τ occurs when $n_0\sim n_i$ (where n_i is the intrinsic carrier concentration), and the curve starts flattening off at concentrations for which the reciprocal of the screening length is of the order of the typical wave vector changes occurring in the Auger transitions.

more orders of magnitude when $n_0 \sim 10^{19}\,\text{cm}^{-3}$. The phonon-assisted lifetime is only about a hundred times larger than the no-phonon lifetime at room temperature, and for a fixed carrier concentration varies linearly with temperature, whereas the no-phonon lifetime increases sharply as the temperature is decreased; thus in highly-doped but trap-free, n-type GaAs, phonon-assisted Auger recombination might be the dominant recombination mechanism below room temperature. In p-type material the temperature below which the phonon-assisted effect dominates the no-phonon effect will be much greater; however, for a given carrier concentration, the phonon-assisted lifetime will be somewhat longer than in n-type material (because some of the factors m_V/m_C in (3.7) will be replaced by m_C/m_V).

Thus, by taking a particular example we have shown that in highly doped materials with simple bands the acoustical phonon-assisted Auger mechanism may dominate recombination at low temperatures. Although the theory also indicates that the phonon-assisted process could dominate again at very high temperatures, it appears that the crystal will melt long before such temperatures are approached.

5.3. *Impact Ionization*

We have shown that the assistance of phonons will lower the threshold energy for impact ionization in a semiconductor with simple bands. However, the cross sections for phonon-assisted ionization are very small, and we expect plots of the probabilities Q and Q' of § 4 against electron energy to look schematically as shown in Fig. 5, Q overtaking Q' at energies only very slightly above the threshold energy E_A (defined in (4.7)). Orders of magnitude may be realized by noting for example that, according to formulae (4.4) and (4.6), for GaAs (putting $|I_{cc}I_{cv}|^2 \sim 10^{-2}$ and taking values from Table 2) $Q'(2E_G) \sim 10^8\,\text{sec}^{-1}$ while $Q(2E_A) \sim 10^{11}\,\text{sec}^{-1}$. It is perhaps of interest to note that the ionization probability will not equal the reciprocal of the scattering time until energies considerably above E_A are reached.

Whether the total ionization rate for the phonon-assisted process becomes greater than that for the simple one depends on whether the larger number of electrons available with energies between E_G and E_A can more than counterbalance the smallness of the probabilities for phonon-assisted ionization. For GaAs, taking a Maxwellian distribution of electrons with a temperature of 100°K and a lattice temperature of 50°K, we find, from (4.8), that the ratio S'/S for the two rates is of the order of 10^3. (At lattice temperatures as low as this the approximation (3.6) will not hold, but the order of magnitude of S'/S should be correct.)

Thus at first sight we might expect that, if we start with a high band gap semiconductor with simple bands at a fairly low temperature, and apply a steadily increasing electric field, then the initial rate of increase of carrier concentration with field would be determined by the rate of phonon-assisted impact ionization. However, this is unlikely to be the case. As has been pointed out by Keldysh (1959), changes in the distribution function for electrons in high fields are likely to produce large changes in the rate of recombination of electrons and holes, and this effect will normally set in at lower electron temperatures than those at which increases in carrier concentration due to impact ionization become important. Also, even if the lifetime of carriers does not change much as the distribution function changes, the carrier temperatures required to give appreciable alteration of carrier concentration by ionization may well be so high that direct impact ionization is the dominant ionization mechanism.

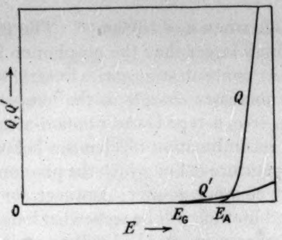

Fig. 5. Schematic plot of direct and phonon-assisted ionization probabilities Q and Q' against electron energy E. E_G is the band gap, and E_A is the threshold energy for direct impact ionization (defined by (4.7) for a semiconductor with simple bands).

There are other types of experiment in which ionization occurs but in which recombination does not take place because of the short times involved (e.g. avalanche breakdown experiments in p–n junctions); however, interpretation of these is usually somewhat difficult.

Hence, although it may be possible to find situations in which phonon-assisted impact ionization could produce observable effects, in view of our lack of detailed knowledge concerning recombination mechanisms and distribution functions in high fields, it does not appear worth while to look for these effects at the present time.

§ 6. Conclusion

It has been shown that phonon-assisted Auger recombination will dominate the direct Auger process in semiconductors with simple bands at low temperatures (the temperatures required being lower for small band gap materials), but that as the temperature is raised the direct process will probably become the more important. In highly doped specimens the recombination rate due to the phonon-assisted Auger effect can be comparable with rates generally expected from other mechanisms.

At low carrier temperatures the rate of phonon-assisted impact ionization will be greater than the direct impact ionization rate. However, phonon-assisted impact ionization may be difficult to detect because of other complications.

It should be noted that the results obtained here have only qualitative significance as it is not to be expected that the simple band model will ever apply at energies of the order of the band gap away from the band extrema.

Acknowledgments

I should like to thank Professor Fröhlich for suggesting this problem to me and for advice on how to treat it. I am also grateful to Mr. J. W. Allen for discussing the work on many occasions and for reading through and criticizing the manuscript for this article.

Acknowledgment is due to the Admiralty for permission to publish this paper.

The Surface States of a Simple Crystal Model

By T. B. GRIMLEY and B. W. HOLLAND
Department of Inorganic and Physical Chemistry, University of Liverpool

MS. received 13*th February* 1961

Abstract. The energies of surface states as functions of a parameter γ, which measures the electron affinity of a surface atom relative to an atom in the interior of the crystal, are calculated for a one-dimensional δ-well chain. The treatment is extended to a three-dimensional simple cubic lattice by using a modified free electron network model. Depending on γ, surface bands can exist in the energy gaps between the volume bands, or a surface band may overlap and lose any number of states to the volume bands below it. Only the lowest volume band, derived from the single bound state of the isolated δ-well, can give rise to a surface band of lower energy.

---

§ 1. Introduction

In view of the mathematical difficulties usually encountered in the theoretical treatment of physical systems, exact solutions for simple models are helpful in three ways. Firstly, however simplified the model, it will exhibit essential features of the real system, and its treatment will therefore indicate important characteristics to be expected in the solution of the real problem. An outstanding example is the model treated by Kronig and Penney (1931) in the early stages of the theory of the electronic structure of solids. Secondly, in attempting to formulate a general mathematical technique for a certain problem, we may be guided by the form of the solution for a model, and by trying out possible methods on the model, select the most simple and direct. Finally, we can use the model to test the reliability of different approximations.

In the problem of the electronic structure of finite crystals, progress was made using simple models when Tamm (1932) first demonstrated the possible existence of surface localized electronic states, and Shockley (1939) derived conditions under which they might exist. In this paper, a simple model of a crystal with a surface is treated exactly to give the dependence of the energies of surface states on a parameter γ which measures the relative electron affinities of the surface atoms and the atoms in the interior of the crystal. For $\gamma=1$ we have a crystal with a clean surface, otherwise the surface is completely covered with foreign atoms. Since we wish to use this model in the development of a general mathematical technique involving orthonormal sets of functions obeying periodic boundary conditions, we follow Koutecký (1957) in choosing a cyclic system.

In §2, the one-dimensional δ-well chain is discussed, and the treatment is made more realistic in §3 by extending it to a modified free electron network model for a simple cubic lattice with a surface.

§ 2. ONE-DIMENSIONAL CASE

2.1. *The δ-well Chain*

Consider a one-dimensional square potential well of depth V_0 and width t. Let $V_0 \to \infty$ as $t \to 0$ so that $V_0 t$ remains constant at the value $\hbar^2\eta/m$, the resulting δ-well being of strength η. Next consider a one-dimensional δ-well chain of separation d, the potential between wells being zero. Numbering from the left, the solution of the one-dimensional Schrödinger equation in the region between wells n and $n+1$ is of the form

$$\psi_n = a_n \sin qx + b_n \cos qx,$$

where a_n and b_n are constants, x having its origin at well n, and range 0 to d, and $q = (2mE)^{1/2}/\hbar$.

The joining conditions at a δ-well for two such segments of a wave function are (Wannier 1959)

$$\psi_n(d) = \psi_{n+1}(0), \qquad \ldots\ldots (1)$$

$$\operatorname{grad} \psi_{n+1}(0) - \operatorname{grad} \psi_n(d) = -2\eta\psi_n(d), \qquad \ldots\ldots (2)$$

from which the relation between the amplitudes of the wave function at adjacent wells is

$$b_{n+1} + b_{n-1} = 2\left[\cos qd - \frac{\eta}{q}\sin qd\right] b_n. \qquad \ldots\ldots (3)$$

This difference equation has the general solution

$$b_n = A \exp(in\theta) + B \exp(-in\theta),$$

where A and B are constants, and on substitution into (3) the following general condition on θ is obtained

$$\cos\theta = \cos qd - \frac{\eta}{q}\sin qd. \qquad \ldots\ldots (4)$$

θ is determined by the boundary conditions. For an infinite δ-well chain of perfect translational symmetry, employing periodic boundary conditions the wave functions are Bloch functions characterized by a wave number $k = 2\pi m/L$, where m is an integer and L is the length of a ground domain. In this case $\theta = kd$.

2.2. *Model for a Crystal with a Surface*

The basic part of this model is the δ-well chain described above, but now the end wells are of strength $\gamma\eta$. There are $2N+1$ wells, the number origin being at the central well. At the end δ-wells, and beyond, the potential has the positive value V. This crude model exhibits the periodicity of potential expected within a crystal, and the rising potential expected at the surface. The end wells of different strength represent foreign atoms interacting with the surfaces, γ measuring the electron affinity of the foreign atom relative to that of a crystal atom. The case of $\gamma = 1$ represents interaction of the surface with an atom of the same type as the crystal atoms, or alternatively a clean surface.

The natural choice of boundary conditions would ensure that the wave functions outside the crystal decrease exponentially with distance from the surface. For reasons stated in § 1, we require periodic boundary conditions and hence a cyclic potential. The basic repeating unit is the potential just described, with the additional stipulation that the unit is symmetrical about the central well, but twice as long as the chain, that is, of length $L = 4Nd$. It will be clear from what follows that if $L \to \infty$, the solutions for finite distances from the crystal surfaces will reduce to those of the non-periodic boundary conditions mentioned above.

2.3. *Relation between γ and the Energy*

The form of the wave function in the region of constant potential beyond the ends of the chain is

$$\psi_N = C\exp(\beta x') + D\exp(-\beta x'),$$

where x' has its origin at the end of a ground domain and range $-L/4$ to $L/4$. Since we are interested in the case $E < V$, β is taken as a real positive quantity, defined by $\hbar^2\beta^2 = 2m(V-E)$. Using (1) and (2) we obtain

$$\frac{b_{N-1}}{b_N} = \cos qd + \frac{\beta - 2\gamma\eta}{q}\sin qd \qquad \ldots\ldots (5)$$

If we are only interested in wave functions with maximum absolute value at the ends of the chain, θ is of the form (Grimley 1958)

$$\theta = i\xi, \qquad \ldots\ldots (6)$$

or

$$\theta = \pi + i\xi, \qquad \ldots\ldots (7)$$

where ξ is real and may be chosen positive. Allowing $L \to \infty$, (5) then becomes

$$\pm\exp(-\xi) = \cos qd + \frac{\beta - 2\gamma\eta}{q}\sin qd, \qquad \ldots\ldots (8)$$

and (4)

$$\pm\cosh\xi = \cos qd - \frac{\eta}{q}\sin qd, \qquad \ldots\ldots (9)$$

the positive sign corresponding to (6) and the negative to (7). Using (8) and (9) to solve for γ,

$$2\gamma = 1 + \left(\epsilon - \frac{q^2}{\eta^2}\right)^{1/2} + R, \qquad \ldots\ldots (10)$$

where $\epsilon\eta^2 = V$, and

$$R = \pm\left[1 - \frac{q^2}{\eta^2} - 2\frac{q}{\eta}\cot qd\right]^{1/2}.$$

From (8), (9) and (10)

$$\pm\sinh\xi = R\frac{\eta}{q}\sin qd, \qquad \ldots\ldots (11)$$

from which it is clear that only one root of (10) is allowed, this being determined by the form of θ and the sign of $q/\sin qd$. Fig. 1 shows the energies of the surface states as functions of γ, with $\epsilon = 22$, and $\eta d = 2$, the bands of non-localized states being determined from (4). The energies of the surface states fall in the gaps between the bands, there being a maximum of one in each gap. The following mechanism for the formation of surface states was confirmed by solving graphically the equations (4) and (5) for the energies of surface and non-localized states for a chain of five wells. For any band there is a range of γ for which there are no surface states in the gap above. As γ decreases, that is the potential rises, naturally the energy of each state rises. That of the highest state of the band rises most rapidly, until at some critical γ it becomes a surface state outside the band. As γ decreases further, the energy of this state rises asymptotically towards the top of the gap, never entering the next higher band. For increasing γ the energies of all states fall, but only the bottom band can lose its lowest state to form a surface state of lower energy. This difference in behaviour appears to be connected with the difference in origin of the bands, the lowest being derived from the single bound state of the isolated δ-well, and the others from the continuum of unbound states.

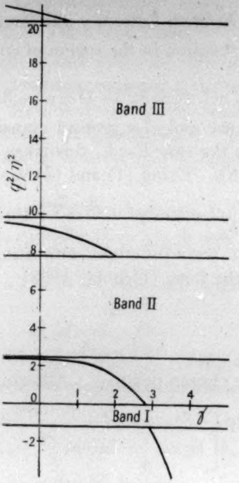

Fig. 1. Variation of the energies of surface states with γ for the one-dimensional case. $\epsilon=22$, $\eta d=2$.

The observed surface states are of the Tamm type, that is, they arise through an imperfection in the translational symmetry of the potential in the end cell, or the region within $\pm\frac{1}{2}d$ of the end well. Shockley states, arising in cases of overlap between band boundaries, cannot occur for this model. Surface states do occur for $\gamma=0$, when the end cell is perfect, but these are of positive energy so that this result does not conflict with Shockley (1939) who considered wave functions decreasing exponentially from the end cell boundary. The states for $\gamma=0$ are obviously in the Tamm category though not strictly Tamm states on the above definition.

A more general model for atom–crystal surface interaction would allow variation in the atom–surface separation, with an accompanying change in potential between them. Such a model has been treated and leads to a much more complicated expression for γ than (10), which is a specially simple case of this general model in which the amplitude of the wave function on the foreign atom satisfies (3). This restricts us to consideration of localized states with maximum absolute value of the wave function on the foreign atom while we should expect states localized on the end crystal to occur also. While the more general model allows for the existence of such states, it does not appear to lead to any important new features in the (energy, γ) curve.

It might be thought instructive to find the energies of surface states as functions of the atom–crystal surface separation. However, the δ-well model is unsuitable for this purpose since it is incapable of representing internuclear repulsion at short range, which would be an important term in the energy of the real system.

The model was also modified to represent an impurity atom in an otherwise perfect lattice, and localized states with very similar behaviour to the surface states were found.

The results for energies near the bottom band are to be expected from current ideas on surface states (Koutecký 1960). New features are observed in the higher energy region, but it seems probable that the most important part of the electronic structure for a real crystal would correspond to negative energies on our model, and to bands derived from the bound states of the isolated atoms.

§ 3. THREE-DIMENSIONAL CASE

If the model is to bear some relation to a crystal problem it must be extended to three dimensions.

3.1. *Modified Free Electron Network Model*

In order to avoid undue complication, the model chosen will be a simple cubic lattice with electrons confined to the bond lines joining nearest neighbour lattice points. At each lattice point is situated a δ-well of strength η with respect to each bond line axis. The potential on the bond lines is zero and the behaviour of an electron is assumed to be governed by the one-dimensional Schrödinger equation. This is a reaonable model for a solid with directed bonds between nearest neighbours, where motion transverse to a bond line can be assumed to remain in the ground state. The LCAO–MO method coupled with the tight binding approximation also in general gives the wave function its greatest absolute value on lines joining nearest neighbours. The main point in favour of the model, however, is that the potential has the same symmetry as that of a crystal of similar atoms with a simple cubic lattice. This is the modified free electron network model treated by Coulson (1955) for the case of an infinite lattice with perfect translational symmetry. The coordinate system is similar to that used in § 2. Choose a certain well as the origin and specify any other by the integers n_1, n_2, n_3 on the bond line axes 1, 2, 3 passing through the origin. The coordinates originating at each well, and ranging from 0 to d, are x_1, x_2, x_3 parallel to axes 1, 2, and 3 severally. For example, the segment of the wave function on a bond line between lattice points n_1, n_2, n_3 and n_1, n_2, n_3+1 is

$$\psi(n_1, n_2, n_3, x_3) = a_3(n_1, n_2, n_3) \sin qx_3 + b_3(n_1, n_2, n_3) \cos qx_3.$$

Following Coulson (1955) we adopt the following joining conditions for segments of the wave function at a δ-well. The wave function is continuous. This is physically essential and leads immediately to the result that $b(n_1, n_2, n_3)$ is independent of bond line direction. $\sum_{i=1}^{n} \operatorname{grad} \psi_i + n\eta\psi_i = 0$, where ψ_i is the value of segment i of the wave function at the well; the gradients are measured away from the well, at which n segments meet. We must have a condition on the gradients, but in the authors' view there is no derivation of such a condition leading uniquely to the above result as there is for (2) which is a special case of it. It should be accepted as a convenient minimal condition on the gradients leading to physically acceptable results, such as the conservation of probability current.

The analysis is very similar to that of § 2. The difference equation analogous to (3) is

$$\sum_{i,j,k=-1}^{1} b(n_1+i, n_2+j, n_3+k)$$
$$= 6\left[\cos qd - \frac{\eta}{q} \sin qd\right] b(n_1, n_2, n_3), \qquad \ldots\ldots (12)$$

which is solved by

$$b(n_1, n_2, n_3) = \prod_{r=1}^{3} X_r(n_r),$$

where

$$X_r(n_r) = A_r \exp(in_r\theta_r) + B_r \exp(-in_r\theta_r)$$

and A_r and B_r are constants depending only on the direction r. The condition for non-trivial solutions of (12) is

$$\cos\theta_1 + \cos\theta_2 + \cos\theta_3 = 3\left[\cos qd - \frac{\eta}{q}\sin qd\right]. \qquad \ldots\ldots(13)$$

For a perfect infinite lattice (Coulson 1955), $\theta_r = k_r d$; cf. § 2.1.

3.2. *Model for the Surface Problem*

The lattice is infinite with perfect translational symmetry in the 2- and 3-directions, the potential in the 1-direction along any line of δ-wells is exactly as in § 2.2. The periodic boundary conditions apply. The crystal surface atoms are in the planes $\pm(N_1 - 1)$, and the complete covering of foreign atoms in the planes $\pm N_1$. The equation analogous to (8) is

$$\pm\exp(-\xi) = 5\cos qd + \frac{\beta - 6\gamma\eta}{q}\sin qd - 2\phi,$$

where $\phi = \cos\theta_2 + \cos\theta_3$, and (13) becomes

$$\pm\cosh\xi = 3\left[\cos qd - \frac{\eta}{q}\sin qd\right] - \phi. \qquad \ldots\ldots(14)$$

Hence

$$6\gamma = 3 + \left(\epsilon - \frac{q^2}{\eta^2}\right)^{1/2} + (2\cos qd - \phi)\frac{q}{\eta\sin q} + R', \qquad \ldots\ldots(15)$$

where

$$R' = \pm\left[q\left(1 - \frac{q^2}{\eta^2}\right) + \left(\frac{q}{\eta\sin qd}\right)^2(8 - 6\phi\cos qd + \phi^2) + 6\frac{q}{\eta}(\phi - 3\cos qd)\right]^{1/2}.$$

Again there is only one allowed root of (15) for fixed ϕ, and this is determined from

$$\pm\sinh\xi = \phi + R'\frac{\eta}{q}\sin qd.$$

Since $\theta_r = k_r d$ for $r = 2$ and 3, ϕ can have M^2 values where Md is the length of a ground domain, so there will be a maximum of M^2 energies for surface states for a given γ, as can be seen from (15). That is, there will be a band of surface states which when complete will have top and bottom values corresponding to $\phi = \pm 2$. Notice also that M^2 is the number of surface atoms per ground domain.

Figure 2 shows the behaviour of the surface bands with varying γ. The points of disappearance of the top and bottom states are determined from (14). A result not expected from the one-dimensional treatment is that overlapping of surface and volume bands can occur. Depending on γ, the surface band may be complete or lose states to the volume band below. Another unexpected result is that although as γ increases the top state is lost from the surface band, it is regained for a still larger γ, and the energy then tends asymptotically towards the bottom of the volume band, so that surface band widths go to zero for infinite γ.

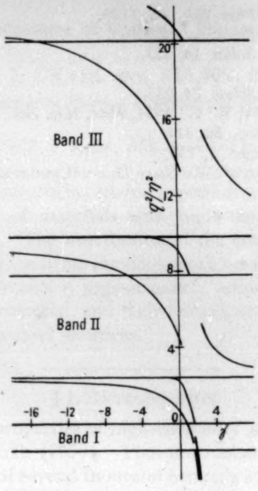

Fig. 2. Variation of the energies of surface states with γ for the three-dimensional case $\epsilon = 22$, $\eta d = 2$.

§ 4. DISCUSSION

The foregoing treatment is clearly incapable of giving any information about effects dependent on electron interaction or a particular form for the potential, and these may be important. However, we may have confidence that it shows the main properties depending on the symmetry of the potential in a crystal with a surface. As expected from § 3.1, the results for energies near the bottom band are in accord with the LCAO–MO treatment by Grimley (1958). As remarked there, the result that the maximum number of localized states is equal to the number of atoms in the surface is dependent on the fact that only the surface cells show any imperfection in the translational symmetry of the potential. The possible incompleteness of the surface bands, depending on the type of foreign atom, provides a possible mechanism for saturation of the surface with respect to adsorption, while it is still not completely covered (Grimley 1960).

Caution is needed in the interpretation of γ. The electron affinity is a property strongly dependent on the electronic structure. Since this is in general markedly different for crystal and free atoms, and since in chemisorption we expect the electronic structure of the adsorbed atom to be radically different from that of a similar free atom, we cannot equate γ to the relative electron affinities of the free atoms, but only to those of interacting crystal and foreign atoms. We might reasonably expect though, that electronically similar types of atoms adsorbed on the same type of crystal surface will show higher initial heats of adsorption the greater the electron affinity of the free atoms.

The Domain Structure of Ordered Platinum–Cobalt Alloy

BY D. J. CRAIK AND FELIÇA NUÑEZ†
Department of Physics, University of Nottingham

Communicated by L. F. Bates; *MS. received* 17*th February* 1961

Abstract. The domain structures in ordered regions of equiatomic platinum–cobalt are found to be typical of materials with high uniaxial anisotropy and low saturation magnetization. The distribution of the easy axes of discrete ordered regions within each grain confirms previous work on the nature of the ordering.

The width of the domains is approximately accounted for in terms of the known properties of the material, and their behaviour in applied fields shown to resemble that of other uniaxial materials.

§ 1. INTRODUCTION

A REVIEW of the properties of high-coercivity materials has recently been made by Wohlfarth (1959). Platinum–cobalt alloys can be produced with coercivities of several thousand oersteds and some of their properties have been the subject of previous investigations in this department (Phillips, Woolley and Street 1955). The high coercive force is associated with the development of an ordered phase, but the processes by which magnetization takes place in these alloys is still uncertain. It therefore seemed worth while to attempt direct observation of some of the magnetic structures and magnetization processes by Bitter figure techniques, preliminary work by D. Lee (unpublished) having revealed the existence of some structures on the surface of a platinum–cobalt specimen.

The clearest explanation of high coercivities is related to particles or regions which are too small to support a domain structure, and in which the magnetization can only be reversed by rotation (Stoner and Wohlfarth 1948). With certain modifications (e.g. Jacobs and Bean 1955, Frei, Shtrikman and Treves 1957) the fine particle theory seems to apply to powder or ellipsoidal single domain magnets (Luborsky, Paine and Mendelsohn 1959) and to precipitation-hardened alloys, in spite of the existence of large-scale domains in both these classes of materials (Craik and Isaac 1960). The impedance of domain-wall motion by inclusions, strain centres, etc., is generally supposed to lead to moderate coercivities only (Kersten 1943, Néel 1946), but a special 'coherency strains' theory has been suggested for high-coercivity materials (Geisler 1953).

§ 2. EXPERIMENTAL PROCEDURE

Studies were made with specimens cut from a polycrystalline ingot of the equiatomic alloy kindly supplied by Johnson, Matthey and Co. Ltd. By the usual Bitter figure techniques, patterns were obtained on mechanically polished surfaces of specimens following different kinds of tempering, but these patterns did not appear to represent internal domain structures. No patterns were obtained in the absence of a magnetic field but, on the application of fields near to or above saturation values, coarse bands of colloid running perpendicular to the direction of the field were formed. Figs 1 (*a*) to (*d*) (Plate I) show how these bands broke up and re-formed on a disk-shaped specimen as it was rotated about an axis perpendicular to the surface and to the applied field, which runs horizontally in the figures. This specimen had been tempered at 600°c for 15 minutes, following a quench from 1000°c, and it had a coercivity of 35 Oe.

---

† Ramsay Memorial Fellow, lately on leave from the University of Madrid.

Patterns studied at higher magnifications (Craik and Griffiths 1958) revealed a finely divided structure within these bands, with a spacing of about $0{\cdot}5\,\mu$ (Fig. 2 (*a*), Plate I). These corresponded roughly in dimensions and in mutual orientation to the etch patterns as shown in Fig. 2 (*b*), which is a carbon replica obtained after etching in aqua regia.

The above patterns were not due to surface undulations, but, in view of their persistence in high fields, they could not be due to domain structures of the usual type. Their formation was clearly dependent on a finely divided structure in the material, which may have formed by plastic deformation in the surface layers.

The method of surface preparation by treatment at high temperatures which was developed for the examination of ferrites (Craik 1960, Knowles 1960) was expected to be particularly useful for this two-phase material on which an entirely new surface should be formed as ordering occurs. Annealing *in vacuo* at 1100°c for 30–60 minutes, after careful mechanical polishing, was inadequate for the relief of surface strains, and annealing for six hours gave rise to a deeply undulating surface, presumably caused by localized flow relieving the grinding strains near the surface. A double treatment was given in which, after prolonged heat treatment, the surface was polished flat using fine diamond powder only, and then annealed once more for 30 minutes. This was found to produce a reasonably flat surface on which clear patterns could be obtained in ordered regions.

When the annealing, which was at a temperature adequate to produce complete disordering, was followed by quenching, the only clear patterns formed were in a few limited regions along some of the grain boundaries, as shown in Fig. 3 (Plate I). The material in these regions clearly had different properties to the remainder, suggesting that a very limit amount of ordering had occurred (see below).

When the annealing was followed by tempering for ten hours at 600°c without further surface treatment, the patterns shown in the figures described in § 3 below were obtained. Their clarity and continuity indicated that the surface was free from extraneous strains due, no doubt, to the transformation of the crystal structure during ordering. To reduce the likelihood of anomalous ordering due to pre-existing strains, as observed by Newkirk, Smoluchowski, Geisler and Martin (1951) near the surfaces of swaged wires, the surface of one of our specimens was etched away to a depth of $50\,\mu$, corresponding to the maximum width of the patterns; the etch patterns were removed by light polishing with $\frac{1}{4}\,\mu$ diamond powder, and the cycle of annealing and tempering repeated, but the patterns were unchanged. Results on two different specimens cut from the same ingot were virtually identical.

The coercivity of the specimens after the tempering for 10 hours at 600°c was 4000 Oe. A demagnetization curve of one of the specimens, required in the description of results, is shown in Fig. 11.

§ 3. RESULTS ON THE ORDERED SPECIMENS

3.1. *The Demagnetized State*

The crystal grains were found to be sub-divided into sharply defined regions, each of which gave a distinct pattern. Fig. 4 (Plate II) shows three major regions within one grain, as well as several smaller regions. The pattern in the middle (AA) is virtually identical with those obtained on the basal planes of hexagonal crystals of barium ferrite or magnetoplumbite, while those on the remaining large regions closely resemble patterns on side surfaces of crystals of these materials or of cobalt which are not strictly parallel to the easy axis. All the patterns observed were variations of these two types, and it is noteworthy that no closure structures were seen. Hence, the basic structure is that for a typical uniaxial material with high anisotropy and relatively low saturation magnetization, as is shown diagrammatically in Fig. 5; i.e. a set of 180° domains with walls which are parallel in the bulk of the crystal but undulate near its surface (Goodenough 1956) and small spikes of reverse magnetization from surfaces normal to the easy axis.

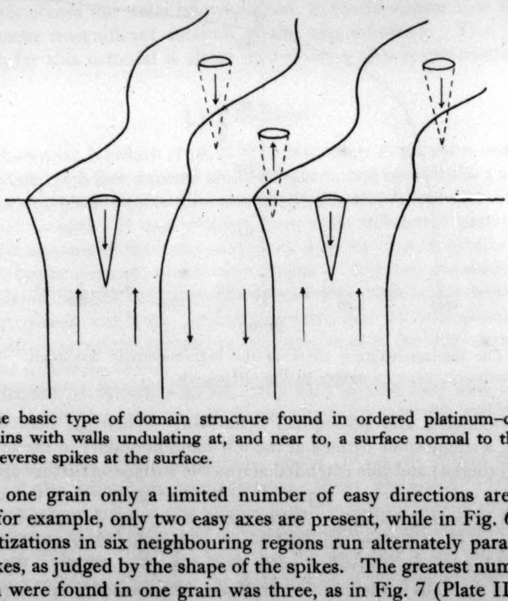

Fig. 5. The basic type of domain structure found in ordered platinum–cobalt: 180° domains with walls undulating at, and near to, a surface normal to the easy axis, and reverse spikes at the surface.

In any one grain only a limited number of easy directions are indicated. In Fig. 4, for example, only two easy axes are present, while in Fig. 6 (Plate II) the magnetizations in six neighbouring regions run alternately parallel to only two easy axes, as judged by the shape of the spikes. The greatest number of easy axes which were found in one grain was three, as in Fig. 7 (Plate II).

The dimensions of the regions vary widely. The largest are about $50\,\mu$ in width, and Fig. 8 (Plate II) shows regions between $1\,\mu$ and $8\,\mu$ wide in which the magnetization is directed alternately parallel and normal to the surface. Regions as narrow as $0{\cdot}1\,\mu$ are clearly represented in the patterns of Fig. 9 (Plate II), and it is found that domains cease to form when the width of the regions is less than $0{\cdot}5\,\mu$. The narrower regions are generally the more elongated, and their magnetizations are generally directed perpendicular to their long axes.

The spacing of the domains increases with the width of the regions, measured parallel to the easy axis, but reliable measurements of the spacing can only be made when the walls are parallel, i.e. when the easy axis is parallel to the surface, a state of affairs which rarely occurs in this polycrystalline material. In view of the pronounced interaction between the regions a great number of measurements would be necessary to derive an empirical relation between spacing and width of the regions, and this has not yet been found.

3.2. *Studies of Wall Movement*

Figures 10 (*a*) to (*f*) (Plate III) show a region which has an easy axis parallel to the long axis of the specimen. In a field of 17 000 Oe applied parallel to the axis of the specimen, no structures remained in this region although some residual structures were observed on other regions having an easy axis normal to the field direction (cf. Fig. 10 (*d*) corresponding to the point *a* on the demagnetization curve, Fig. 11). These residual structures were distinguished from striations by their orientation and subsequent behaviour. When the field was reduced to 1500 Oe, a single spike formed at the left-hand boundary of the central region (Fig. 10 (*b*) ringed) and this extended across the surface as further spikes formed (Fig. 10 (*c*)), until the region appeared to be demagnetized as the applied field approached zero (Fig. 10 (*d*)). At the same time, the domains in the regions near the top of these figures, directed nearly perpendicular to the field direction, grew in width until the individual walls were seen (Fig. 10 (*d*)). When the field was reversed the walls in the middle were again transformed to spikes (Fig. 10 (*e*)), which retracted towards the left-hand boundary (Fig. 10 (*f*)), to disappear when the field was −2000 Oe.

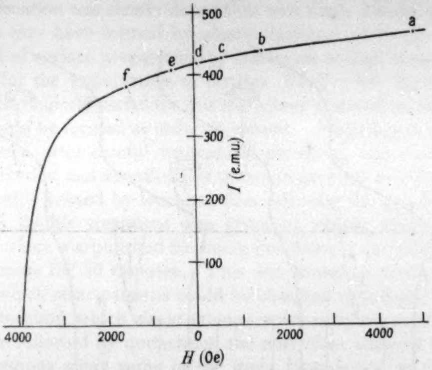

Fig. 11. The demagnetization curve of the high-coercivity specimen. The point *a* refers to Fig. 10 (*a*), etc.

The effect of fields applied parallel to the surface but normal to an easy axis is demonstrated more clearly by Fig. 12 (Plate III). In a field of 17 000 Oe the domains ran right across the region, but alternate domains were very narrow. When the field was reduced to 600 Oe the pattern of domains was replaced by one of walls with nearly uniform spacing (Fig. 12 (*b*)). When the field was reversed and given negative values above 500 Oe, the pattern of walls was replaced once more by domains of unequal width, occupying the alternate positions to those in Fig. 12 (*a*).

The behaviour of the domains directed parallel to the field direction is similar to that which has been observed on uniaxial single crystals, i.e. the transformation of parallel walls to spikes based on the boundaries normal to the magnetization, so that the pattern of free poles is maintained until the internal field approaches $4\pi I_s$ or, as in this case, a considerably lower value due to the interaction with neighbouring regions. The spikes are only seen along one of the boundaries owing to a slight misorientation of the surface. The spike which disappeared last as saturation was approached occupied the same position as that which nucleated first, thus indicating the importance of non-uniform demagnetizing fields on this part of the magnetization cycle.

The change in the width of the domains magnetized approximately normal to the field direction (Fig. 12) may be ascribed to a small component of the field parallel to the easy axis. Assuming that the condition of no divergence of magnetization across the walls is maintained, it would appear that fields up to 17 000 Oe cause insignificant rotation of the magnetization. The 'anisotropy field' $2K/I_s$ for this material is about 45 000 Oe, which is extremely high.

§ 4. Discussion

It was shown by Newkirk *et al.* (1951) that when a specimen initially in the disordered state, with face-centred cubic structure, was annealed at a temperature in or near the two-phase region, discrete regions of ordered, face-centred tetragonal material were formed. It was inferred from x-ray diffraction patterns that the minimum dimensions of the ordered regions were very much greater than $0{\cdot}1\,\mu$, and that the lattice was not considerably strained. Microscopic studies indicated that the ordered regions had plate-like shapes with their major faces parallel to (110) matrix planes, and it was further suggested that the orthogonal axes of the tetragonal lattice remained parallel to the cubic axes of the disordered phase, so as to impose minimum strain.

The existence of discrete regions, each with its own easy axis within every grain, clearly arises from the two-phase nature of this material, and has not been found elsewhere. The general form of the domain structures corresponds to the high value of the crystal anisotropy, about 10^7 erg cm^{-3}, and the relatively low value of the saturation magnetization, about 450 e.m.u. (Martin 1957). Since the tetragonal cell has one unique axis it is not surprising to find that the anisotropy has a uniaxial form, and comparison with the orthoferrites (Sherwood, Remeika and Williams 1959) suggests that the easy axis is the tetragonal *c*-axis.

It was not to be expected that the distribution of the easy axes within any one grain would generally be clearly revealed in patterns on a polycrystalline material. According to Newkirk, however, the distribution of the axes should be particularly simple on a surface which is a matrix (100) plane, since this should contain three mutually perpendicular tetragonal axes. In Fig. 8 the 180° walls on alternate regions are very nearly parallel, so that the axes must lie close to the surface which could thus be a (100) or a (110) plane of the original cubic system. The patterns on the intervening regions indicate that their easy axes are normal to the surface, thus defining the plane as the (100). Since the intersection of the

(110) plane with a (001) surface is perpendicular to the [100] direction, a section along a line such as *xx′* for example, can be represented diagrammatically as in Fig. 13.

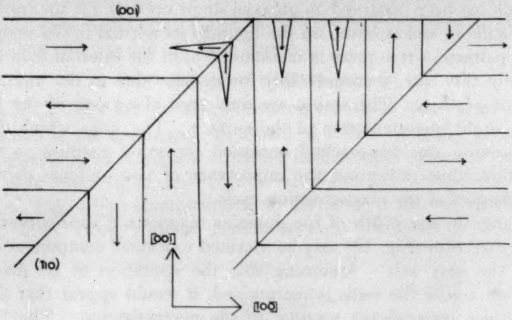

Fig. 13. Formal interpretation of the patterns shown in Figs 4 and 7. (Section normal to the surface and to the long axes of the lamellae.)

Figure 4 may be interpreted similarly, and in this case it is interesting that towards the right-hand boundary of the central region the walls undulate progressively less and less, which is consistent with the decrease in depth measured parallel to the axis, as indicated in the diagram. The structures in Fig. 6 indicate that the magnetization makes a considerable angle with the surface (Isaac 1960), and since the projections of the easy directions on the surface are parallel, the domains in a cross section normal to the surface and to the long axes of the regions may be represented by Fig. 14.

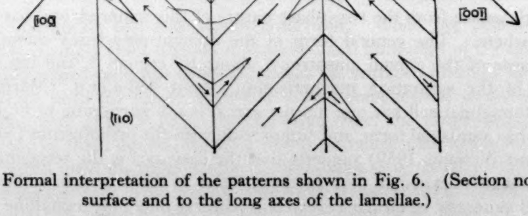

Fig. 14. Formal interpretation of the patterns shown in Fig. 6. (Section normal to the surface and to the long axes of the lamellae.)

These diagrams explain the continuity of the walls between neighbouring regions in which the easy axes are perpendicular; if the boundaries between the regions were parallel and normal to the neighbouring easy axes no continuity of the flux would be possible. In fact, the normal component of the magnetization at the boundaries would vanish if these were strain-free and the regions would always tend in the demagnetized state to be single domains whatever their size.

If each region were considered to be magnetically isolated, the spacing of the domains d could be calculated in terms of the width L measured in the direction of the easy axis, according to the relation

$$d = \left(\frac{\sigma L}{1{\cdot}7 I_s^2/2}\right)^{1/2} \text{ cm},$$

on replacing I_s by its 45° component, $I_s/\sqrt{2}$, in the formula due to Kittel (1949). This formula is expected to apply, approximately at least, after measurements made on magnetoplumbite (Kaczĕr and Gemperle 1960).

In the above expression σ is the wall energy, given by

$$\sigma = 2(KA)^{1/2} = 2\sqrt{20} = 9 \text{ erg cm}^{-2},$$

taking the exchange constant A as 2×10^{-6} and K as 10^7 erg cm^{-3}. This gives $d = 8{\cdot}2\times10^{-3}\sqrt{L}$ cm or, transferring to micron measurements, $d = 0{\cdot}82\sqrt{L}$ microns.

The following Table may be compiled from measurements on Fig. 8 and other figures in which the regions have the same boundary conditions.

L (μ)	16	14	14	8	3
d (μ)	6	5	4	4	2
$0{\cdot}82\sqrt{L}$	3·3	3·1	3·1	2·3	1·4
$d/0{\cdot}82\sqrt{L}$	1·8	1·6	1·3	1·7	1·4

The greater magnitude of the measured wall spacing compared with the calculated value is to be expected because of flux closure between the regions. The data indicate that the effective value of the flux density at the boundaries between the regions is about $4\pi(I_s/1{\cdot}6)$ gauss.

§ 5. CONCLUSIONS

The general form of the domains found in ordered regions of platinum–cobalt alloy is consistent with the magnitudes of the magnetic anisotropy and the saturation magnetization, and indicates that the anisotropy is of the uniaxial type. The size of the domains is in reasonable agreement with that expected from the theoretical relations, although some uncertainty is involved because of flux closure between the regions. The distribution of the easy axes within each grain, together with the orientation of the boundaries of the ordered regions, support the findings of Newkirk *et al.* on the way in which ordering occurs, viz. that the ordered regions are generally bounded by (110) planes and that the orthogonal axes of the tetragonal ordered lattice remain parallel to the cubic axes of the original disordered phase.

If the results obtained can be assumed to be representative of high-coercivity specimens in general, they clearly weigh against the application of the fine particle theories, only a very small proportion of the ordered regions being found to be single domains in the demagnetized state. However, in spite of the precautions taken, it was not certain that ordering did not occur to a greater extent near to the surfaces than throughout the bulk of the specimens, since very nearly all of the material appeared to be ordered. Noting, however, that the methods used are capable of demonstrating the structures in regions down to less than 1 μ in width, by further work on this and similar alloys it should be possible to elucidate such problems fully.

ACKNOWLEDGMENTS

We wish to record our thanks to Professor L. F. Bates for his interest in this work, to Dr. J. H. Phillips for much advice and help concerning the specimens kindly provided by Messrs. Johnson Matthey and Co. Ltd., and to Mr. A. Rudman for assistance with the heat treatments. One of us (F. N.) is greatly indebted to the Ramsay Memorial Fellowships Committee for the award of a Fellowship which made possible her stay in the University of Nottingham. D. J. C. thanks Messrs. Boots Drug Co. Ltd., for permission to use the electron microscope on this project.

The Estimation of Domain Wall Velocity in a ' Square Loop ' Ferrite, and some Observations on the Reversal Process

By J. E. KNOWLES
Mullard Research Laboratories, Salfords, Surrey

MS. received 9th February 1961

Abstract. Bitter pattern observations were used to investigate the relationship between the applied field and wall velocity in a polycrystalline manganese–magnesium ferrite. The wall velocity was found to lie in the range 500 to 1000 cm sec^{-1} (effective Oe)$^{-1}$ and the motion of the wall was shown to be impeded by Néel spike domain structures around pores in the material. The quasi-static nucleation and reversal process was also investigated: it was found that after saturation nuclei of reverse magnetization appeared on pores on the grain boundary, which evolved into trapezoidal domain structures. Nucleation appeared to play no part in the low field (± 3 Oe) reversal process.

§ 1. INTRODUCTION

THE velocity attained by the domain walls in a ferrite when the magnetization is reversed by a pulse field is generally determined from measurements on a ' picture frame ' sample carrying only one wall, cut from a single crystal of the required composition: see for example Dillon and Earl (1959). This method produces accurate results but is not without certain limitations. Measurements may perhaps be made only at low temperatures, single crystals of the required composition must be available, and the preparation of the sample requires much time and skill. Also, when studying the reversal process in polycrystalline materials it is of interest to know the velocity the domain walls reach in very imperfect crystallites, as distinct from the velocity they may have in a more nearly perfect ' single crystal ' of the same composition. Accordingly a method was devised, based on the observation of Bitter patterns, for estimating wall velocities in polycrystalline samples.

§ 2. THE PRINCIPLE OF THE METHOD

A grain similar to that described in earlier Bitter pattern observations (Knowles 1960) was located in the surface of a toroid of ' square loop ' ferrite: i.e. the grain had an approximately rectangular shape and showed well-defined 180° walls lying almost parallel to the field direction. A single magnetizing pulse of known amplitude and duration was then applied. This pulse caused the wall to move through a certain distance which was readily observed, and thus the domain wall velocity could be estimated. There were a number of sources of error which made the method one of low precision, for example the wall area was very probably a function of its position. It may be supposed that the wall energy also varied with wall position so that after the pulse ended the wall moved immediately to an adjacent site where its energy was a minimum, thus introducing an error into the velocity determination. Furthermore there was a possibility that whilst the wall was in motion it might have encountered an obstacle which brought it to rest before the termination of the pulse. To remove this uncertainty the distance moved by the wall during a pulse was used as a basis for a domain wall velocity determination only in those cases where a second field pulse caused the wall to move further. For a similar reason the duration of the pulse was always chosen to be less than the reversal time of the polycrystalline sample when driven by a field of the same magnitude. Finally, it has been assumed that under these conditions the wall moved as an entity. It is possible, though much less plausible, that the magnetization reversed by a rotational process and the wall afterwards reformed in a new position.

§ 3. EXPERIMENTAL TECHNIQUE

Pulse fields of up to 5 Oe amplitude and 0·2 to 1·2 μsec duration were obtained by discharging a coaxial line through a wetted contacts mercury relay. In order that the rise time of the pulses should be very short, of the order of a few nanoseconds, it was necessary to use a small toroidal sample wound with a small number of turns. To satisfy these conditions a thin walled toroid, 4 mm in diameter, was wound with a single turn of a multistrand wire, arranged so that it covered one-third of the circumference.

The surface of the specimen was prepared by the method used previously (Knowles 1960): the technique used to observe the Bitter patterns is described in an appendix to the present paper. Grains having a suitable shape, domain structure, and orientation were difficult to find, and a full series of measurements was made on only one grain of a sample of nominal composition $Mn_{0\cdot47}Mg_{0\cdot84}Fe_{1\cdot69}O_4$. Fig. 1 (Plate I) shows a rather large grain, 90 μ long, carrying two domain walls. The shape of the closure domains indicates that these are very probably 180° walls. Before each measurement one of the walls was moved until it was adjacent to the top edge of the grain. A field pulse was then applied, and the distance moved by the wall was measured with a graticule in the eyepiece of the microscope. The wall usually moved through about 6 μ, a small distance compared with the length of the grain.

It was noticed that if the wall was driven by a series of, for example, negative pulses and then made to reverse its direction by applying a positive pulse, this latter caused the wall to move about 20% further than subsequent positive pulses: the results to be described are based on these 'first' pulses. This effect was attributed to the influence of Néel spikes and tubes (Néel 1944) running between pores in the material and the wall. Suppose that the mean distance between pores was much greater than the wall thickness. Then when the negative pulse ended, the wall was left in a position where it passed through a number of pores which firmly anchored it, whilst Néel tubes connected the wall to some of the adjacent pores through which the wall had just passed. Owing to the fairly high anisotropy energy, about 2×10^4 erg cm^{-3}, the wall had a tendency to remain plane so that it was only locally distorted by the tension in the tubes. If another negative pulse was applied the wall as it moved first stretched and then broke the tubes so that Néel spikes reformed about the pores. If on the other hand a positive pulse was applied the tubes actually assisted the initial motion of the wall, and so the first positive pulse drove the wall a little further than did subsequent positive pulses.

A plot of apparent wall velocity against applied field H_a ($H_a = H\cos\theta$ where θ was about 9°) is shown in Fig. 2: it may be seen that the velocity varied with field according to the equation

$$V_a = 985(H_a - 0{\cdot}62)\,\mathrm{cm\,sec^{-1}}$$

where H_a was in oersteds. This relationship is of the same form as that found by Dillon and Earl (1959) and other workers using 'single crystal' samples. Measurements were also made starting with the walls in the position shown in Fig. 1. The spread of the results was rather greater and the wall velocity lower, about 500 cm sec^{-1} Oe^{-1} with an indeterminate 'coercive force'.

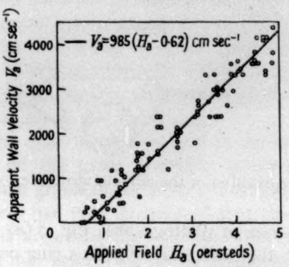

Fig. 2. The variation of apparent wall velocity with applied field for a 'square loop' ferrite.

§ 4. OBSERVATIONS OF NÉEL SPIKES

If the surface of a sample was prepared by the earlier method the pores did not intersect the surface of the grains. What appear to be pores in Fig. 1 are actually small hillocks which, it is believed, are the sites of dislocations made visible by thermal etching, much as pits may be formed by a chemical etch. It is not proposed to discuss these further in this paper.

In order to examine a surface intersected by pores a different method of preparation was adopted. A toroid of the same composition as before, dense and with large grains, was made by firing for 19 hours at 1350°c in oxygen. The face was then ground and polished, finishing with 1 μ diamond paste. The pores which were revealed were either essentially spherical in shape or had sharply defined re-entrant cusped forms. To relieve the stresses induced by the polishing process the surface was then annealed by reheating for 20 minutes at 1320°c (Craik 1960). The heat treatment also etched the surface so that the grain boundaries and dislocations were revealed. The spherical pores were found to lie within the grains away from the grain boundaries, and the other type occurred between the corners of grains and sometimes extended along the boundaries.

As before, a grain of rectangular shape ($130\,\mu \times 110\,\mu$) with 180° domain walls lying parallel to the field was found. Fig. 3 (Plate I) shows the powder pattern when the material was demagnetized: it may be seen that nearly all the pores support Néel spikes. Fig. 4 (*a*) gives an interpretation of the domain structure on the wall together with that of a spike domain. It will be noticed that the closure domain structure can move along the wall without any change in wall energy. As in the grain described earlier the wall was a 180° wall lying in the (211) plane, the surface of the grain lying in the (110) plane. The Néel spikes were much less elongated than those observed by Williams, Bozorth and Shockley (1949) on silicon iron, a result which was in accordance with a rough theoretical estimate of the expected length/diameter ratio, similar to that made by Williams *et al.* A series of photographs, Fig. 5 (*a*)–5 (*c*) (Plate II), shows the wall moving through the pore marked with a ring on Fig. 3. Starting with the wall intersecting the pore, as the field was increased from zero (*a*), the wall first bowed and then became linked to two pores by a triangular domain structure ((*b*), 0·67 Oe). As the field was further increased the left-hand side of the wall first broke free leaving behind a spike ((*c*), 1·9 Oe), and as the wall continued to move forward it was seen to be caught on two more pores. An interpretation of the domain structure of Fig. 5 (*b*) is given in Fig. 4 (*b*). The two walls drawn in with a broken line could not be observed on the photograph, but one of them was seen in a subsequent visual observation.

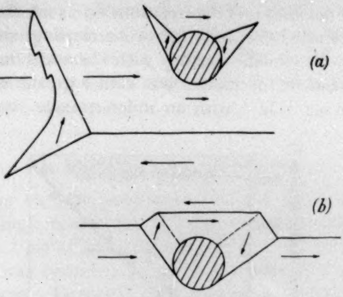

Fig. 4. An interpretation of the domain structures of Figs 3 and 5.

§ 5. The General Reversal Process, and Discussion

Measurements of domain wall velocity on the grain which has been described, together with some isolated results on other grains of the same composition, showed that the domain wall velocity in $Mn_{0.47}Mg_{0.84}Fe_{1.69}O_4$ lay in the region 500–1000 cm sec^{-1} (effective Oe)$^{-1}$. From Barkhausen effect measurements on samples of the same composition J. Roche (unpublished) estimated that the wall velocity lay in the range 300–1000 cm sec^{-1} (effective Oe)$^{-1}$.

These values at first sight appear to be rather low, for the grains shown in Figs 1 and 3 would both take much longer to reverse their magnetization than did the polycrystalline toroid. The explanation is that these very simple domain structures are not typical of the grains in general, or even of these particular grains. The grain of Fig. 1 can support up to four parallel walls, and when the material was taken around a hysteresis loop the domain structure remained essentially simple. The domain configuration of the grain of Fig. 3 was usually considerably more complicated than that shown in the illustration. To investigate the nucleation and reversal process in this grain it was first technically saturated by subjecting it to a field of +28 Oe. This removed all the domains except for a few Néel spikes around the pores both in the body of the grain and in the grain boundaries. When the field was slowly reduced the spike domains on the boundaries began to increase their volume by spreading sideways, and one or two spike domains immediately adjacent to the original spikes appeared. As the field was further decreased these nuclei coalesced and sometimes spread out into trapezoidal arrangements with either one or two 180° walls: both types appear in Fig. 6 (*a*) which shows the grain when the field was + 1·4 Oe. It will be noticed that the domains carry closure structures of the type shown in Fig. 4(*a*). (On other occasions, the domain arrangement whilst essentially similar to that shown was rather more complex.) After the field was decreased to zero and then reversed the domains rapidly increased their size until they began to touch (Fig. 6 (*b*), − 1·59 Oe). The wall area was now at a maximum. As the reversal process continued some of the walls annihilated each other (Fig. 6 (*c*), − 2·54 Oe), sometimes resulting in a wall spreading across the width of the grain. It was not always possible to trace a wall along its entire length because of the numerous pores. If the toroid was now cycled with a field of two or three oersteds the magnetization reversed by the motion of the sections of 180° walls, together with movement of the 'kinks' along the walls.

The pores within the grain played no part in the nucleation process, and it is evident that pores on the grain boundary generally had a much higher demagnetizing factor than grains in the body of the material. This was because the grain boundary pores had very irregular shapes (those shown in the figures were rounded-off in the annealing process) and also because of the very large free pole energy which may arise from the differing orientation of neighbouring grains (cf. Goodenough 1957).

What proportion of the coercive force arises from porosity and what proportion from other mechanisms cannot at present be assessed, but it seems very possible that the pores are those 'barriers' to domain wall motion discussed in the earlier papers (Knowles 1961 a, b). This question can only be satisfactorily resolved by preparing a pore-free sample of the same composition.

APPENDIX

A TECHNIQUE FOR OBSERVING BITTER PATTERNS

The colloid was prepared according to the recipe given by Bozorth (1951).

The domain patterns were observed with a microscope fitted with a Wrighton Beck illuminator and a 2 mm oil immersion objective. The specimens were too small for the usual cover glass technique to be employed, and so the objective was converted into a water immersion objective with an extremely short working

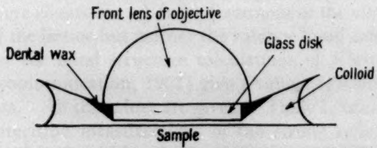

Fig. 7. The modification of an oil immersion objective to facilitate Bitter pattern observations.

distance. This was done by replacing the immersion oil by a glass disk (of the same refractive index) cemented to the underneath of the front lens of the objective (Fig. 7). The thickness of the disk was adjusted by trial and error until it was just possible to focus the objective when the disk was temporarily stuck to it, water being used to fill the remaining small space between the glass and surface of the sample. When a disk of a suitable thickness was found it was fixed in position with an optical cement: during this process the front cell of the objective was unscrewed and the hemispherical lens supported from the back. The cement was protected from the colloid by flushing dental wax round the joint.

ACKNOWLEDGMENT

The author would like to thank the management of Mullard Research Laboratories for permission to publish this paper, and Dr. G. H. Jonker for a stimulating discussion.

The Electronic Distribution in Diamond and the Intensities of X-ray Reflections

By H. C. BOLTON AND J. W. HEATON†

Physics Department, King's College, Newcastle upon Tyne, 1

MS. received 3rd February 1961

Abstract. A theoretical calculation of the electronic charge distribution in the diamond lattice is presented. The method used is that of Thomas and Fermi and two angular terms are included to represent the departure from spherical symmetry round each carbon atom. The charge density has been used to calculate the structure factors which appear in the X-ray reflections and these calculated structure factors have been compared with recent experimental values. To some extent, both the fine details of the strong lines and the presence of the so-called 'missing reflection' 222 are accounted for on the present theory.

§ 1. INTRODUCTION

FOR many years, the measurements of Brill, Grimm, Hermann and Peters (1939) on the intensities of X-ray reflections from diamond have been accepted as the most accurate and there have been several discussions of the electron density of diamond based on these measurements (Brill 1950, 1959, Neuhaus 1960, Carpenter 1960). Recently, however, there have appeared the measurements of Göttlicher and Wölfel (1959) which seem to be more accurate than those of Brill *et al.* These new measurements are supported in part by measurements of Brill and Barth (1959) and together they have revealed the inadequacy in the details of the existing theoretical calculations of the charge density in diamond and its Fourier components. The simplest model for the charge density is to take separate carbon atoms each in the spherically symmetrical valence state. Berghuis *et al.* (1955) have given the best calculations and while they give a good overall fit to the measured form factors $f(hkl)$, there are, as Göttlicher and Wölfel point out, significant discrepancies for low values of hkl where the valence electrons contribute the most to the scattering. These discrepancies arise because this model of the diamond lattice employing separate atoms has ignored the effect of bonding: higher order reflections are accounted for entirely by the core electrons. A fuller treatment of the electrons will include the periodic field of the lattice but neither the valence bond calculations of Ewald and Hönl (1936) or the band structure calculations of Kleinman and Phillips (1959 and private communication, 1961) give f values agreeing closely with the recent measurements. All the values are given in Table 1, later in this paper. In addition to these precision measurements of the strong reflections there exists the 222 reflection which should be absent if the atoms at the lattice sites were spherically symmetrical. The best value of the 222 is that of Renninger (1955). Ewald and Hönl calculated a value for $f(222)$ only one-fifth of the experimental value, but Kleinman and Phillips (1961, private communication) recently

† Now at Services Electronics Research Laboratory, Baldock, Herts.

calculated a value about two-thirds of the experimental value. It is with all these theoretical and experimental results in mind that the following calculations are presented.

A final comment is needed about the lattice structure itself. Neuhaus (1960) believes that an intrinsic double refraction can be observed in diamond which would be absent if the lattice were the familiar one given by Bragg and assumed by all later workers. Neuhaus suggests that there are two modifications of diamond and discusses the charge density in terms of the data of Brill *et al.* (1939). It is difficult to see how Neuhaus' suggestion can be used at present and the following discussion is based, as are all previous theoretical calculations, on the traditional diamond lattice of Bragg.

The discussion uses the Thomas–Fermi method. It is known that this cannot give accurate values for the charge distribution, especially for a small density of electrons. However, the overall picture for the effect of the lattice periodicity is expected to be satisfactory and the method certainly enables the non-spherical nature of the charge distribution to be readily introduced.

§ 2. THE THOMAS–FERMI METHOD APPLIED TO CRYSTALS

Reviews of Thomas–Fermi theory have been given by Gombas (1949) and March (1957). It is sufficient here to state that a solution is required of the non-linear equation

$$\nabla^2 V = \mu V^{3/2} \qquad \ldots\ldots (2.1)$$

where V is the Thomas–Fermi potential and μ the constant $8\sqrt{2}/3\pi e^{1/2} a_0^{3/2}$, a_0 being the first Bohr radius (Gombas 1949, p. 34). The simplest solution for atoms in crystals was given by Slater and Krutter (1935). The solution was found inside a Wigner–Seitz cell (the lattice polyhedron): each atom is surrounded by a similar space-filling cell. The solution of the problem within one of these cells is sufficient to provide a solution for the whole crystal. For many crystals, the Wigner–Seitz cell closely resembles a sphere and Slater and Krutter replaced the Wigner–Seitz cell by a sphere of equal volume and assumed the potential inside the sphere was radially symmetrical. The boundary condition at the surface of the sphere enabled the atom inside the cell to be neutral.

Although the Slater–Krutter technique has been successfully applied to face-centred cubic and body-centred cubic lattices, it is not justified for the diamond lattice. We have here only four neighbours for each atom and the Wigner–Seitz cell differs widely from a sphere. The Wigner–Seitz cell in diamond was first described by Kimball (1935) and is basically a regular tetrahedron which has had its four corners removed to create four large hexagonal faces: on each corner is a small prism. We expect that the outer portions of the carbon atom in diamond will show fairly considerable tetrahedral distortion: this is an expression of the concept of strong chemical bonding.

To go beyond the Slater–Krutter approximation and to use the symmetry of the Wigner–Seitz cell, it is necessary to include angular terms in the potential. March (1954†) was the first to do this in a discussion of silicon and an important result of his analysis was that the first lattice harmonic in the potential was not enough to give an adequate account of the angular dependence. Payne (1958) studied copper (face-centred cubic) not by using the lattice harmonics explicitly but by developing an iterative method for improving the Thomas–Fermi potential, starting from a summation over simple free atom Thomas–Fermi solutions centred at each lattice site. We have used this method for diamond and it has confirmed the need to use more than one lattice harmonic. Hum (1959) obtained a Thomas–Fermi solution for Fe (body-centred cubic) by introducing two lattice harmonics into the potential directly. Since March, Payne and Hum all inserted the angular terms into the potential as perturbations, there are close links between their work. We shall present our analysis in a form very close to that of Hum.

§ 3. EQUATIONS FOR THE POTENTIAL

The origin of the spherical polar coordinates is at the carbon nucleus, with the polar axes along a (100) axis. The Thomas–Fermi potential is written as

$$V(r,\theta,\phi)=S(r)+AR(r)+Bf(\theta,\phi)F(r)+Cg(\theta,\phi)G(r) \qquad \ldots\ldots(3.1)$$

where $S(r)$ is the Slater–Krutter approximation for the lattice, $R(r)$ is a spherically symmetrical correction to this, $f(\theta,\phi)$, $g(\theta,\phi)$ are the first two lattice harmonics for diamond,

$$f(\theta,\phi)=xyz/r^3=\sin^2\theta\cos\phi\sin\phi\cos\theta$$

$$g(\theta,\phi)=(x^4+y^4+z^4)/r^4-\tfrac{3}{5}=\sin^4\theta\cos^4\phi+\sin^4\theta\sin^4\phi+\cos^4\theta-\tfrac{3}{5}$$

and $F(r)$, $G(r)$ are the radial terms of the angular dependent functions.

Since $S(r)$ is the Slater–Krutter solution it satisfies

$$\nabla^2 S(r)=\mu S^{3/2}(r). \qquad \ldots\ldots(3.2)$$

We rewrite (2.1) as

$$\nabla^2 S+\nabla^2(V-S)=\mu[S+(V-S)]^{3/2} \qquad \ldots\ldots(3.3)$$

and expand, when the right-hand side becomes

$$\mu S^{3/2}+(3/2)\mu S^{1/2}(V-S)$$

if we ignore terms of the order of $(V-S)^2$.

Hence

$$\nabla^2(V-S)=(3/2)\mu S^{1/2}(V-S). \qquad \ldots\ldots(3.4)$$

Now $V-S=AR+BfF+CgG$, and we write

$$S=Ze\phi_s(r)/r,\quad R(r)=Ze\phi_0(r)/r,\quad F(r)=Ze\phi_3(r)/r,\quad G(r)=Ze\phi_4(r)/r$$

and introduce the conventional Thomas–Fermi non-dimensional coordinate $u=r/b$ where $b=(3/32\pi^2)^{2/3}h^2/2me^2Z^{1/3}=0{\cdot}88534a_0/Z^{1/3}$; a_0 is the first Bohr radius and Z is the nuclear charge. Eqn (3.4) then reduces to the following three equations:

$$\left.\begin{aligned}\phi_0''&=H(u)\phi_0\\ \phi_3''&=[H(u)+12/u^2]\phi_3\\ \phi_4''&=[H(u)+20/u^2]\phi_4\end{aligned}\right\} \qquad \ldots\ldots(3.5)$$

where $H(u)=3S^{1/2}(u)/2$.

As Hum points out, increasing the number of harmonics in the series (3.1) would add more differential equations but the boundary conditions become increasingly difficult to apply as more harmonics are added to the problem. The series solutions in terms of the slope $(-m)$ of the Slater–Krutter solution at $u=0$ are:

$$S=1-mu+(4/3)u^{3/2}-(2/5)mu^{5/2}\ldots \qquad \ldots\ldots(3.6)$$

$$\left.\begin{aligned}\phi_0&=u+(2/5)u^{5/2}-(3m/35)u^{7/2}+(2/15)u^4-(m^2/84)u^{9/2}\ldots\\ \phi_3&=u^4+(2/17)u^{11/2}-(3m/95)u^{13/2}+(2/51)u^7\ldots\\ \phi_4&=u^5+(2/21)u^{13/2}-(3m/115)u^{15/2}+(2/63)u^8\ldots\end{aligned}\right\}. \qquad \ldots\ldots(3.7)$$

Starting values were obtained from (3.7) and Eqns (3.5) then solved numerically. The Slater–Krutter solution was generated using a Ferranti PEGASUS programme which had been developed to solve the Thomas–Fermi equation in a single variable for any given initial slope. Various initial slopes were tried and the solution examined at the Wigner–Seitz sphere radius u_0 where the boundary condition is

$$\left(\frac{d\phi_s}{du}\right)_{u=u_0} = \frac{\phi_s(u_0)}{u_0}. \qquad \ldots\ldots(3.8)$$

§ 4. Boundary Conditions

At the origin we must have $\lim_{r\to 0} rV = Ze$ which is satisfied by our solution. At $r=0$ only the Slater–Krutter solution remains. For the remaining boundary condition we consider the potential inside one Wigner–Seitz cell and we expect to find that the potential and its gradient will be continuous across the cell surfaces. We must also impose the condition that each cell is electrically neutral.

One Wigner–Seitz cell is rotated with respect to a neighbour by $\pi/3$ about an axis connecting the two nuclei (the bond direction). The hexagonal faces of the Wigner–Seitz cell touch on a plane at right angles to the bond at its midpoint but this is not a plane of symmetry for the lattice, even though the midpoint of the bond is a centre of inversion. Our boundary conditions are:

V and $(\partial V/\partial n)_s$ are both continuous over the surface S of the Wigner–Seitz cell. ......(4.1)

With only three constants A, B and C to determine, (4.1) cannot be satisfied exactly. Point matching of the potential and its gradient across the surface is unreliable due to the many possible alternative selections of the points. Guided by the experience of March (1954†), and of Bell *et al.* (1953) in similar problems on band structure calculations, we have attempted to reduce as much as possible the mismatch across the surface by minimizing

$$K = \int_s (V_\alpha - V_\beta)^2 dS \qquad \ldots\ldots(4.2)$$

$$L = \int_s \left\{\left(\frac{\partial V}{\partial n}\right)_\alpha - \left(\frac{\partial V}{\partial n}\right)_\beta\right\}^2 dS \qquad \ldots\ldots(4.3)$$

where α, β refer to neighbouring Wigner–Seitz cells. To keep each cell neutral we require

$$J = \int_s \left(\frac{\partial V}{\partial n}\right)_s dS = 0. \qquad \ldots\ldots(4.4)$$

The integrals needed were performed on the Ferranti PEGASUS and full details are given by Heaton (1960). Since K is identically zero for a Slater–Krutter solution (which is spherically symmetrical) it was considered better to minimize L with respect to A, B and C keeping $J=0$. The value for L for $A=B=C=0$ is $5{\cdot}704\times 10^{-3}$; the final values of A, B, C are

$$A = 2{\cdot}0080\times 10^{-3}, \quad B = 1{\cdot}0892\times 10^{-3}, \quad C = -0{\cdot}081215\times 10^{-3},$$

and the minimum value of $L = 0{\cdot}975\times 10^{-3}$.

We return to Eqn (3.3) to examine the error in the approximation. In the expansion of (3.3) the term $(3/8)S^{-1/2}(V-S)^2$ was neglected compared with $(3/2)S^{1/2}(V-S)$. If we define D to be the ratio of these two terms,

$$D = (V-S)/4S = (A\phi_0 + Bf\phi_3 + Cg\phi_4)/4\phi_s,$$

† See previous footnote.

$D_{\max} \simeq 0{\cdot}1$ and numerically decreases extremely rapidly as r becomes smaller. Hum (1959) found $D_{\max} \simeq 0{\cdot}05$ and he said that in lattices other than of cubic-type symmetry, $D_{\max}$ may become large due to the large departure of the crystal field from radial symmetry. The above analysis shows that the increase in D values for diamond over those for cubic lattices is not excessive. However D does become larger for the other possible boundary condition (minimization of K keeping $J=0$).

When the potential just calculated is plotted and compared with the Slater–Krutter values then there is an increase of potential along the bond direction corresponding to an increase of charge in this region. In the opposite (antibond) direction there is a decrease of charge. The number density (number of electrons per cubic ångström) resulting from the potential is

$$n=(28{\cdot}20/u)\{\phi_s''+A\phi_0''+Bf[\phi_3''-12\phi_3/u^2]+Cg[\phi_4''-20\phi_4/u^2]\}. \qquad \ldots\ldots(4.5)$$

§ 5. X-RAY SCATTERING

There are two tests which can be applied to the value of the charge density in diamond: (1) How do the calculated structure factors compare with the experimental values for the strong lines? (2) Does the charge density account for the presence of the so-called 'forbidden' x-ray reflections, especially the 222 line?

Since the diamond lattice consists of two interpenetrating face-centred cubic lattices with the basis (000) and $(\frac{1}{4}\frac{1}{4}\frac{1}{4})$, the structure factor for the (hkl) reflection is given by

$$F(hkl)=(f_0+f_1\exp[\tfrac{1}{2}i\pi(h+k+l)])S \qquad \ldots\ldots(5.1)$$

where S is the structure factor of the face-centred cubic lattice and f_0, f_1 are the atomic scattering factors of the two face-centred cubic lattices. Expressions for $F(hkl)$ for the first few reflections are given in column (1) of Table 1, in particular $F(222)+4(f_0-f_1)$.

It is usual to assume that all the carbon atoms are identical in diamond: this is a familiar assumption in crystallography. In diamond, each carbon atom is assumed to be in the 'valence state' which is spherically symmetrical and f_0 is identical with f_1 for all reflections. On this assumption,

$$F(hkl)=0, \quad h+k+l=4n+2, \quad n \text{ zero or integer.}$$

This assumption, that all the carbon atoms are spherically symmetrical, is only a first approximation, and a better approximation is the assumption made in the present paper that the separate carbon atoms have angular dependent charge distributions. Also, since nearest neighbours are rotated with respect to each other we can no longer say that f_0 is equal to f_1 and the existence of the 222 reflection is explained.

It is worth emphasizing here that we are still using the approximation of separate carbon atoms: each atom is contained in its own Wigner–Seitz cell, with the charge density given by the expression (4.5). Thus the region of integration needed to evaluate f_0 and f_1 is the Wigner–Seitz cell, not all space as it is in the simpler assumption of spherically symmetrical overlapping atoms. This simple assumption is almost universal in crystallography and indeed is quite adequate when the positions of the atoms are the important quantities. However, when the fine details of intensities are being discussed, especially with the increasing precision of measurement, this simple assumption is inadequate and has

Table 1. Values of Structure Factors for Diamond

hkl	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)

(1) $F(hkl)$; (2) experiment, Göttlicher and Wölfel (1959), Renninger (1955) ; (3) experiment, Brill *et al.* (1939), Brill and Barth (1959); (4) Hartree–Fock, Berghuis *et al.* (1955); (5) bonded atoms theory, McWeeny (1954); (6) band theory, Kleinman and Phillips (1959 and private communication, 1961); (7) valence bond theory, Ewald and Hönl (1936); (8) Thomas–Fermi finite spherical atom; (9) Thomas–Fermi ($f, g=0$), Bolton and Heaton; (10) Thomas–Fermi (all terms), Bolton and Heaton; (11) $f_{\rm val}/f_{\rm total}$, McWeeny (1951); (12) $f_{\rm val}/f_{\rm total}$, Kleinman and Phillips (1959).

to be replaced with that being discussed in the present article or a similar assumption such as the band theory of Kleinman and Phillips (1959). Since the angular distortion of the charge density will occur mainly in the outer valence electrons the inadequacy of the simple assumption will be revealed most strongly in the light atoms with a relatively large number of valence electrons. Another aspect of this is examined in § 6. Göttlicher and Wölfel (1959) present evidence for some anomalies in the intensities from silicon and their explanation must be similar to that being presented here for their results on diamond.

The actual calculation of the form factors $f(hkl)$ for the carbon atom depends on the geometry of the Wigner–Seitz cell. The reduction of the integration is long but straightforward and is omitted here. An important step is to employ the following theorem.

The only terms of the integrand $f(xyz)$ which contribute to the integral

$$\int_{\mathrm{WC}} f(xyz)\,dxdydz$$

which is taken over the Wigner–Seitz cell, are those which are completely odd or completely even in x, y and z. It then follows that

$$f_0=\int_{\mathrm{WC}}\rho(xyz)\times\left[\cos 2\pi\frac{hx}{a}\cos 2\pi\frac{ky}{a}\cos 2\pi\frac{lz}{a}-i\sin 2\pi\frac{hx}{a}\sin 2\pi\frac{ky}{a}\sin 2\pi\frac{lz}{a}\right]dxdydz \qquad \ldots\ldots(5.2)$$

$$f_1=\int_{\mathrm{WC}}\rho(xyz)\times\left[\cos 2\pi\frac{hx}{a}\cos 2\pi\frac{ky}{a}\cos 2\pi\frac{lz}{a}+i\sin 2\pi\frac{hx}{a}\sin 2\pi\frac{ky}{a}\sin 2\pi\frac{lz}{a}\right]dxdydz \qquad \ldots\ldots(5.3)$$

and

$$(f_0-f_1)=-2i\int_{\mathrm{WC}}\rho(xyz)\left[\sin 2\pi\frac{hx}{a}\sin 2\pi\frac{ky}{a}\sin 2\pi\frac{lz}{a}\right]dxdydz. \qquad \ldots\ldots(5.4)$$

This gives at once that a reflection of the type $h+k+l=4n+2$ will vanish even on the present model if one of the indices is zero. This explains the non-appearance of the 200 reflection from diamond. This conclusion was also proved using a different approach by Konobeyevsky (1957).

The integrals appearing in Eqns (5.2) and (5·3) were evaluated on the PEGASUS computer for several low order reflections and the results are presented in column (10) of Table 1: they will be discussed in § 6. In order to estimate the effect of the angular dependent terms in the potential the calculations were repeated using a potential of the form

$$V(r)=S(r)+A'V_0(r) \qquad \ldots\ldots(5.5)$$

where A' is determined by the restriction

$$\int_s\left(\frac{\partial V}{\partial n}\right)_s dS=0. \qquad \ldots\ldots(5.6)$$

We find $A'=0{\cdot}02023\times 10^{-3}$. Expression (5.5) has no angular terms and the charge distribution inside the Wigner–Seitz cell has only radial terms.

§ 6. DISCUSSION OF X-RAY DATA

The most recent experimental values for the reflections are those of Göttlicher and Wölfel (1959) for the strong lines and that of Renninger (1955) for the (222) Natural diamonds are divided broadly into two types: type I, which appear to contain many defects and type II, which is rarer and appears to be substantially perfect structurally. Grenville-Wells (1952) and Champion (1956) gave summaries of several properties and correlations of many diamonds and Champion attempted a more detailed classification in terms of various possible defects. In type I diamonds there are secondary extra reflections which Hoerni and Wooster (1955) have suggested are due to tetragonal lattice distortion. Renninger said that there was no difference in scattering power for the (222) line between type I and type II diamonds though there is some contrary evidence (Grenville-Wells and Wooster, private communication) that large variations can occur which may depend on the type. We have here accepted Renninger's values, subject to some doubt. Table 1 gives a full collection of recent theoretical and experimental data for some of the structure factors of diamond. For the purposes of the table, the experimental data of Göttlicher and Wölfel were converted to the values for atoms at rest using the temperature factors quoted by the experimenters. The data were obtained using both Cu and Mo radiation: the errors in column (2) are those quoted by Göttlicher and Wölfel who say that the intensity measurements with Cu and Mo radiation agree to within these limits. These errors are small and perhaps we must accept them cautiously until further experimental work on the intensities is done. The (111) value in column (3) is the latest experimental figure of Brill and Barth (1959). This value confirms the value of (111) given by Göttlicher and Wölfel. We would expect the band theory calculations of Kleinman and Phillips to give the best theoretical values: columns (6) and (2) are indeed in substantial agreement and this theoretical value of (222) is much better than either Ewald and Hönl (7) or the present calculation (10). Nevertheless the values of $F(hkl)$ for the strong reflections given by the Hartree–Fock valence state calculations of Berghuis *et al.* (4) are as good as (6), and neither agrees with the large value of $F(111)$. Only the first few reflections are influenced strongly by the valence electron density. This may be readily demonstrated using the technique of McWeeny (1951, 1954) for the calculations of atomic scattering factors employing Slater orbitals. McWeeny considers the valence state $2s2p^3$, which is spherically symmetrical. Writing a 1s unnormalized orbital as $\exp(-\mu r)$ and the radial part of the valence Slater orbital as $r\exp(-\nu r)$ and putting $X=(\sin\theta)/\lambda$, $x=2\pi X/\mu$, $y=2\pi X/\nu$, then if unorthogonalized Slater orbitals are used (sufficiently accurate for this purpose) we get a simple expression for the f factor of the valence state

$$f=\frac{2}{(1+x^2)^2}+\frac{4(1-y^2)}{(1+y^2)^4}. \qquad \ldots\ldots (6.1)$$

The proof of this follows from the definitions of the special functions introduced by McWeeny (1951). The first term on the right of (6.1) arises from the core electrons and the second from the valence shell. The proportional contribution of the valence shell orbitals to the total atomic scattering factor is given in column (11). These values agree well with those of Kleinman and Phillips (1959) who gave enough data for us to calculate column (12). Thus about 40% of $F(111)$ is due to the valence electrons. The lack of agreement between the theoretical and experimental value of $F(111)$ must be due to a description of the valence electrons which is still incomplete. One uncertainty attached to the experimental result is the temperature correction of Göttlicher and Wölfel but it has the smallest value for the (111) reflection: $F(111)_{\text{rest}}/F(111)_{\text{obs}} = 1{\cdot}012$. McWeeny's attempt to improve the description of the valence electrons has led to a worse agreement. The figures in column (5) were interpolated from his published tables.

Columns (9) and (10) give the results of the present calculations. In column (9) are presented the results without the angular terms $f(\theta, \phi)$ and $g(\theta, \phi)$; they have been included in the results of column (10). We cannot expect good agreement from a Thomas–Fermi calculation: nevertheless, the overall picure presented by (10) is fairly good. The values for a finite spherical Thomas–Fermi atom are given in (8), taken from the data of Umeda and Tomishima (1955): the value of $F(111)$ is a long way in error.

Table 2.

hkl	(1)	(2)	(3)	(4)
111	1·078	0·9925	1·076	1·135
220	0·9881	0·9267	0·9808	0·932
311	0·9323	0·9663	0·9308	0·945
400	0·9236	1·006	1·000	1·023
331	1·031	1·039	1·032	1·047

(1) F (Göttlicher and Wölfel)/F (Berghuis); (2) F (Ewald and Hönl)/F (Berghuis); (3) F (Bolton and Heaton all terms)/F (Bolton and Heaton, $f = g = 0$); (4) F (Thomas–Fermi, finite spherical atom)/F (Thomas–Fermi, infinite spherical atom).

The $F(111)$ is the most important figure of all the strong reflections. Ignoring column (8), no theoretical value is large enough but we would expect column (4) to be the best values for isolated atoms in the valence state. The ratio of column (3) to column (4) is thus some measure of the influence of the lattice on the structure factors, and is given in Table 2, column (1) together with other ratios. Ewald and Hönl started from atomic orbitals so that the ratio of their structure factors to those of Berghuis *et al.* is also given in Table (2), column (2) and it is seen that there is no indication of the pattern of the experimental results. However, the pattern is reproduced in the Thomas–Fermi calculations, shown in column (3) of Table 2 which is the ratio of the structure factors with and without the angular terms. We should strictly only be concerned with the 111 and 220 values since only for these does the valence charge density play an important part. The Thomas–Fermi theory contains this pattern also even if a full lattice argument is not employed. Umeda and Tomishima (1955) give tables of scattering factors for both finite and infinite spherical atoms from which we have calculated column (4) of Table 2, and the pattern of the experimental results is repeated but not as accurately as in column (3). The finite-atom Thomas–Fermi solution is the Slater–Krutter solution for diamond.

The Thomas–Fermi theory fails to give a satisfactory estimate for $F(222)$. The reason must be partly the great sensitivity in the difference between f_0 and f_1 to the charge distribution in the Wigner–Seitz cells. Another factor contributing to the low value of $F(222)$ must be the fact that Thomas–Fermi charge densities fall off too slowly so that in the anti-bond direction the charge density in the present calculation must be higher than it should be. The enhancement of the charge density in the bond direction is thus not so marked as it ought to be and it is this 'bond charge' which dominates the $F(222)$. The low value of $F(222)$ given by Ewald and Hönl is probably an indication that a first-order valence bond treatment is a poor approximation for a covalent structure.

ACKNOWLEDGMENTS

We are pleased to acknowledge discussions with Professor M. H. L. Pryce (Bristol), Professor P. P. Ewald (New York), Dame Kathleen Lonsdale (London) and Dr. J. C. Phillips (Chicago), and the opportunities afforded at Diamond conferences to present this work.

One of us (J.W.H.) is grateful to Industrial Distributors for a research grant.

A Note on Peak Displacements in X-ray Diffractometry

By A. J. C. WILSON
Viriamu Jones Laboratory, University College, Cardiff, Wales

MS. received 24th February 1961

Abstract. It is shown that at moderately high Bragg angles the shifts $\Delta(2\theta)$ of the peaks of x-ray diffraction maxima resulting from *geometrical* aberrations of the apparatus are to a first approximation the same as those of the centroids. A second approximation to $\Delta(2\theta)$ is obtained by adding $Vh'''/2h''$ to the centroid shift, where V is the variance of the aberration and h'' and h''' are the second and third derivatives of the observed line profile at its maximum. Forms of the correction suitable for practical application are discussed.

The peak shifts resulting from dispersion and the Lorentz factor cancel to a first approximation. *Physical* aberrations, such as absorption, that multiply the line profile $I(\lambda)d\lambda$ by a factor $f(\lambda)$ depending on wavelength, shift the peak by approximately $\Delta(2\theta) = -2f'I\tan\theta/\lambda f I''$, where f, f', I, I'' are the values of the functions and their derivatives at the peak.

§ 1. INTRODUCTION

An apparatus for x-ray diffraction experiments consists of a source of x-rays, a specimen and a detector. Ideally, the emitted x-rays are monochromatic, characterized by a single wavelength λ; the specimen is free from strain and other intrinsic defects; and source, specimen and detector are of negligible physical dimensions. The diffraction angle 2θ is then related to the wavelength λ by the non-linear transformation (Bragg's law, 1913)

$$\lambda = 2d\sin\theta, \qquad \ldots\ldots(1)$$

where d is the spacing of the diffracting planes. When accuracy greater than about 0·5% is sought deviations from this ideal picture have to be considered; the deviations can be divided broadly into two groups: physical and geometrical (Wilson 1959). The physical aberrations arise from variations in the wavelength of the x-rays: the change in wavelength and direction of a ray as it enters a crystal is the simplest; the distribution of intensity over a finite range of wavelengths in even the most 'monochromatic' emission line is the source of more difficult problems. The geometrical aberrations arise from the fact that source, specimen and detector must all be of finite size if the diffracted x-rays are to be of measurable intensity; typical geometrical aberrations arise from the equatorial (Wilson 1950) and axial divergence (Eastabrook 1952, Pike 1957) of the x-ray beam. The relative magnitudes of the various aberrations vary considerably with the angle of diffraction. At low angles the physical aberrations are generally of a very much smaller magnitude than the geometrical aberrations, whereas the reverse is true for high angles.

In making use of Eqn (1) to determine lattice spacings with high accuracy it is necessary (i) to choose some feature of the wavelength distribution $I(\lambda)d\lambda$ as representing 'the' wavelength of the x-ray emission line, and (ii) to correct the observed value of 2θ corresponding to this feature for the effect upon it of the various aberrations. The easiest feature of the wavelength distribution to measure is the peak (mode), whereas the easiest corrections to calculate are those to the centre of gravity (centroid, mean) (Spencer 1931–1949, Parrish and Wilson 1959). The experimenter is thus in a dilemma, but in the present state of knowledge it seems that the highest accuracy can only be obtained by the use of centroids. For moderate accuracy it would seem possible to use peaks in one of two ways, either (i) to draw up a set of empirical correction curves based on peak shifts measured under various conditions for substances of known lattice spacings (Parrish 1957, private communication), or (ii) to derive theoretically peak corrections of admittedly lower accuracy than those known for the centroids. This note is concerned with possibility (ii).

It has been shown (Wilson 1950) that in the range of moderately high Bragg angles the peak shifts produced by specimen transparency and specimen flatness are to a first approximation the same as the centroid shifts. The argument is readily extended to include the other geometrical aberrations and to obtain a second approximation to the peak displacement. The second approximation requires a knowledge of the mean-square broadening (variance) of the geometrical aberration and of the second and third derivatives of the observed line profile at its peak. Experimental work would be necessary to discover whether these derivatives can be obtained in practice with sufficient ease and accuracy to make the use of peak positions valuable. The variances of most of the geometrical aberrations have been calculated, and values of some are given in the Table. These values of the variance are useful in discussions of line broadening (Eastabrook 1952, Tournarie 1956), as well as in correcting for geometrical aberrations.

Alexander (1948, 1950, 1954) has considered peak displacements from a line-synthesis viewpoint, but his results are not easily applied in practice.

Of the physical aberrations, regular refraction shifts the line profile bodily, so that the peak shift is the same as the centroid shift. (The small broadening produced by irregular refraction (Wilson 1940) will not affect the peak position to the order of accuracy in question here.) Dispersion, as such, would shift the peak to lower angles, but to a first approximation the effect is cancelled by the shift to higher angles caused by the $\sec\theta$ part of the Lorentz factor (Pike and Wilson 1958). The peak shift caused by absorption in the filter etc. (Wilson 1958) is generalized below to cover any effect that simply multiplies the intensity by a factor varying with λ. The expression is applicable in principle to the polarization factor and the remaining part of the Lorentz factor, but the effects of these factors on the peak are not significant in the present context.

§ 2. GEOMETRICAL ABBERRATIONS

The wavelength line profile $I(\lambda)d\lambda$ can be transformed to a function, $g(2\theta)d(2\theta)$, of the diffraction angle 2θ by the use of Eqn (1) and the relation

$$g(2\theta)d(2\theta)=LPI(\lambda)d\lambda \qquad \ldots\ldots(2)$$

where L is the Lorentz factor, P is the polarization factor, and it is assumed that the lattice spacing d of the diffracting crystals is constant. To a close approximation (Pike and Wilson 1958) this leads to

$$g(2\theta)=I(2d\sin\theta). \qquad \ldots\ldots(3)$$

Centroid and Variance of Certain Geometrical Aberrations

Aberration	$F = \langle \Delta(2\theta) \rangle$	$V = \langle [\Delta(2\theta) - F]^2 \rangle$	Reference
Zero-angle calibration	Constant	Zero	
Specimen displacement	$-2s \cos\theta / R$	Zero	Wilson (1950)
Specimen transparency			Wilson (1950), Tournarie (1956), and unpublished
Thick specimen	$-\sin 2\theta / 2\mu R$	$\sin^2 2\theta / (2\mu R)^2$	
Thin specimen	$-t \cos\theta / R$	$t^2 \cos^2\theta / 3R^2$	
2 : 1 mis-setting	Zero if centroid of illuminated area of specimen centred on axis of rotation	$\frac{1}{3}\alpha^2\beta^2 \cot^2\theta$	Unpublished
Inclination of plane of specimen to axis of rotation	Zero if centroid of illuminated area on equator of specimen	$4\gamma^2 h^2 \cos^2\theta / 3R^2$ for uniform illumination	Unpublished
Flat specimen	$-\frac{1}{6}\alpha^2 \cot\theta$	$\frac{1}{45}\alpha^4 \cot^2\theta$	Wilson (1950) and unpublished
Focal-line width	Zero	$\sim f_2^2/12R^2$, but depends on intensity variation across focal line	Unpublished
Receiving-slit width	Zero	$r_1^2/12R^2$	Unpublished
Cross term between equatorial extensions of focal line and specimen	Zero if adjustment reasonable	$\sim \alpha^2 f_1^2 / 144R^2$, but depends on intensity variation across focal line	Unpublished
Cross term between equatorial extension of specimens and non-equality of source–specimen and specimen–receiving-slit distances	Proportional to r_2 and distance between axis of rotation and centroid of illuminated area, and thus vanishes if the latter is centred	$\alpha^2 r_2^2 / 12R^2$	Unpublished
Axial divergence			
A. No Soller slits			
(i) Source and receiver small in comparison with specimen	$-h^2 \cot\theta / 3R^2$	$4h^4 \cot^2\theta / 45R^4$	Lipson and Wilson (1941), Eastabrook (1952)
(ii) Source, specimen and receiver equal	$-h^2(2\cot 2\theta + \operatorname{cosec} 2\theta)/3R^2$	$h^4(16\cot^2 2\theta + 28\cot 2\theta \operatorname{cosec} 2\theta + 19\operatorname{cosec}^2 2\theta)/45R^4$	Pike (1957)
B. One set of Soller slits	$-h^2[Q_1 \cot 2\theta + Q_2 \operatorname{cosec} 2\theta]/3R^2$	Complex	Pike (1957)
(i) Narrow slits (q small)	$Q_1 = 1$, $Q_2 = 0$	$7h^4 \cot^2 2\theta / 45R^4$	
(ii) $q < 2$	$Q_1 = (1 - \frac{1}{3}q + \frac{3}{8}q^2 - \frac{1}{10}q^3)/(1 - \frac{1}{6}q)$ $Q_2 = (\frac{1}{4}q^2 - \frac{3}{40}q^3)/(1 - \frac{1}{6}q)$	Complex	
(iii) Wide slits ($q > 2$)	$Q_1 = \left(2 - \frac{29}{15q}\right) \Big/ \left(1 - \frac{2}{15q}\right)$ $Q_2 = \left(1 - \frac{2}{5q}\right) \Big/ \left(1 - \frac{2}{15q}\right)$	Complex	
C. Two sets of Soller slits			
(i) Narrow slits	$-\frac{1}{6}\delta^2 \cot 2\theta$	$\frac{1}{360}\delta^4(10 + 17\cot^2 2\theta)$	Eastabrook (1952)
(ii) Wide slits	See Pike (1957)		

Notation: α = equatorial divergence of the beam; β = angle of mis-setting of 2 : 1 ratio; γ = angle of inclination of plane of specimen to axis of rotation; δ = angular aperture of Soller slits; μ = linear absorption coefficient; r_1 = width of receiving slit; r_2 = distance of receiving slit from focusing circle; R = diffractometer radius; t = specimen thickness; s = specimen–surface displacement; f_1 = width of focal line; f_2 = projected width of focal line; h = half height of focal line, specimen and receiving slit, taken as equal; $q = R\delta/h$; Q_1 and Q_2 defined in table.

For convenience of manipulation let $x=2\theta$. If $f(x)$ is the profile of any geometrical aberration function, the resultant line profile is given by the fold

$$h(x)=\int f(y)g(x-y)dy. \qquad \text{......(4)}$$

It is easily shown by direct integration that the centroid of h,

$$H=\int xh(x)dx \Big/ \int h(x)dx, \qquad \text{.....(5)}$$

is given by

$$H=G+F, \qquad \text{......(6)}$$

where G and F are the centroids of g and f. There is no such simple exact relation between the peaks of h, g and f, but if one of g and f is much wider than the other an approximation can be obtained.

At high angles $g(x)$ will have a width several times larger than that of $f(x)$. Let the maximum of $g(x)$ come at $x=X$, and expand $g(x)$ in a power series about its maximum. Then

$$\begin{aligned} g(x-y) &= g\{X+(x-y-X)\} \\ &= g(X)+(x-y-X)g'(X) \\ &\quad +\frac{1}{2!}(x-y-X)^2 g''(X)+\ldots \\ &= g+0+\frac{1}{2!}(x-y-X)^2 g''+\ldots \\ &\quad +\frac{1}{n!}(x-y-X)^n g^n+\ldots, \end{aligned} \qquad \text{......(7)}$$

where g, g'', etc. are short for $g(X)$, $g''(X)$, etc.

Substitution in Eqn (4) gives

$$\begin{aligned} h(x)=\int f(y)\Big\{g+\frac{1}{2!}(x-y-X)^2 g''+\frac{1}{3!}(x-y-X)^3 g''' \\ +\ldots+\frac{1}{n!}(x-y-X)^n g^n+\ldots\Big\}dy, \end{aligned} \qquad \text{......(8)}$$

and if $f(y)$ is normalized (as may be assumed without loss of generality) integration gives

$$\begin{aligned} h(x)=g+\frac{1}{2!}g''J_2(x-X)-\frac{1}{3!}g'''J_3(x-X)+\ldots \\ +\frac{(-)^n}{n!}g^n J_n(x-X)+\ldots, \end{aligned} \qquad \text{......(9)}$$

where $J_n(x-X)$ is the nth moment of $f(y)$ about the point $x-X$. Similarly

$$\begin{aligned} h'(x)=-g''J_1(x-X)+\frac{1}{2!}g'''J_2(x-X)+\ldots \\ -\frac{(-)^n}{n!}g^{n+1}J_n(x-X)+\ldots, \end{aligned} \qquad \text{......(10)}$$

$$\begin{aligned} h''(x)=g''-g'''J_1(x-X)+\frac{1}{2!}g^{\text{iv}}J_2(x-X)+\ldots \\ +\frac{(-)^n}{n!}g^{n+2}J_n(x-X)+\ldots, \end{aligned} \qquad \text{......(11)}$$

$$h'''(x)=g'''-g^{\mathrm{iv}}J_1(x-X)+\ldots-\frac{(-)^n}{n!}g^{n+3}J_n(x-X)+\ldots \qquad \ldots\ldots(12)$$

We wish to find the maximum of $h(x)$, which will occur for $h'(x)$ equal to zero. From Eqn (10), to a first approximation this will occur for $J_1(x-X)=0$, that is for

$$x-X-F=0 \quad \text{or} \quad x=X+F, \qquad \ldots\ldots(13)$$

where

$$F=\int yf(y)dy \qquad \ldots\ldots(14)$$

is the centroid of the aberration. Eqn (13) is thus a recovery of Wilson's result.

A second approximation is obtained by inserting this value of x in the second term of Eqn (10); $J_2(x-X)$ becomes the variance of the aberration function f, say V. The second approximation to the maximum is then given by

$$h'(x)=0=-g''(x-X-F)+\frac{1}{2!}g'''V+\ldots, \qquad \ldots\ldots(15)$$

$$x=X+F+Vg'''/2g''. \qquad \ldots\ldots(16)$$

The use of Eqn (16) involves a knowledge of the values of the second and third derivatives of $g(x)$ at its maximum. A similar argument shows, however, that these are to a first approximation equal to the second and third derivatives of the observed line profile at its maximum. The maximum thus occurs approximately at

$$x=X+F+Vh'''/2h'', \qquad \ldots\ldots(17)$$

h'' and h being measured at the peak of the observed profile. Eqn (17) may be expressed in other ways in order to obtain forms more suited to practical application. If the slope of the observed profile is measured at distances of $\pm\delta$ from its peak, it may be shown that the second correction term $Vh'''/2h''$ is equal to

$$\frac{\text{(sum of the slopes)}}{\text{(difference of the slopes)}}\times\frac{V}{\delta}. \qquad \ldots\ldots(18)$$

Alternatively, if the amounts by which the line profile falls below its peak value are measured at distances of $\pm\delta$ from the peak, the second correction term can be expressed as

$$\frac{3}{2}\times\frac{\text{difference of amounts}}{\text{sum of amounts}}\times\frac{V}{\delta}. \qquad \ldots\ldots(19)$$

These two forms would have the advantage that the constancy of the correction for different values of δ could be checked. It might be thought that a similar argument could be applied at lower angles, $g(x)$ being interpreted as the fold of all aberrations other than the one being considered. However, the argument depends on $g(x)$ being a reasonable function of x near its peak, and most aberrations are rather spiky, if not discontinuous or with discontinuous derivatives. Any such interpretation would be risky, without a full empirical investigation first. The argument will be valid up to high angles, but may fail in the extreme back-reflection region if the variation of, for example, the Lorentz factor over the range of 2θ for which $f(x)$ is appreciable becomes large.

§ 3. PHYSICAL ABERRATIONS

For the present purpose refraction has been sufficiently treated in § 1 above. The effect of absorption, and of other factors that modify the intensity as a function of wavelength, on the positions of the peaks can be estimated in terms of the radii of curvature of the peaks, but the accuracy of the estimate is difficult to assess, particularly in the presence of geometrical aberrations. If the factor modifies the original distribution $I(\lambda)d\lambda$ to $f(\lambda)I(\lambda)d\lambda$ the maximum will occur for the value of λ for which

$$\frac{d}{d\lambda}[f(\lambda)I(\lambda)]=f'(\lambda)I(\lambda)+f(\lambda)I'(\lambda)=0. \qquad \ldots\ldots(20)$$

Let λ_m be the wavelength at which $I(\lambda)$ has its maximum. If $f(\lambda)$ does not change too rapidly as a function of wavelength (or more accurately, if its second derivative is not too great) $f(\lambda)$ may be approximated by a straight line and $I(\lambda)$ by a parabola in the neighbourhood of λ_m. Eqn (20) then becomes

$$f'\left[I+\frac{1}{2!}(\lambda-\lambda_m)^2 I''\right]+[f+(\lambda-\lambda_m)f'](\lambda-\lambda_m)I''+\ldots=0,$$

or

$$\lambda-\lambda_m=-\frac{f'I}{fI''}+\ldots, \qquad \ldots\ldots(21)$$

where I, I'', f, f' are to be understood as the values of the functions at $\lambda=\lambda_m$. The peak wavelength is thus shifted by $-f'I/fI''$, and the peak angle by

$$\Delta(2\theta)=2(\lambda-\lambda_m)\frac{d\theta}{d\lambda}=\frac{-2f'I\tan\theta}{\lambda fI''}, \qquad \ldots\ldots(22)$$

from Eqns (1) and (21). The shift is thus directly proportional to the slope of the aberration factor and inversely proportional to the peak curvature.

For absorption in a filter or window

$$f(\lambda)=\exp(-\mu t), \qquad \ldots\ldots(23)$$

where μ is the linear absorption coefficient and t is the thickness of absorber traversed, so that the peak shift in wavelength is

$$\lambda-\lambda_m=\frac{tI}{I''}\frac{\partial\mu}{\partial\lambda} \qquad \ldots\ldots(24)$$

and in angle

$$\Delta(2\theta)=\frac{tI\tan\theta}{I''\lambda}\frac{\partial\mu}{\partial\lambda}. \qquad \ldots\ldots(25)$$

For μ varying as λ^3 these reduce to

$$\lambda-\lambda_m=3\mu tI/\lambda I'' \qquad \ldots\ldots(26)$$

and

$$\Delta(2\theta)=6\mu tI\tan\theta/\lambda^2 I'', \qquad \ldots\ldots(27)$$

as previously stated (Wilson 1958).

The effect of absorption in the filter and windows is covered by the preceding treatment, but the effect of absorption in the specimen itself is more obscure. The less absorbed rays penetrate more deeply into the specimen, so that a greater volume is effective in diffracting them, and they are enhanced relative to the more absorbed rays. The weighting factor is proportional simply to μ^{-1}, so that the peak shift in wavelength is, from Eqn (21),

$$\lambda-\lambda_m=\frac{I}{\mu I''}\frac{\partial\mu}{\partial\lambda}. \qquad \ldots\ldots(28)$$

For μ varying as λ^3 this reduces to

$$\lambda-\lambda_m=3I/\lambda I''\,; \qquad \ldots\ldots(29)$$

since I'' is negative the shift is to lower λ or lower 2θ.

This correction is, however, of the same order of magnitude as the difference between the effects of dispersion and the Lorentz factor. The three together weight the intensity by μ^{-1}, $\cos\theta$ and $\tan\theta$ respectively, so that the resultant is

$$f(\lambda)=\mu^{-1}\cos\theta\tan\theta=\lambda/2d\mu. \qquad \ldots\ldots(30)$$

The peak shift in wavelength is then

$$\lambda-\lambda_m=-\frac{I}{I''}\left[\frac{1}{\lambda}-\frac{1}{\mu}\frac{\partial\mu}{\partial\lambda}\right] \qquad \ldots\ldots(31)$$

in general, and for μ varying as λ^3 is

$$\lambda-\lambda_m=\frac{2I}{\lambda I''}, \qquad \ldots\ldots(32)$$

which is only two-thirds of the value given by Eqn (29). As for the centroid (Pike 1959, Ladell 1961, Pike and Ladell 1961), the peak displacements resultiny from dispersion, Lorentz factor, and absorption in the specimen are closely involved.

The peak shifts $\Delta(2\theta)$ corresponding to the wavelength shifts $\lambda-\lambda_m$ of Eqns (28), (29), (31) and (32) are obtained in each case by multiplying by $2\tan\theta/\lambda$.

ACKNOWLEDGMENTS

I am indebted to Dr. W. Parrish and Dr. E. R. Pike for much helpful discussion and criticism.

Energy Levels in the Forbidden Gap of Insulating Diamonds

By R. R. URLAU, THE LATE H. J. LOGIE AND F. R. N. NABARRO
Department of Physics, University of the Witwatersrand, Johannesburg, South Africa

MS. received 21st November 1960

Abstract. Two type I diamonds and one type IIa have been examined for the following properties: counting of beta particles in the dark, counting under space charge, effect of monochromatic illumination on counting under an applied field and under space charge, change of total charge while counting and while conducting, and photoconductivity. On the basis of these observations and of the known optical absorption of diamonds of these types a preliminary level scheme is proposed as follows:

(i) A level 0·94 ev above the valence band. This level provides traps for holes, and is normally filled, but gives rise to photoconductivity after exposure to electron bombardment or irradiation with energetic ultra-violet light.

(ii) A level 1·6 ev above the valence band. This level also provides traps for holes and is tentatively identified with the Kaiser–Bond nitrogen level.

(iii) A level 3·3 ev above the valence band. This level is partly filled and provides traps for electrons. It can give rise to either n- or p-type photoconductivity.

---

§ 1. INTRODUCTION

While the electronic energy level structure, which imperfections and impurities produce in the forbidden gap between the valence and the conduction bands, is well known today for germanium and silicon, relatively little is known for the same crystallographic structure of carbon, namely diamond. This is mainly so for two reasons: firstly, it still seems to be impossible to make artificially diamond crystals of a known content of impurities large enough for experiments to be performed on them; secondly, as the most accurate measurements are made electrically one has to have crystals which are semiconducting and not insulating. This last point has up to now effectively limited the investigation of the level structure in natural diamonds to the semiconducting diamonds which were discovered and classified as crystals of type IIb by Custers (1952). In contrast to crystals of this type, diamonds of types I and IIa are highly insulating, having resistivities between 10^{14} and 10^{16} ohm cm at room temperature.

Although, in principle, the methods usually employed to determine the positions of levels in the forbidden gap in semiconductors, namely measurements of the temperature dependence of the electric conductivity of the crystal and of the polarity of the majority free charge carriers by means of the Hall effect, are also applicable to insulating crystals, in practice these methods fail because of the extremely small currents to be measured. On insulating diamonds a complete set of such measurements has never been made, although separate measurements on the temperature dependence of the resistance (Wartenberg 1912, Mendelssohn and Dember 1942) and measurements on the Hall effect (Lenz 1925, Klick and Maurer 1951, Redfield 1954) of insulating diamonds have been reported in the literature. A further point which has to be considered in conjunction with the methods mentioned above and which may provide great difficulties is that ohmic contacts should be employed for accurate measurements. Whether such contacts are obtainable on insulating diamonds has never been investigated. An exact solution of this problem is very difficult.

In insulating crystals possessing such large forbidden gaps as diamond (5·4 ev), effects may become apparent which do not occur in ordinary semiconducting materials and which are due (Allen 1960) to levels the distances of which from the valence or conduction band are large compared with the thermal energy kT at room temperature (k is Boltzmann's constant, T the absolute temperature). The occupation of such levels can remain for long times out of equilibrium even at room temperature, and this can give rise to large space charge effects. Moreover, the traps are 'deep' in the sense that the associated orbits do not spread over many atoms, so that the properties of diamond at room temperature are not analogous to those of silicon or germanium at low temperatures.

Another way of investigating energy levels in the forbidden gap is by irradiating a crystal with light. If the irradiating light gives rise to transitions between a level in the forbidden gap and either one of the bands the following effects will occur.

(i) The optical absorption coefficient for this light will rise above the background.

(ii) The electric conductivity of the crystal will change.

(iii) If an electric field is applied to the crystal and the irradiating light frees mainly charge carriers of one type, these charge carriers will be swept out of the crystal. Provided that the ratio between the relative permittivity of the crystal and its conductivity is large enough, the crystal will acquire a total charge of a polarity opposite to that of the charge carriers freed.

(iv) If the crystal is used as a crystal counter the pulse height obtainable from the crystal may, depending on circumstances, change during or after prior irradiation of the crystal with light.

Although optical absorption experiments can be very precise, it is virtually impossible to deduce a level structure from their results only, as not all absorption lines or bands need necessarily arise from transitions between a level in the gap and either one of the two bands. In addition, such a level structure would not be unambiguous as far as the locations of the levels with respect to the two bands are concerned. The latter argument also applies to results obtained from changes in the electric conductivity.

Measurements of the changes in the total charge of a crystal may lead to the correct level structure, but, in general, these measurements are best when they are considered in conjunction with measurements of other kinds. Finally, crystal counting experiments also lead, in general, to an ambiguous level structure, but in certain cases the correct position of a level can be deduced.

The measurements to be reported here were made on crystal counting, on the total charge, and on photoconductivity. The results are finally compared with typical optical absorption spectra exhibited by crystals of type I.

In the literature, data on energy levels in the forbidden gap of insulating diamonds are scarce and vague. In most cases the levels were postulated to account for certain experimental observations, but in no instance were the positions of these levels unambiguously determined by further and independent measurements. A summary of these levels is given in the Table. The second column of this Table shows the positions of these levels in the forbidden gap or the activation energies measured. In the third column is briefly indicated how and, if possible, in which type of crystal these positions or energies were arrived at.

§ 2. EXPERIMENTAL

Three diamonds were investigated, which were of the common octahedral form, although this form was not developed in each crystal to the same extent. Two of them, C1 and C9, were of type I, whereas crystal CIIa was of type IIa.

The type I crystals had been sorted from a parcel of stones on the basis of weak fluorescence under irradiation with ultra-violet light. During all the experiments the crystals were not specifically treated except to be thoroughly cleaned, and no special electrodes were ever put on the crystals. Their thicknesses were between 1 and 2 mm and their other dimensions were of the same order.

2.1. *Counting Experiments*

In the counting experiments the crystals were tightly clamped between two copper electrodes. The electrodes had a hole of 1 mm diameter at their centres. In this way the crystals could be bombarded either perpendicularly to the direction of the applied field or through one of the electrodes. In addition, the crystal could simultaneously be irradiated with light in a direction perpendicular to that of the applied field. The voltage applied to the crystals was provided by a set of dry batteries, the maximum voltage being 1500 v.

The first amplification of the pulses was obtained in a pre-amplifier described by Cottini, Gatti, Gianelli and Rozzi (1956). From the pre-amplifier the pulses were fed to a Tracerlab single-channel pulse height analyser which had a ratemeter and a recorder. The noise level beyond which all the pulses due to noise vanished corresponded to a charge at the grid of the input valve of the pre-amplifier of about 3200 electron charges. The input capacity was found to be 14 pF.

During the counting experiments the crystals, which were kept in air, were counting beta particles emitted by $^{90}Sr^{90}Y$ sources. The strengths of the sources were about 10 μc and 130 μc. The counting rate recorded comprised all pulses above the noise level. Monochromatic light was obtained from two sources: firstly, from a projector in combination with a continuous interference filter for light in the visible region and secondly, from a Zeiss f/10 quartz prism monochromator for light between 0·496 ev (2500 n.m.) and 6·2 ev (200 n.m.).

2.2. *Charge Experiments*

In these experiments the crystals were suspended on a quartz fibre and clamped between two electrodes in the crystal holder. After the crystal had been bombarded with beta particles or irradiated with light, the crystal was taken out of the holder in darkness and brought into the electric field of a plate condenser, where it did not touch either of the electrodes. The movement of the crystal in the field due to its charge was observed with a travelling microscope. The sensitivity of this arrangement was about 10^7 electron charges per division deflection. The values usually found were between 10^7 and 10^9 electron charges. Only changes of polarity of charge were taken into account but not changes in magnitude of charge of the same polarity. In this way mistakes, which might have arisen from friction between the crystal and its holder, were made less likely.

2.3. *Photoconductive Experiments*

Photoconductive currents were measured by means of a Keithley electrometer, the power of the incident light by means of a Hilger and Watts FT 16 vacuum thermopile. The resultant e.m.f. of the thermopile was measured by compensation. The monochromatic light was obtained from the quartz monochromator, the slit width of which was kept constant at 0·2 mm in the infra-red and visible region and at 0·6 mm in the ultra-violet region. The crystal holder and the thermopile were mounted on a swivel so that either the crystal or the slit of the thermopile could be brought into the path of light which came from the monochromator and was focused by a quartz lens.

The photoconductive currents measured ranged between 10^{-14} and 10^{-10} A, while the dark currents were of the order of 10^{-13} A at an applied voltage of 1000 v. This voltage was large enough to be in the region where the photoconductive currents did not depend on the voltage applied.

During the measurements the voltage was continuously applied, and the irradiating light was cut off after each measurement. In the dark periods the current slowly decreased to its value in darkness, sometimes during a time of more than ten minutes. While the crystal was irradiated with light the current was not constant. In the experiments the largest value of the current was recorded. This was usually obtained during the first seconds of irradiation.

§ 3. Results

3.1. *Counting Experiments*

3.1.1. *Counting in darkness.* Characteristic changes in the counting rate with time and the applied voltage, when the crystals were kept in darkness, are shown in Fig. 1. In this particular set of measurements made on crystal C1 the stronger beta source was used and the beta particles were incident perpendicularly to the direction of the applied field. After the field had been applied the counting rate

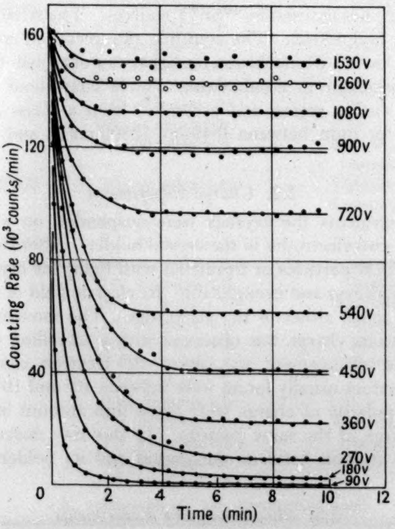

Fig. 1. The variation of counting rate of crystal C1 in darkness with time and the applied voltage during bombardment with beta particles from a ^{90}Sr ^{90}Y source. Thickness of the crystal: 1·69 mm.

fell immediately until it reached a steady value which seemed to persist indefinitely. The decrease in counting rate was large at small field strengths and small at high field strengths. The rate of this decrease at a particular time in the initial stage decreased with increasing field strength. The time required to reach the steady state depended on the field strength employed and on the flux of the incident particles. At high field strengths or high fluxes this time was shorter than at low field strengths or low fluxes.

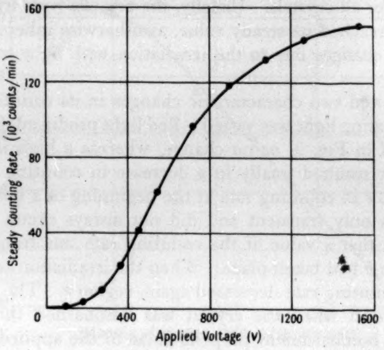

Fig. 2. Steady counting rate of crystal C1 in darkness as a function of the applied voltage.

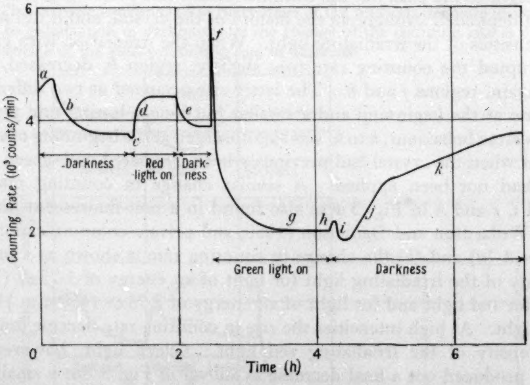

Fig. 3. Typical variations of the counting rate of crystal C1 in darkness and during irradiation with intense light.

Although this behaviour was typical for all crystals and did not depend on the direction of the incident particles it was found that the percentage decrease of the counting rate was smaller during bombardment through the cathode than during bombardment through the anode. The steady counting rate as a function of the applied voltage is shown in Fig. 2.

At small fluxes and high field strengths the counting rate did not fall immediately after the field had been applied, but rose briefly. This is shown in Fig. 3, where this rise is designated *a*. Such an increase has been observed by several authors (Willardson and Danielson 1950, and private communication, Freeman 1952, Champion and Dale 1956). The subsequent decrease *b* corresponds to the decrease in counting rate as shown in Fig. 1.

3.1.2. *Counting under irradiation with light.* If the crystals were simultaneously irradiated with light when counting took place the counting rate exhibited changes which, although they were characteristic for a particular crystal, were not in general the same for all crystals. Usually, the crystals were irradiated when the counting rate had reached its steady value, as otherwise inherent changes in the counting rate and changes due to the irradiation with light could not easily be distinguished.

Crystal C1 showed two characteristic changes in its counting rate when the energy of the irradiating light was varied. Red light produced, finally, an increase in counting rate, *d* in Fig. 3, or no change, whereas a high intensity of green, blue or white light resulted finally in a decrease in counting rate, *g* in Fig. 3. The small decrease *c* in counting rate at the beginning of a period of irradiation with red light was only transient and did not always occur. The increase *d* was never so large that a value of the counting rate was reached equal to that before the decrease *b* had taken place. When the irradiation with that light was interrupted, the counting rate decreased again, region *e*. The effect of red light was most pronounced when the crystal was bombarded through the anode. It was less during bombardment perpendicular to the applied field and almost negligible when the incident beta particles struck the crystal through the cathode.

The height of the peak *f* at the commencement of a period of irradiation with green light depended strongly on the history of the crystal, and it did not appear at low intensities of the irradiating light. When the irradiation with green light was interrupted the counting rate rose slightly, region *h*, decreased, region *i*, and rose again, regions *j* and *k*. The latter rise occurred at two different rates, a larger rate at the beginning and a smaller but longer lasting rate towards the end. This same behaviour, *h* to *k*, was also observed at the beginning of a counting experiment when the crystal had previously been irradiated with green light and the field had not been applied. A similar change in counting rate to that designated *i*, *j* and *k* in Fig. 3 was also found in a non-fluorescent diamond of type I by Willardson and Danielson (1950, and private communication).

In Figs. 4 (*a*) and (*b*) the change in counting rate is shown as a function of the intensity of the irradiating light for light of an energy of 1·75 ev (710 n.m.) as typical for red light and for light of an energy of 2·75 ev (450 n.m.) as typical for green light. At high intensities the rise in counting rate became independent of the intensity of the irradiating red light. Green light, however, at low intensities produced not a final decrease as shown in Fig. 3 but a small increase in counting rate.

The energies of light for which a rise in counting rate could be observed ranged from about 1·0 ev (1240 n.m.) to about 2·0 ev (620 n.m.). On the low energy side the increase became undetectably small, whereas on the high energy side effects became apparent which were characteristic for irradiation of the crystal with intense green light. The effects due to high intensities of the latter light became marked for light of an energy of 2·1 ev (590 n.m.) or more; that is, at this energy and all higher energies the counting rate finally decreased. No change in counting rate was observed during irradiation with low intensities

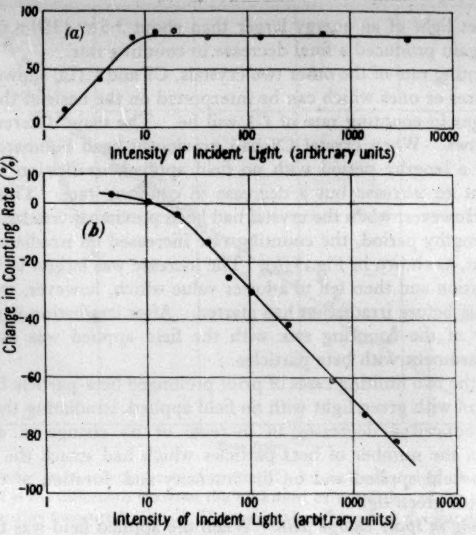

Fig. 4. The variation in counting rate of crystal C1 as a function of the intensity of the irradiating light the energy of which was (*a*) 1·75 ev (710 n.m.), (*b*) 2·75 ev (450 n.m.). (*a*) The increase is expressed as percentage of the previous decrease in counting rate due to polarization in darkness; (*b*) the change of the counting rate is expressed as percentage of the steady counting rate in darkness.

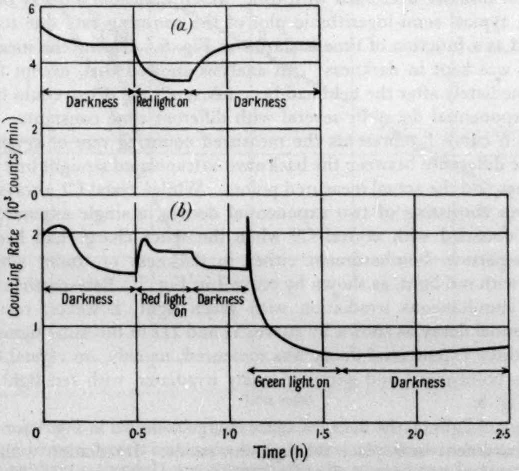

Fig. 5. Typical variations of the counting rate of crystal C9 in darkness and during simultaneous irradiation with light after different previous treatments of the crystal in the absence of an applied field: diagram (*a*) after previous beta-particle bombardment, (*b*) after previous irradiation with green light.

of ultra-violet light of an energy larger than about 3·5 ev (350 n.m.); but high intensities again produced a final decrease in counting rate.

The counting rate of the other two crystals, C9 and CIIa, showed, in general, similar features or ones which can be interpreted on the basis of the same model as the changes in counting rate of C1 will be. The main differences observed were as follows. When crystal C9 had previously been bombarded with beta particles for a lengthy period with no field applied, irradiation with red light produced not an increase but a decrease in counting rate. This is shown in Fig. 5 (*a*). However, when the crystal had been previously irradiated with green light for a lengthy period, the counting rate increased on irradiating the crystal with red light, as shown in Fig. 5 (*b*). The increase was largest at the beginning of the irradiation and then fell to a lower value which, however, was still higher than the value before irradiation had started. After irradiation with green light the recovery of the counting rate with the field applied was extremely slow under bombardment with beta particles.

Between the two limiting cases of prior prolonged beta-particle bombardment and irradiation with green light with no field applied, irradiating the crystal with red light produced a decrease, an increase or no change in counting rate depending on the number of beta particles which had struck the crystal when there was no field applied and on the intensity and duration of the preceding irradiation with green light.

3.1.3. *Counting in space charge field.* When the applied field was taken off after the crystal had been counting under continued bombardment with beta particles, pulses were obtained which were of opposite sign to those obtained under an applied field. These pulses of opposite sign were due to the field of a space charge set up in the crystal during bombardment with beta particles under an applied field. Their number decreased with time, which indicated a decay of the space charge. A typical semi-logarithmic plot of the counting rate due to the space charge field as a function of time is shown in Fig. 6. During the measurements the crystal was kept in darkness. An analysis showed that, except for a short period immediately after the field had been taken off, the decay could be resolved into one exponential decay or several with different time constants.

In Fig. 6 curve I represents the measured counting rate of crystal C1 and curve II the difference between the backward extrapolated straight line I obtained at large times and the actual measured points. While crystal C1 always exhibited decay curves consisting of two exponential decays, a single exponential decay curve was obtained with crystal C9 when the space charge had been formed under beta-particle bombardment either in darkness or under simultaneous irradiation with red light, as shown by curve I in Fig. 7. Beta-particle bombardment and simultaneous irradiation with green light, however, resulted in a two-exponential decay as shown by curves II and III in the same figure. In one instance a three-exponential decay was measured, namely, on crystal CIIa after it had been bombarded and simultaneously irradiated with red light. This is shown in Fig. 8.

The effect of light on the decay of space charge is shown in Fig. 9 for crystal C1 when bombardment took place through the anode. Irradiation with red light did not affect the space charge field appreciably, but irradiation with green light did. Irradiation with this light with the field applied resulted in a longer lasting, although initially smaller, space charge field than when the crystal had either

The heavy lines at the base indicate the periods during which an external electric field was applied. The broken lines show the counting rate during the time the crystal was irradiated with intense light of an energy given in ev in the first column.

been irradiated with red light or not irradiated at all. Irradiation with green light during the decay or at a time when the beta-particle bombardment was interrupted gave rise to a very rapid decay of the space charge, in contrast to irradiation with red light. When the crystal was left in complete darkness under no bombardment after a space charge field had been formed, pulses could still be observed after weeks.

3.2. *Charge Experiments*

The charge acquired by all three crystals was small and positive when the crystals were left in the dark under an applied field. Bombardment with beta particles through the anode or perpendicular to the applied field resulted in a strong positive charge, whereas bombardment through the cathode gave rise to a negative charge.

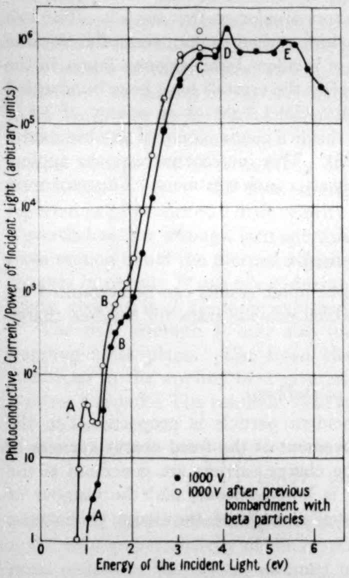

Fig. 10. The variation of the photoconductive current per unit power of incident light of crystal C9 as a function of the energy of the incident light. The results with crystal C1 were very similar.

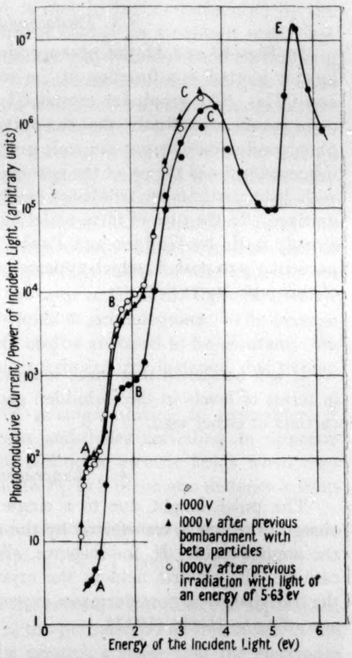

Fig. 11. The variation of the photoconductive current per unit power of incident light of crystal CIIa as a function of the energy of the incident light.

After bombardment of crystals C1 and CIIa through the anode, prolonged irradiation with red light produced a change in polarity from positive to negative. Crystal C9 exhibited the same change after the crystal had been bombarded with no field applied. Irradiation with green light always rendered the crystals positively charged. The transition between the two opposite effects of red and green light occurred at about 2·1 ev (590 n.m.). At higher energies crystals C1 and C9 always acquired a positive charge. Crystal CIIa, however, exhibited the following effect: after it had been irradiated with light of an energy of about 2·2 ev (560 n.m.) and its charge had become positive, subsequent irradiation with light of an energy of about 3·1 ev (400 n.m.) for several minutes produced a reversal of polarity. Continued irradiation with the latter light, however, eventually rendered the crystal positive again. This is a confirmation of Redfield's (1954) observation that light of this energy gave rise to either n- or p-type photoconductivity in diamonds.

3.3. *Photoconductivity Experiments*

In Figs 10 and 11 the photoconductive current per unit power of incident light is plotted as a function of the energy of the incident light for crystals C9 and CIIa. The graph for crystal C1 is very similar to that for C9. The two main results are: firstly, that the curves show several peaks; secondly, that the photoconductive current per unit power of incident light becomes larger in the infra-red and red region of the spectrum after the crystals have been bombarded with beta particles or irradiated with ultra-violet light of an energy of 3·5 ev or more. In the case of ultra-violet light this is a confirmation of an observation already made by Gudden and Pohl (1923). This increase in response applied particularly to peak A, which appeared only after such treatment. The maximum of this peak lay at 0·94 ev.

§ 4. DISCUSSION

It will be shown that these somewhat complex results can be accounted for in terms of levels in the forbidden gap which provide traps for the free charge carriers of either sign.

4.1. *Experiments in Darkness*

The pulse height due to a single incident particle is proportional to the charge Q which is transferred by the movement of the freed charge carriers in the applied field. If, for instance, all the charge carriers are generated at the cathode, the electric field in the crystal is homogeneous, and the number of the free charge carriers decreases exponentially with time, the charge Q becomes, according to Hecht (1932),

$$Q = n_0 e \frac{vTF}{s}\left[1 - \exp\left(-s/vTF\right)\right],$$

where n_0 is the number of electron–hole pairs produced by a single incident particle, e the electronic charge, v the mobility and T the lifetime of the free electrons, F the electric field strength, and s the electrode separation. If the electron–hole pairs are not generated exclusively at the cathode and the holes are also mobile the contribution of the movement of the latter to the charge Q must also be taken into account.

Provided that the geometrical arrangement, the amplification of the pulses, the threshold setting of the pulse height analyser, and so on, are all kept constant, changes in counting rate are solely due to changes in pulse height. This applies even if the incident beta particles have a wide range of energies, as was the case in the experiments reported in § 3.1. Thus a change in counting rate must indicate a change in one or several of the quantities which determine the pulse height. These are n_0, e, s, v, T and F. The electronic charge e and the electrode separation s are constant. The number n_0 of electron–hole pairs for monoenergetic particles of the same kind can also be considered to be constant. If the incident particles are not monoenergetic, n_0 will be different for different energies, but provided that the energy distribution of the incident particles does not change during the experiment, a variation in the distribution of n_0 should not occur. The mobility v can also be considered to be constant provided that the temperature is kept constant, although it may in fact be influenced by the filling of trapping centres and the consequent change in Coulomb scattering. The lifetime T of a free charge carrier is predominantly determined by trapping processes and by recombination processes via states in the forbidden gap. Thus $T = 1/N\sigma u_{\mathrm{th}}$, where N is the density of states which can trap a free charge carrier or lead to its recombination with a charge of opposite sign, σ is the average capture cross section of these states, and u_{th} is the thermal velocity of the free charge carriers. The validity of the above formula, strictly, requires the drift velocity of the free charge carriers in the electric field to be much smaller than their thermal velocity. On the assumption of a homogeneous field resulting from the applied voltage and of a mobility of the free charge carriers in diamond of $1{\cdot}5 \times 10^3\,\mathrm{cm}^2\,\mathrm{v}^{-1}\,\mathrm{sec}^{-1}$ the field strengths generally used in the experiments reported in § 3 produced a drift velocity of the same order as the thermal velocity. Nevertheless, for a rough estimate this formula is still adequate. The average cross section σ and the thermal velocity u_{th} can be assumed to be constant. As changes in density N can occur during an experiment, for instance, due to trap filling, changes in T are to be expected.

The field strength F may also undergo changes during an experiment if trapping takes place. The freed electrons and holes travelling in opposite directions in the applied field give rise to additional electric fields when they become trapped. The resultant field strength F_{R} in a plane at a distance x from the anode becomes

$$F_{\mathrm{R}} = \frac{V}{s} + \left(\frac{1}{\epsilon_{\mathrm{r}}\epsilon_0 A s}\right)\left\{\int_x^s [q_{\mathrm{e}}(\xi) - q_{\mathrm{h}}(\xi)](s-\xi)\,d\xi - \int_0^x [q_{\mathrm{e}}(\xi) - q_{\mathrm{h}}(\xi)]\xi\,d\xi\right\},$$

where V is the potential difference across the crystal, s the electrode separation, ϵ_{r} the relative permittivity of the crystal, ϵ_0 the permittivity of free space, A the cross section of the crystal assumed to be of such a shape that the electrodes attached to it form without the crystal a homogeneous field and $q_{\mathrm{e}}(\xi)$ and $q_{\mathrm{h}}(\xi)$ the charges due to trapped electrons and holes, respectively, evenly distributed in a plane parallel to the electrodes at a distance ξ from the anode.

During perpendicular bombardment of the crystal, for instance, the field strength will rise near the electrodes and decrease in the centre of the crystal. However, whatever the resultant field distribution may be, the overall effect on the pulse height will be a decrease. This polarization is probably the cause of the decrease in counting rate shown in Fig. 1 and in Fig. 3, region *b*. The increase *a* in counting rate in the latter figure is ascribed to an increase in lifetime due to trap filling. The two effects, increase in counting rate due to an increase in lifetime and decrease in counting rate as a result of polarization, always occur, but if the flux of the incident beta particles is high enough, the time during which an increase in counting rate takes place becomes too small to be observed.

Although the most energetic beta particles from the ^{90}Sr^{90}Y sources were able to penetrate the crystals completely, most of the beta particles were stopped near the surface. Consequently the majority of the free charge carriers were produced in a surface layer. From the observation that polarization was most pronounced when the crystals were bombarded through the anode it follows that the polarization effects are mainly caused by trapped holes, as the holes in this case have the longer way to travel in the crystal.

The underlying principle of the charge measurements is as follows. Even if electrons can flow freely between the electrodes and the surface layers of the crystal in both directions, this flow cannot occur more rapidly than the space charges within the crystal can readjust themselves. The latter process is governed by the intrinsic relaxation time T_R of the material of the crystal. If this relaxation time is long enough, free charge carriers which leave the crystal are consequently not immediately replenished by others which enter the crystal. As a result of this the crystal will acquire a total charge of opposite polarity to that of the charge carriers having left the crystal. The relaxation time $T_R = \epsilon_r \epsilon_0 / \kappa$, where κ is the conductivity of the crystal. The relative permittivity of diamond is 5·68. Hence a conductivity of about 10^{-15} (ohm cm)$^{-1}$ results in the large value for T_R of about 500 sec. Under bombardment or irradiation the conductivity of a crystal increases and hence the relaxation time decreases. In all the charge experiments bombardment or irradiation was stopped before the applied voltage was switched off. Thus it was essentially the dark relaxation time which determined the readjustment of the space charges.

No measurements of the total charge in diamond crystals have been reported in the literature. Stöckmann (1956, 1957) predicted the possibility of extraction and injection of majority carriers in insulating crystals, with the extraction of these carriers the predominating process. He obtained this result on the assumptions that the density of the excess charge carriers is small compared with the total charge carrier density when the crystal is in the dark and that the contacts are ohmic. In practice, photoconductive currents in diamonds are large compared with the dark current and the contacts are most probably not ohmic. Rectifying contacts, however, should not reverse the result, as these contacts always favour the passage of majority carriers from the crystal to the metal electrode. There is also no obvious reason why photoconductive currents larger than the dark current should reverse the sign of the total charge of the crystal.

In general, contacts between metals and semiconductors are rectifying, unless special precautions are taken in making them. On the assumption that the diamond–electrode contacts used in the experiments were rectifying, the results of the charge measurements when the crystal was in darkness indicated that electrons could be considered to be the majority charge carriers. The conclusion drawn from the positive charge of the crystal when bombarded perpendicularly is that the free electrons have a larger product vT of mobility v and lifetime T than the holes or that their passage from the crystal to the electrode is easier than for the holes, or both. The positive charge resulting from bombardment through the anode and the negative charge from bombardment through the cathode arise from the fact that the majority of the free charge carriers are produced near the surface at such bombardment. If this surface is near an electrode it is more difficult for those charge carriers to leave the crystal which have to travel to the opposite electrode than for those charge carriers which leave by the electrode near which they are formed.

4.2. *Experiments under Irradiation with Light*

The effects of irradiation with light on the counting rate are interpreted by postulating different levels in the forbidden gap which are affected by red light and green light. Red light, it is suggested, frees predominantly charge carriers which have been trapped during the preceding bombardment with beta particles, because firstly, the counting rate increased under irradiation with this light, region *d* in Fig. 3, secondly, the increase became independent of the intensity of the incident light at high intensities, Fig. 4 (*a*), and thirdly, the increase never exceeded the previous decrease due to polarization. From the charge measurements, and also from the observation that the increase in counting rate resulting from irradiation with this light was most pronounced when the crystal had been bombarded through the anode, it follows that the level affected by this light must lie above the valence band. By taking into account the photoconductive measurements as well one finds that there are in fact two levels, level α at 0·94 ev and level β at about 1·6 ev above the valence band. These levels are normally practically filled. By irradiation with ultra-violet light or bombardment with beta particles electrons are excited from the valence band to levels which are further from it than level β, or to the conduction band. The holes generated in the valence band become trapped in levels α and β and give rise to photoconductive currents on subsequent irradiation with red light.

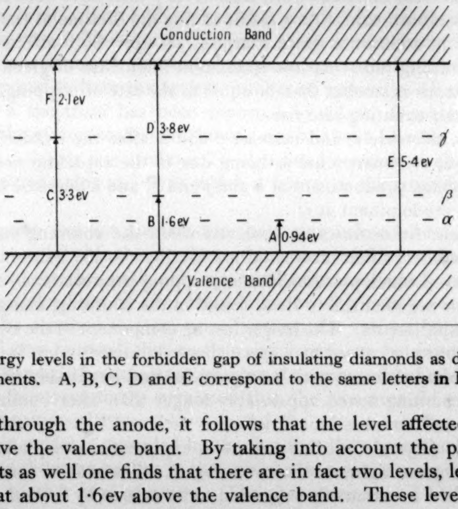

Fig. 12. Energy levels in the forbidden gap of insulating diamonds as deduced from the experiments. A, B, C, D and E correspond to the same letters in Figs 10 and 11.

The effects of irradiation with green light on the counting rate are explained if green light affects a level, the states of which are partly occupied by electrons. The charge measurements indicate that this level lies below the conduction band, and the onset of the effects of green light on the counting rate shows that the depth of this level γ below the conduction band is about 2·1 ev. All three levels are shown in Fig. 12.

On the basis of this energy level structure the other observed effects are interpreted as follows.

The small transient decrease *c* in counting rate as shown in Fig. 3 is ascribed to a decrease in lifetime of the free holes as more traps are made available for these charge carriers during irradiation with red light. The decrease in counting rate during irradiation with the same light after prolonged beta-particle bombardment as shown in Fig. 5 (*a*) for crystal C9 arises from a large number of trapped holes in levels α and β. Red light frees these holes, thereby decreasing the lifetime of free holes in the valence band and also decreasing the effective field strength by setting up a space charge. Prolonged irradiation with green light, however, fills the levels α and β, and irradiation with red light then only frees holes which were trapped during the preceding beta-particle bombardment. This decreases the space charge set up and thus increases the counting rate.

The peak *f* in Fig. 3 is ascribed to a transient increase in the noise level of the crystal due to the generation of free electrons by excitation from the level γ to the conduction band. It can be described as a photopeak. Continued irradiation with green light frees more electrons from level γ than have been trapped during the previous bombardment. As a result of this the lifetime of the free electrons decreases, and in addition a space charge is set up. Both effects give rise to a decrease in counting rate. At low irradiation intensities of green light the rate of freeing electrons is smaller than or equal to the rate of trapping electrons, and consequently the counting rate rises.

The rise *h*, decrease *i*, and increase *j* and *k* after the irradiation with light was interrupted, are interpreted as being due to the superimposed effects of an increase in lifetime, predominant at *h* and *j* and *k*, and a decrease of the effective field strength, predominant at *i*.

The different time constants observed when the counting rate due to the decaying space charge field decreased are ascribed to the existence of trapping levels, the states of which possess different trapping cross sections. It is suggested that these levels are identical to those found in the counting, charge, and photoconductivity experiments. The longer lasting component in the two-exponential decay is thought to be caused by a space charge localized in level γ, because after simultaneous bombardment with beta particles and irradiation with green light the decay in counting lasted appreciably longer than after bombardment with beta particles and simultaneous irradiation with red light, as shown in Fig. 9 for crystal C1. Crystal C9 exhibited a two-exponential decay after it had been irradiated with green light, as shown in Fig. 7. The second component of the space charge field is tentatively suggested to be caused by level β.

The curves in Figs 10 and 11 are interpreted as follows. Peak A which occurs after bombardment or irradiation with energetic ultra-violet light is due to transitions between the valence band and level α. Peak B arises from transitions between the same band and level β. Peak C originates from transitions between the valence band and level γ. Peak D is ascribed to transitions between level β and the conduction band and peak E to those between the valence and conduction bands.

It is surprising that no indication of a peak at about 2·1 ev was found, as light of this energy produced a large effect both on the counting rate and in the charge experiments. It is suggested that this peak is masked by the neighbouring peak appearing at 3·3 ev.

As peak D only appeared in crystals C1 and C9 and as these crystals were of type I, level β is suggested to be that level which causes the secondary absorption edge (Clark, Ditchburn and Dyer 1956). Tentatively it is suggested that this level is identical with the deep-lying donor level due to substitutional nitrogen suggested by Kaiser and Bond (1959) and discussed by Elliott (1960). In crystal CIIa the density of states in this level is assumed to be much smaller, and therefore no peak has been observed. However, the slight shift of the peak C towards higher energies with this crystal may well have been caused by a small, but unobservable peak in position D. Peak E was rather weak with crystal C9, but most predominant with crystal CIIa. It did not occur with crystal C1. It is suggested that this is due to a high density of states in level β in this crystal. This high density gives rise to such large optical absorption that the photoconductive current is reduced by the large annihilation rate of the free charge carriers in the thin surface layer of the crystal penetrated by the light.

4.3. *Optical Absorption*

The density of states in a level required to produce a detectable optical absorption is several orders higher than that needed for an observable photoconductive response. Therefore it appears most appropriate to consider the level structure in relation to a typical absorption spectrum for crystals of type I, which are supposed to have the largest number of impurities (Kaiser and Bond 1959). Such a spectrum has been reported by Clark, Ditchburn and Dyer (1956). The absorption coefficient shows a rise at about 1·5 ev, a very small rise at about 2·1 ev, a larger one at about 2·6 ev, a band centring at about 3·3 ev and a large increase beginning at 3·74 ev which is known as the secondary absorption edge.

The absorption was not measured in the region below 1·2 ev. On the other hand, it is very improbable that an absorption corresponding to the peak A could have been found, as this peak only appeared after prolonged irradiation with energetic ultra-violet light or after bombardment with beta particles. The rise at 1·5 ev may be ascribed to transitions between the valence band and level β. The rise at 2·1 ev is so small that no firm conclusion can be drawn from it. As the effects of green light became stronger when the energy of the light was increased beyond 2·1 ev it is tentatively suggested that the rise near 2·5 ev nevertheless arises from transitions between level γ and the conduction band. A further support for this model is provided by the fact that the absorptions at 2·6 ev and 3·3 ev are due to the same centres in the crystal, whereas the secondary absorption edge is due to another kind of centre. The absorption near 1·5 ev was too weak to be definitely assigned to one of the centres.

§ 5. CONCLUSION

From beta-particle counting experiments under various conditions, total charge measurements and photoconductivity measurements, an electronic energy level scheme consisting of three levels in the forbidden gap of insulating diamonds has been found. The measurements did not provide any data on the density of states in the levels. The occupation of the states in a level could be deduced from the experiments, but only in so far as they were fully, partly, or not occupied. Differences in the experimental results obtained from different diamonds could be attributed to different degrees of occupation of the same levels and to different absolute numbers of states in the levels.

Acknowledgments

We wish to thank Messrs. Industrial Distributors (1946) Limited for financing this research and for providing a maintenance grant for one of us (R. R. U.), and the Council of the University of the Witwatersrand for making certain grants available. Thanks are also due to Dr. J. F. H. Custers, Director of Research, Diamond Research Laboratory, Johannesburg, for supplying the diamonds and for helpful discussions.

Quantum Theory of Magnetoresistance—I: Low Fields

By R. B. STINCHCOMBE[†]

Department of Mathematical Physics, University of Birmingham

Communicated by R. E. Peierls; *MS. received 9th February* 1961

Abstract. The conventional treatment of magnetoresistance is based upon the Boltzmann equation for a distribution function $f(\mathbf{k})$, and an equation which gives the average current in terms of $f(\mathbf{k})$. With the usual definition of $f(\mathbf{k})$ neither equation is exact: the derivation of the Boltzmann equation requires $\omega\tau < 1$ where ω is the cyclotron frequency and τ is the relaxation time. In this paper a representation is proposed which exploits the properties of homogeneous systems in a uniform magnetic field. We redefine $f(\mathbf{k})$ as the diagonal element of the density matrix in the new representation. Then the usual equation for obtaining the current becomes exact. Proceeding from the equation of motion of the density matrix we then give a weak-coupling derivation of the Boltzmann equation in the manner used by Kohn and Luttinger in 1957 for field-free systems. The derivation is restricted to the case of non-interacting carriers elastically scattered by impurities or lattice vibrations, and moving in a lattice which in the absence of the magnetic field gives rise to non-overlapping bands. The conductivity yielded by this method is found to be accurate as long as $\hbar\omega$, $\hbar/\tau$ are small compared with the Fermi energy, and $\hbar\omega$ is less than the thermal energy. The condition $\omega\tau < 1$ does not arise.

§ 1. Introduction

The usual treatment of magnetoresistance is based upon the application of the Boltzmann equation

$$\frac{1}{\hbar}\frac{\partial f(\mathbf{k})}{\partial \mathbf{k}}\cdot\left(e\mathfrak{E}+\frac{e}{c}\frac{1}{\hbar}\frac{\partial E_{\mathbf{k}}}{\partial \mathbf{k}}\wedge\mathbf{H}\right)+\frac{2\pi}{\hbar}\sum_{\mathbf{k}'}W_{\mathbf{k}\mathbf{k}'}[f(\mathbf{k}')-f(\mathbf{k})]=0 \qquad \ldots\ldots(1.1)$$

to the Bloch independent-electron model of a metal, together with the prescription for obtaining the total current

$$\bar{j}_\mu=\frac{e}{\hbar}\int\frac{\partial E_{\mathbf{k}}}{\partial \mathbf{k}_\mu}f(\mathbf{k})d^3\mathbf{k}. \qquad \ldots\ldots(1.2)$$

In Eqns (1.1), (1.2) e and m are respectively the charge and mass of the electron, $\hbar$ is Planck's constant divided by 2π, $\mathfrak{E}$ is the electric field and $\mathbf{H}$ is the magnetic field. $W_{\mathbf{k}\mathbf{k}'}$ is the probability per unit time that the scattering should in the absence of the fields cause a transition from state $\mathbf{k}$ to state $\mathbf{k}'$, and $E_{\mathbf{k}}$ is the Bloch energy of an electron in state $\mathbf{k}$.

[†] Now at Physics Department, Cornell University, Ithaca, N.Y., U.S.A.

$f(\mathbf{k})$ is usually defined for a one-band model as the probability that the Bloch state $\psi_{\mathbf{k}}$ will be found occupied by an electron: if the exact electron wave function Ψ is expanded in terms of the Bloch waves,

$$\Psi = \int \alpha(\mathbf{k})\psi_{\mathbf{k}}(\mathbf{r})\, d^3\mathbf{k}$$

then $f(\mathbf{k}) = |\alpha(\mathbf{k})|^2$. With this definition of $f(\mathbf{k})$ Eqn (1.2) is not exact since the three components $j_\mu = (e/m)(p_\mu - (e/c)A_\mu)$ of the current operator are not all diagonal in the Bloch representation. They do not even commute with each other. Furthermore in the derivation of the Boltzmann equation (1.1) for $|\alpha(\mathbf{k})|^2$ the 'repeated random phase assumption' was required in the treatment of the collision term, and $|\alpha(\mathbf{k})|^2$ could only be shown to change under the influence of the fields according to

$$\left[\frac{\partial|\alpha(\mathbf{k})|^2}{\partial t}\right]_{\text{fields}} = \frac{1}{\hbar}\left(e\mathbf{\mathfrak{E}} + \frac{e}{c}\frac{1}{\hbar}\frac{\partial E_{\mathbf{k}}}{\partial \mathbf{k}} \wedge \mathbf{H}\right)\cdot\frac{\partial|\alpha(\mathbf{k})|^2}{\partial \mathbf{k}}$$

for times small compared with mc/eH. The derivations were therefore subject to the condition $\omega\tau \ll 1$ where τ is the relaxation time and $\omega = eH/mc$ is the cyclotron frequency. It should be understood that the derivations which treat the system classically are not open to this objection (Peierls 1931, 1932). In these treatments f is a function of the velocity and its rate of change under the influence of the electromagnetic field is given exactly by the Lorentz force equation.

The purpose of this paper is to justify the usual prescription (1.1), (1.2). We shall give a definition of $f(\mathbf{k})$ which makes (1.2) exact. By considering a simple model in which electrons move independently through a perfect periodic lattice and are elastically scattered by randomly distributed impurities we shall then show without the use of the random phase assumption that the new function satisfies the Boltzmann equation (1.1) for magnetic fields small enough to eliminate quantum effects but for which $\omega\tau$ may be arbitrarily large.

We thereby give some justification for the recent theories of magnetoresistance proposed by Lifshitz and Peschanskii (1959, 1960) and by Ziman (1958). Here the two equations (1.1) and (1.2) are applied for $\omega\tau \gtrsim 1$ to models in which the important features of the metal structure are included. The theories predict for single crystals that the dependence of the magnetoresistance ratio on the magnetic field should vary with the orientation of the crystal with respect to the field, saturating in high fields for certain orientations and increasing without limit as H^2 for others. These phenomena have since been observed by Alekseevskii and Gaidukov (1959). The field dependence in polycrystalline specimens is the result of averaging these different field dependences, and for filamentary specimens at least the linear law of Kapitza (1924) can be accounted for.

There have recently been attempts to provide a new basis for the treatment of high field magnetoresistance (see for instance Argyres 1958 a, b). These attempts have all treated the simple model of free electrons for which the exact field-dependence can be retained by using the Landau states of an electron in a uniform magnetic field. The generalization to more realistic models of a metal is of course extremely difficult: for this one requires the wave function of the electron in the lattice in the magnetic field. This difficulty does not arise in the method presented in this paper. We do not attempt to derive an equation of motion valid for arbitrarily high fields but instead demonstrate that (1.1) and (1.2) can be used whenever quantum effects are unimportant. For the application of (1.1), (1.2) one needs only the wave functions of the electron in the perfect lattice in the absence of the field.

The new $f(\mathbf{k})$ is defined as the diagonal element of the density matrix in a non-orthogonal representation (Dirac 1947). We select this representation by requiring that it should diagonalize any operator which is the sum of functions of the separate current components and any periodic function of the coordinates. (1.2) follows at once. Also because the scattering interaction is on the average homogeneous, its matrix elements in the new representation will have certain diagonality properties. We exploit these by writing the quantum mechanical equation of motion of the density matrix in the new representation. It is then possible to show that in a consistent limiting procedure certain terms are small and can be eliminated. The remaining terms furnish an equation of motion for the diagonal elements of ρ alone, which is just the Boltzmann equation (1.1).

In § 2 the non-orthogonal representation is established and its properties demonstrated. The Boltzmann equation is derived in § 3 by considering the lowest order terms in the limiting procedure. In § 4 some of the higher order terms are investigated and the corrections they give rise to are estimated. These corrections are small provided

$$\hbar\omega \begin{matrix}\ll\zeta \\ \lesssim kT\end{matrix}\,; \quad \hbar/\tau\ll\zeta \qquad \ldots\ldots(1.3)$$

where ζ is the Fermi energy and kT is the thermal energy. These are the conditions under which the Boltzmann equation (1.1) is valid.

§ 2. THE NEW REPRESENTATION

In the absence of a magnetic field the systems encountered in transport problems have the following property, called by Van Hove (1955) "the diagonal singularity property":

$$\langle E\alpha|WAW|E'\alpha'\rangle \sim \delta_{EE'}\delta_{\alpha\alpha'}\langle E\alpha|WAW|E\alpha\rangle. \qquad \ldots\ldots(2.1)$$

Here W is the scattering interaction and A is any operator diagonal in a representation E, α which diagonalizes the Hamiltonian of the unperturbed system. For the free electron model of a metal this representation is the momentum representation, and the property (2.1) is sufficient to establish the Boltzmann equation for the diagonal matrix elements $\langle\mathbf{k}|\rho|\mathbf{k}\rangle$ of the density operator.

When, however, a magnetic field is imposed no orthogonal representation is known which diagonalizes the unperturbed Hamiltonian exactly except in the case of free electrons. In this case the representation is based on the Landau states and the matrix elements of the scattering interaction no longer have the diagonal singularity property.† However the average translation invariance of the field-free system, reflected in (2.1) when we identify $|E\alpha\rangle$ with $|\mathbf{k}\rangle$, is not completely destroyed by the magnetic field. The overall invariance to translations in a plane containing the field direction can be maintained with a suitable choice of gauge. Making transformations between the gauges corresponding to different

† An exception is the special case which has been treated by Argyres (1958 a, b) in which the scattering is caused by a random array of zero-range scatterers.

planes we shall show in this section that a non-orthogonal representation can be found which diagonalizes the unperturbed Hamiltonian and in which the matrix elements of the scattering interaction have the required property. Moreover this representation exists whether or not we assume the electrons to be free. It can be chosen in such a way that with $f(\mathbf{k})$ equal to the diagonal matrix element of ρ in this representation, (1.2) is an exact equation for computing average currents. For this we require that the representation diagonalizes all operators of the type

$$D=\alpha(\mathbf{r})+\sum_{\mu}\beta_{\mu}(j_{\mu}) \qquad \ldots\ldots(2.2)$$

where β_μ is any function of the μth component of the current, and α is any function of the coordinates which has the periodicity of the lattice. Consider

$$\langle\mathbf{r}_1|D|\mathbf{r}_2\rangle=\alpha(\mathbf{r}_1)\delta(\mathbf{r}_1-\mathbf{r}_2)+B(\mathbf{r}_1,\mathbf{r}_2) \qquad \ldots\ldots(2.3)$$

where

$$B(\mathbf{r}_1,\mathbf{r}_2)=\langle\mathbf{r}_1|\sum_{\mu}\beta_{\mu}(j_{\mu})|\mathbf{r}_2\rangle \qquad \ldots\ldots(2.4)$$

and suppose that the magnetic field is in the z direction. The value of B depends on the choice of gauge. Two possible choices for the vector potential are:

$$\mathbf{A}_1:\ (0,Hx,0)\ \ldots\ldots(2.5\,a) \qquad \mathbf{A}_2:\ (-Hy,0,0).\ \ldots\ldots(2.5\,b)$$

In the first gauge B becomes B_1, the matrix element in configuration space of an operator that commutes with p_y and p_z. Therefore B_1 depends only on x_1, x_2 and the differences of y_1 and y_2 and of z_1 and z_2:

$$B_1=B_1(x_1,x_2,y_1-y_2,z_1-z_2). \qquad \ldots\ldots(2.6\,a)$$

Similarly in the second gauge B becomes

$$B_2=B_2(x_1-x_2,y_1,y_2,z_1-z_2). \qquad \ldots\ldots(2.6\,b)$$

Now we could write

$$B_1=\sum_{\beta}\langle\mathbf{r}_1|\beta\rangle_1\beta\langle\beta|\mathbf{r}_2\rangle_1 \qquad \ldots\ldots(2.7\,a)$$

where $\langle\mathbf{r}_1|\beta\rangle_1$ is the eigenfunction of the operator $\sum_\mu\beta_\mu(j_\mu)$ expressed in the first gauge. The eigenvalue of this operator in this state is β. Corresponding to this eigenvalue there will be another function $\langle\mathbf{r}_1|\beta\rangle_2$ which is the eigenfunction of $\sum_\mu\beta_\mu(j_\mu)$ expressed in the second gauge:

$$B_2=\sum_{\beta}\langle\mathbf{r}_1|\beta\rangle_2\beta\langle\beta|\mathbf{r}_2\rangle_2. \qquad \ldots\ldots(2.7\,b)$$

Now under a change of gauge

$$\mathbf{A}\to\mathbf{A}'=\mathbf{A}-\nabla f \qquad \ldots\ldots(2.8)$$

the wave function changes according to

$$\langle\mathbf{r}|\beta\rangle\to\langle\mathbf{r}|\beta\rangle'=\langle\mathbf{r}|\beta\rangle\exp\left(+\frac{ie}{\hbar c}f\right) \qquad \ldots\ldots(2.9)$$

(Pauli 1933). It follows that

$$\langle\mathbf{r}_1|\beta\rangle_2=\langle\mathbf{r}_1|\beta\rangle_1\exp\left(+i\epsilon x_1y_1\right) \qquad \ldots\ldots(2.10)$$

where $\epsilon=eH/\hbar c$. Hence

$$B_2=\exp\{+i\epsilon(x_1y_1-x_2y_2)\}B_1. \qquad \ldots\ldots(2.11)$$

Let us write

$$B_1=\exp\left(-i\epsilon Xy\right)G(x_1,x_2,y,z) \qquad \ldots\ldots(2.12)$$

where

$$\mathbf{R} : (X, Y, Z) = \tfrac{1}{2}(\mathbf{r}_1 + \mathbf{r}_2) \text{ and } \mathbf{r} : (x, y, z) = \mathbf{r}_1 - \mathbf{r}_2.$$

Then

$$B_2(x, y_1, y_2, z)\exp(-i\epsilon Yx) = G(x_1, x_2, y, z). \qquad \ldots\ldots (2.13)$$

The left-hand side depends only on x, not on both x_1 and x_2. The right-hand side must therefore also depend only on x. That is: $G = G(x, y, z)$. Hence

$$B_1(\mathbf{r}_1, \mathbf{r}_2) = \exp(-i\epsilon Xy)G(\mathbf{r}). \qquad \ldots\ldots (2.14)$$

In the new variables $\alpha(\mathbf{r}_1)\delta(\mathbf{r}_1 - \mathbf{r}_2)$ is $\alpha(\mathbf{R})\delta(\mathbf{r})$, and α is periodic with the lattice periodicity. Therefore with the first choice of gauge the matrix element of D has the form

$$\langle \mathbf{r}_1|D|\mathbf{r}_2\rangle = \exp(-i\epsilon Xy)\mathscr{D}(\mathbf{r}, \mathbf{R}) \qquad \ldots\ldots (2.15)$$

where $\mathscr{D}(\mathbf{r}, \mathbf{R})$ has the periodicity of the lattice with respect to its $\mathbf{R}$-dependence. From now on we shall use only the first form (2.5 *a*) of the vector potential. Eqn (2.15) can now be used to find a non-orthogonal representation in which D is diagonal. We define $\{l_1|D|l_2\}$ by

$$\{l_1|D|l_2\} = \int\!\!\int \exp(+i\epsilon yX)\langle \mathbf{r}_1|D|\mathbf{r}_2\rangle \psi_{l_1}{}^*(\mathbf{r}_1)\psi_{l_2}(\mathbf{r}_2)\, d^3\mathbf{r}_1\, d^3\mathbf{r}_2 \qquad \ldots\ldots (2.16)$$

where $\psi_l(\mathbf{r}) = \exp(i\mathbf{k}.\mathbf{r})u_{k\nu}(\mathbf{r})$ is the Bloch wave function for the electrons in the perfect lattice and l denotes the complete label $(\mathbf{k}, \nu)$ in the reduced zone scheme. If in (2.16) we change the integration variables to $\mathbf{R}$ and $\mathbf{r}$, since we have shown that $\exp(+i\epsilon yX)\langle \mathbf{r}_1|D|\mathbf{r}_2\rangle$ has the periodicity of the lattice with respect to its dependence on $\mathbf{R}$, $\exp[i(\mathbf{k}_2 - \mathbf{k}_1).\mathbf{R}]$ is the only factor in the integrand which does not depend in this way on $\mathbf{R}$. The integration with respect to $\mathbf{R}$ therefore gives zero unless $\mathbf{k}_1$ and $\mathbf{k}_2$ differ only by a vector of the reciprocal lattice. Thus in the reduced-zone scheme

$$\{l_1|D|l_2\} = \delta_{\mathbf{k}_1\mathbf{k}_2}\{\mathbf{k}_1\nu_1|D|\mathbf{k}_1\nu_2\}. \qquad \ldots\ldots (2.17)$$

Functions of the type (2.2) are therefore diagonal within a band, in the new representation defined by (2.16). For simplicity we shall limit ourselves from now on to a single band, when $\mathbf{k}$ labels the state completely. The treatment of the more general case is quite straightforward.

As an example of (2.17) suppose that for D we take the unperturbed Hamiltonian

$$\mathscr{H}_0 = \frac{1}{2m}\left(\mathbf{p} - \frac{e}{c}\mathbf{A}\right)^2 + V_0(\mathbf{r}), \qquad \ldots\ldots (2.18)$$

where V_0 is the lattice potential. Substituting into (2.16) one finds that

$$\{\mathbf{k}_1|\mathscr{H}_0|\mathbf{k}_2\} = E_{\mathbf{k}_1}\delta_{\mathbf{k}_1\mathbf{k}_2}. \qquad \ldots\ldots (2.19)$$

In the new representation the matrix elements of the scattering interaction have the diagonal singularity property for all values of the magnetic field. For if

$$\langle \mathbf{k}|WAW|\mathbf{k}'\rangle = \delta(\mathbf{k} - \mathbf{k}')\langle \mathbf{k}|WAW|\mathbf{k}\rangle \qquad \ldots\ldots (2.20)$$

when A is diagonal in the Bloch representation, it follows that

$$\{\mathbf{k}|WBW|\mathbf{k}'\} = \delta_{\mathbf{k}\mathbf{k}'}\{\mathbf{k}|WBW|\mathbf{k}\} \qquad \ldots\ldots (2.21)$$

when $\{\mathbf{k}|B|\mathbf{k}'\} = \delta_{\mathbf{k}\mathbf{k}'}\{\mathbf{k}|B|\mathbf{k}\}$. Here we have labelled matrix elements in the orthogonal (Bloch) representation by the bracket notation of Dirac, and matrix elements in the non-orthogonal representation are denoted by a curly bracket.

The representation (2.16) is therefore entirely analogous to that used by Van Hove (1955) and Kohn and Luttinger (1957) in the field-free case. We shall now show that the diagonal elements of the density matrix in this representation provide a function suitable for averaging all components of the current. The average value of the μth component of the current j is $\mathrm{Tr}\,[\rho j_\mu]$. Taking the trace in x-representation the density matrix can be written in terms of $\{\mathbf{k}|\rho|\mathbf{k}'\}$ by using the inverse of the transformation (2.16):

$$\langle \mathbf{r}_1|\rho|\mathbf{r}_2\rangle = \exp(-i\epsilon yX)\int\!\!\int d^3\mathbf{k}_1\, d^3\mathbf{k}_2 \psi_{\mathbf{k}_1}(\mathbf{r}_1)\psi_{\mathbf{k}_2}{}^*(\mathbf{r}_2)\{\mathbf{k}_1|\rho|\mathbf{k}_2\}. \qquad \ldots\ldots(2.22)$$

The properties of the Bloch functions and current operators are such that the trace reduces exactly to the very simple form:

$$\overline{j_\mu} = \int d^3\mathbf{k}\{\mathbf{k}|\rho|\mathbf{k}\}\frac{e}{\hbar}\frac{\partial E_{\mathbf{k}}}{\partial \mathbf{k}}. \qquad \ldots\ldots(2.23)$$

Hence (1.2) is exact if $f(\mathbf{k})$ is the diagonal element of ρ in the new representation, or any quantity that differs from $\{\mathbf{k}|\rho|\mathbf{k}\}$ only by a part which contributes zero to the integral in (2.23).

The averaging properties of $\{\mathbf{k}|\rho|\mathbf{k}\}$ are striking. When integrated with respect to the parameters k_ν, k_σ connected with the other components of the current, it gives the correct quantum mechanical probability for any value $\partial E_{\mathbf{k}}/\partial \mathbf{k}_\mu$ of the μth component of the current. This suggests that $\{\mathbf{k}|\rho|\mathbf{k}\}$ is closely connected with the distribution function defined by Wigner (1932). The correspondence with the Wigner function is complete if in transforming the density matrix according to (2.16) we do not perform the integrations $\int\!\!\int d^3\mathbf{r}_1\, d^3\mathbf{r}_2$ but instead integrate with respect to $\mathbf{r}$ only. For when $l_1 = l_2 = \mathbf{k}$, the function $g(\mathbf{k}, \mathbf{R})$ so obtained gives for the sum of a function α of coordinates and functions β_μ of the separate current components the correct expectation value by the normal probability calculation:

$$\overline{\alpha + \sum_\mu \beta_\mu} = \int d^3\mathbf{R}\, d^3\mathbf{k}\left[\alpha(\mathbf{R}) + \sum_\mu \beta_\mu\left(\frac{\partial E_{\mathbf{k}}}{\partial k_\mu}\right)\right]g(\mathbf{k}, \mathbf{R}). \qquad \ldots\ldots(2.24)$$

§ 3. THE DERIVATION OF THE BOLTZMANN EQUATION IN A MAGNETIC FIELD

The treatment presented here is a generalization of the method of Kohn and Luttinger (1957) and of Greenwood (1958) to the case when a uniform magnetic field is present. The essential difference is that we use the non-orthogonal representation discussed in § 2 rather than the usual Bloch representation.

The system considered is one of non-interacting electrons moving in a perfect periodic lattice under the influence of an external electric and magnetic field. The electrons are scattered by a random array of static impurity centres. The total Hamiltonian of each electron is

$$H_{\mathrm{T}} = \mathscr{H}_0 + W + H_{\mathrm{F}}. \qquad \ldots\ldots(3.1)$$

Here W is the interaction with the static impurities, H_{F} is the interaction with the electric field $\mathfrak{E}^t$ and $\mathscr{H}_0$ is defined by (2.18). Suppose ρ_{T} is the density matrix of the complete system. Its equation of motion is

$$i\hbar\dot{\rho}_{\mathrm{T}} = [H_{\mathrm{T}}, \rho_{\mathrm{T}}]. \qquad \ldots\ldots(3.2)$$

We assume that in the infinite past the system was in equilibrium in the absence of the electric field. Then $\rho_{\mathrm{T}}(-\infty) = \rho_0(\mathscr{H}_0 + W)$ is the Fermi function of $(\mathscr{H}_0 + W)$. If the electric field is switched on in the following manner:

$$\mathfrak{E}^t = \mathfrak{E}\mathrm{e}^{st}, \qquad s > 0, \qquad \ldots\ldots(3.3)$$

we may write

$$\rho_{\mathrm{T}}(t) = \rho_0 + \rho_{\mathrm{F}}(t) \qquad \ldots\ldots(3.4)$$

where ρ_{F} is the change in the density matrix due to the electric field, and so $\rho_{\mathrm{F}}(-\infty) = 0$. For the Ohmic conductivity we need ρ_{F} only to first order in $\mathfrak{E}$. To this order (3.2) becomes

$$i\hbar\dot{\rho}_{\mathrm{F}} = [\mathscr{H}_0 + W, \rho_{\mathrm{F}}] + [H_{\mathrm{F}}, \rho_0]. \qquad \ldots\ldots(3.5)$$

Since

$$H_{\mathrm{F}} = H_1\mathrm{e}^{st} \quad \text{where} \quad H_1 = -e\mathfrak{E}.\mathbf{x} \qquad \ldots\ldots(3.6)$$

the above equation and initial condition are satisfied if

$$\rho_{\mathrm{F}} = f\mathrm{e}^{st} \qquad \ldots\ldots(3.7)$$

where f is time-independent. f is the correction to the density matrix at time $t = 0$, when the field has reached the value $\mathfrak{E}$. From Eqn (3.5) we find that

$$i\hbar sf = [\mathscr{H}_0 + W, f] - C \qquad \ldots\ldots(3.8)$$

where $C = [\rho_0, H_1]$ and is in principle known.

Using the representation defined by (2.16) and again considering only a single band we can write Eqn (3.8) as

$$\begin{aligned} &i\hbar s\{\mathbf{k}_1|f|\mathbf{k}_2\} + \{\mathbf{k}_1|C|\mathbf{k}_2\} \\ &\quad = \int d^3\mathbf{r}_1\, d^3\mathbf{r}_2\, d^3\mathbf{r}_3\, d^3\mathbf{k}_3\, d^3\mathbf{k}_4 \exp(i\epsilon y_{12}X_{12})\psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_2}(\mathbf{r}_2)\{\mathbf{k}_3|f|\mathbf{k}_4\} \\ &\qquad \times \left\{ \begin{array}{l} \langle\mathbf{r}_1|\mathscr{H}_0 + W|\mathbf{r}_3\rangle \exp(-i\epsilon y_{32}X_{32})\psi_{\mathbf{k}_3}(\mathbf{r}_3)\psi_{\mathbf{k}_4}{}^*(\mathbf{r}_2) \\ -\langle\mathbf{r}_3|\mathscr{H}_0 + W|\mathbf{r}_2\rangle \exp(-i\epsilon y_{13}X_{13})\psi_{\mathbf{k}_3}(\mathbf{r}_1)\psi_{\mathbf{k}_4}{}^*(\mathbf{r}_3) \end{array} \right\}, \qquad \ldots\ldots(3.9) \end{aligned}$$

where

$$\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j, \qquad \mathbf{R}_{ij} = \tfrac{1}{2}(\mathbf{r}_i + \mathbf{r}_j).$$

Since the new representation is equivalent to that used in the field-free case by Kohn and Luttinger (1957) we expect that the properties of the scattering should produce a sharp distinction between $\{\mathbf{k}_1|f|\mathbf{k}_2\}$ and $\{\mathbf{k}_1|f|\mathbf{k}_1\}$. We therefore split Eqn (3.9) into diagonal and off-diagonal equations. These are

$$\begin{aligned} &i\hbar s\{\mathbf{k}_1|f|\mathbf{k}_1\} + \{\mathbf{k}_1|C|\mathbf{k}_1\} \\ &\quad = \int d^3\mathbf{r}_1\, d^3\mathbf{r}_2\, d^3\mathbf{r}_3 \sum_{\mathbf{k}_3} \exp(i\epsilon y_{12}X_{12})\psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_1}(\mathbf{r}_2)\{\mathbf{k}_3|f|\mathbf{k}_3\} \\ &\qquad \times \left\{ \begin{array}{l} \langle\mathbf{r}_1|\mathscr{H}_0 + W|\mathbf{r}_3\rangle \exp(-i\epsilon y_{32}X_{32})\psi_{\mathbf{k}_3}(\mathbf{r}_3)\psi_{\mathbf{k}_3}{}^*(\mathbf{r}_2) \\ -\langle\mathbf{r}_3|\mathscr{H}_0 + W|\mathbf{r}_2\rangle \exp(-i\epsilon y_{13}X_{13})\psi_{\mathbf{k}_3}(\mathbf{r}_1)\psi_{\mathbf{k}_3}{}^*(\mathbf{r}_3) \end{array} \right\} \\ &\qquad + \int d^3\mathbf{r}_1\, d^3\mathbf{r}_2\, d^3\mathbf{r}_3 \sum_{\mathbf{k}_3} \sum_{\mathbf{k}_4 \neq \mathbf{k}_3} \exp(i\epsilon y_{12}X_{12})\psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_1}(\mathbf{r}_2)\{\mathbf{k}_3|f|\mathbf{k}_4\} \\ &\qquad \times \left\{ \begin{array}{l} \langle\mathbf{r}_1|\mathscr{H}_0 + W|\mathbf{r}_3\rangle \exp(-i\epsilon y_{32}X_{32})\psi_{\mathbf{k}_3}(\mathbf{r}_3)\psi_{\mathbf{k}_4}{}^*(\mathbf{r}_2) \\ -\langle\mathbf{r}_3|\mathscr{H}_0 + W|\mathbf{r}_2) \exp(-i\epsilon y_{13}X_{13})\psi_{\mathbf{k}_3}(\mathbf{r}_1)\psi_{\mathbf{k}_4}{}^*(\mathbf{r}_3) \end{array} \right\}, \qquad \ldots\ldots(3.10) \end{aligned}$$

$$
\begin{aligned}
i\hbar s\{\mathbf{k}_1|f|\mathbf{k}_2\} &+ \{\mathbf{k}_1|C|\mathbf{k}_2\} \\
&= \int d^3\mathbf{r}_1\, d^3\mathbf{r}_2\, d^3\mathbf{r}_3 \sum_{\mathbf{k}_3} \exp(i\epsilon y_{12} X_{12})\psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_2}(\mathbf{r}_2)\{\mathbf{k}_3|f|\mathbf{k}_3\} \\
&\quad \times \left\{ \begin{array}{l} \langle \mathbf{r}_1|\mathscr{H}_0 + W|\mathbf{r}_3\rangle \exp(-i\epsilon y_{32} X_{32})\psi_{\mathbf{k}_3}(\mathbf{r}_3)\psi_{\mathbf{k}_3}{}^*(\mathbf{r}_2) \\ -\langle \mathbf{r}_3|\mathscr{H}_0 + W|\mathbf{r}_2\rangle \exp(-i\epsilon y_{13} X_{13})\psi_{\mathbf{k}_3}(\mathbf{r}_1)\psi_{\mathbf{k}_3}{}^*(\mathbf{r}_3) \end{array} \right\} \\
&\quad + \int d^3\mathbf{r}_1\, d^3\mathbf{r}_2\, d^3\mathbf{r}_3 \sum_{\mathbf{k}_3} \sum_{\mathbf{k}_4 \neq \mathbf{k}_3} \exp(i\epsilon y_{12} X_{12})\psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_2}(\mathbf{r}_2)\{\mathbf{k}_3|f|\mathbf{k}_4\} \\
&\quad \times \left\{ \begin{array}{l} \langle \mathbf{r}_1|\mathscr{H}_0 + W|\mathbf{r}_3\rangle \exp(-i\epsilon y_{32} X_{32})\psi_{\mathbf{k}_3}(\mathbf{r}_3)\psi_{\mathbf{k}_4}{}^*(\mathbf{r}_2) \\ -\langle \mathbf{r}_3|\mathscr{H}_0 + W|\mathbf{r}_2\rangle \exp(-i\epsilon y_{13} X_{13})\psi_{\mathbf{k}_3}(\mathbf{r}_1)\psi_{\mathbf{k}_4}{}^*(\mathbf{r}_3) \end{array} \right\}. \qquad \ldots\ldots(3.11)
\end{aligned}
$$

Since these equations are complex and we are only concerned with their structure we shall write them in the following way:

$$i\hbar s f_{\mathrm{d}} + C_{\mathrm{d}} = (\mathscr{H} + \mathscr{W})^{\mathrm{d}}{}_{\mathrm{d}} f_{\mathrm{d}} + (\mathscr{H} + \mathscr{W})^{\mathrm{d}}{}_{\mathrm{nd}} f_{\mathrm{nd}} \qquad \ldots\ldots(3.12)$$

$$i\hbar s f_{\mathrm{nd}} + C_{\mathrm{nd}} = (\mathscr{H} + \mathscr{W})^{\mathrm{nd}}{}_{\mathrm{d}} f_{\mathrm{d}} + (\mathscr{H} + \mathscr{W})^{\mathrm{nd}}{}_{\mathrm{nd}} f_{\mathrm{nd}}. \qquad \ldots\ldots(3.13)$$

The subscripts d, nd denote diagonal and non-diagonal parts of $\{f\}$ or $\{C\}$ and the definition of the integral operators $\mathscr{H}$ and $\mathscr{W}$ and their kernels $\mathscr{H}(\mathbf{k}_1\mathbf{k}_2|\mathbf{k}_3\mathbf{k}_4)$ and $\mathscr{W}(\mathbf{k}_1\mathbf{k}_2|\mathbf{k}_3\mathbf{k}_4)$ follows by comparison with Eqns (3.10), (3.11).

We cannot hope to solve these coupled equations exactly. We can however simplify them in the weak scattering limit. In the treatment by Kohn and Luttinger (1957) of the field-free case, it is shown that in this limit the equations have a solution which is independent of the rate s at which the electric field is switched on provided $s \ll 1/\tau$. We shall take the weak scattering limit in such a way that s is about equal to $1/\tau$ or less (τ depends inversely on the strength of the scattering) and only later make use of the fact that in practice the rate of application of the electric field is always such that $s\tau \ll 1$. We shall find however that the restriction $s \sim 1/\tau$ is not the only one that has to be imposed; in a similar way the size of the magnetic field has to be introduced into the limiting process. To show this we demonstrate how an attempt to solve the equations in the weak scattering limit for arbitrary fields fails.

We replace W by $\lambda_w W$ where λ_w is a dimensionless parameter measuring the strength of the scattering interaction. Since $\tau \propto \lambda_w{}^{-2}$ our restriction on s requires that $s = \lambda_s{}^2 s_0$ where $\lambda_s \sim \lambda_w$ and s_0 is some reference frequency independent of λ_w. A short calculation shows that for $\lambda_w \ll 1$, $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{nd}}$, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}$, $C_{\mathrm{d}} \sim \lambda_w{}^0$ and $\mathscr{W}^{\mathrm{d}}{}_{\mathrm{d}}$, $\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}$, $\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}$, $C_{\mathrm{nd}} \sim \lambda_w$. Suppose that to leading order, f_{d} is of order $\lambda_w{}^r$, where r is not necessarily positive, or even an integer. Taking the terms of lowest order in λ_w from Eqn (3.13) the following equation is obtained for f_{nd} in terms of f_{d}:

$$\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}} f_{\mathrm{nd}} = \left\{ \begin{array}{ll} C_{\mathrm{nd}} & \text{if } r > 1 \\ C_{\mathrm{nd}} - \mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}} f_{\mathrm{d}} & \text{if } r = 1 \\ -\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}} f_{\mathrm{d}} & \text{if } r < 1 \end{array} \right\}. \qquad \ldots\ldots(3.14)$$

Substituting this back into (3.12) we find that the only consistent choice of r is $r = 0$ with f_{d} given by the equation

$$\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}} f_{\mathrm{d}} = C_{\mathrm{d}} + \mathscr{H}^{\mathrm{d}}{}_{\mathrm{nd}} (\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}})^{-1} \mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}} f_{\mathrm{d}}, \qquad \ldots\ldots(3.15)$$

where the existence of the operator inverse to $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}$ has been assumed. Now in the limit of zero field the integral operators $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{nd}}$ and $\mathscr{W}^{\mathrm{d}}{}_{\mathrm{d}}$ vanish. For in this limit the general kernel becomes

$$\begin{aligned}
&[\mathscr{H}(\mathbf{k}_1\mathbf{k}_2|\mathbf{k}_3\mathbf{k}_4)+\mathscr{W}(\mathbf{k}_1\mathbf{k}_2|\mathbf{k}_3\mathbf{k}_4)]_{\text{zero field}}\\
&\quad=\langle\mathbf{k}_1|\mathscr{H}_{0_{H=0}}|\mathbf{k}_1\rangle\delta_{\mathbf{k}_1\mathbf{k}_3}\delta_{\mathbf{k}_2\mathbf{k}_4}-\langle\mathbf{k}_2|\mathscr{H}_{0_{H=0}}|\mathbf{k}_2\rangle\delta_{\mathbf{k}_1\mathbf{k}_3}\delta_{\mathbf{k}_2\mathbf{k}_4}\\
&\qquad+\langle\mathbf{k}_1|W|\mathbf{k}_3\rangle\delta_{\mathbf{k}_2\mathbf{k}_4}-\langle\mathbf{k}_4|W|\mathbf{k}_2\rangle\delta_{\mathbf{k}_1\mathbf{k}_3}
\end{aligned}\qquad\ldots\ldots(3.16)$$

since $\mathscr{H}_{0_{H=0}}$ is diagonal in the Bloch representation. If either $\mathbf{k}_1=\mathbf{k}_2$ or $\mathbf{k}_3=\mathbf{k}_4$ the kernel $\mathscr{H}_{\text{zero field}}$ vanishes, and if both $\mathbf{k}_1=\mathbf{k}_2$ and $\mathbf{k}_3=\mathbf{k}_4$, $\mathscr{W}_{\text{zero field}}=\mathscr{W}^{\mathrm{d}}{}_{\mathrm{d}_{\text{zero field}}}$ vanishes. Hence in zero field the coefficient of f_{d} in Eqn (3.15) is zero. Thus this equation only gives a solution valid in the weak scattering limit provided the field $\mathbf{H}$ is not too small, and when this is so f_{d} becomes independent of the strength of the scattering. This is to be contrasted with the behaviour of f_{d} in zero field when $f_{\mathrm{d}}\sim\lambda_w^{-2}$ as $\lambda_w\to0$ (Kohn and Luttinger 1957). These different dependences reflect the different mechanisms which limit the momentum acquired by the electrons under the influence of the electric field: when $\mathbf{H}=0$ the scattering is entirely responsible; if there is a magnetic field perpendicular to the electric field the electrons execute circular motion under the influence of the Lorentz force and this mechanism dominates in the weak scattering limit. This limiting process ($\lambda_w\to0$) can therefore provide a basis for the calculation of the transverse magnetoconductance in high fields. A high field theory of this type will be developed in a second paper. For low fields a different method of attack has to be devised.

The method we use takes into account the vanishing of $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{nd}}$, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}}$ as the field goes to zero. This is accomplished by ordering the Eqns (3.12), (3.13) not only with respect to λ_w, but also with respect to a parameter λ_H measuring the size of the field. We assume that each of λ_w and λ_H is small compared with unity. The limiting process $\lambda_H\to0$ is the extra condition referred to earlier. The exact nature of this will be made clear subsequently. We define the parameter λ_H by the equation $\hbar\omega=\lambda_H{}^2E$ where E is an energy independent of λ_w. The possible energies are ζ, kT and a screening energy giving the range of the potential of a single scatterer.

It can be shown that to leading order in λ_H, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}$, $\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}$, $\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}$ are of order $\lambda_H{}^0$ while $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{nd}}$, $\mathscr{W}^{\mathrm{d}}{}_{\mathrm{d}}$ go linearly with the field to zero, that is they are of order $\lambda_H{}^2$. To leading order $C_{\mathrm{d}}\sim(\lambda_w{}^0)\lambda_H{}^0$ and $C_{\mathrm{nd}}\sim(\lambda_w)\lambda_H{}^0$. From Eqns (3.12), (3.13) it is now possible to deduce the leading order of f_{d}, f_{nd}. From (3.12)

$$f_{\mathrm{nd}}=[i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}-\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}]^{-1}[(\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}}+\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}})f_{\mathrm{d}}-C_{\mathrm{nd}}].\qquad\ldots\ldots(3.17)$$

In the inverse operator $i\hbar s$ and $\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}$ can at once be discarded since $\lambda_s{}^2$, λ_w are each very much less than one. Inserted into (3.13) this gives an equation for f_{d}:

$$\begin{aligned}
i\hbar sf_{\mathrm{d}}+C_{\mathrm{d}}&=(\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{d}})f_{\mathrm{d}}\\
&\quad+(\mathscr{H}^{\mathrm{d}}{}_{\mathrm{nd}}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}})(-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}})^{-1}[(\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{d}}+\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}})f_{\mathrm{d}}-C_{\mathrm{nd}}].
\end{aligned}\qquad\ldots\ldots(3.18)$$

In the limit $\lambda_H\to0$, λ_w, $\lambda_s\to0$ with $\lambda_w/\lambda_s\to$a constant, the coefficient of f_{d} reduces to $i\hbar s-\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}-\hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}}(-\hat{\mathscr{H}}^{\mathrm{nd}}{}_{\mathrm{nd}})^{-1}\hat{\mathscr{W}}^{\mathrm{nd}}{}_{\mathrm{d}}$ and the inhomogeneous term to $\hat{C}_{\mathrm{d}}$. Here the circumflex means that the integral operators and inhomogeneous term are to be evaluated to leading order in λ_w, λ_H. So far nothing has been said about the relative order of λ_w and λ_H. Now $i\hbar s \sim \lambda_s^2$, $\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}} \sim \lambda_H^2$ and $\hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}}(-\hat{\mathscr{H}}^{\mathrm{nd}}{}_{\mathrm{nd}})^{-1}\hat{\mathscr{W}}^{\mathrm{nd}}{}_{\mathrm{d}} \sim \lambda_w^2$. We have already supposed that $\lambda_s \sim \lambda_w$. If we further assume that $\lambda_w \sim \lambda_H$ the terms in Eqn (3.18) of leading order in both the field and the scattering are retained. In any other limiting process some of these terms disappear. For instance for the high field approach already mentioned we would assume $\lambda_w/\lambda_H \to 0$ and the scattering interaction would disappear from Eqn (3·18).† We therefore impose the limiting process

$$\lambda_s \to 0, \qquad \lambda_w \to 0, \qquad \lambda_H \to 0 \qquad \ldots\ldots (3.19)$$

in such a way that λ_w/λ_s, λ_w/λ_H *each tends to a finite limit.*

Then

$$f_{\mathrm{d}} \to \hat{f}_{\mathrm{d}} \sim \lambda_w^{-2} \text{ function of } (\lambda_H/\lambda_w, \lambda_s/\lambda_w) \qquad \ldots\ldots (3.20)$$

$$f_{\mathrm{nd}} \to \hat{f}_{\mathrm{nd}} \sim \lambda_w^{-1} \text{ function of } (\lambda_H/\lambda_w, \lambda_s/\lambda_w). \qquad \ldots\ldots (3.21)$$

These are consistent with the results obtained by Kohn and Luttinger (1957) in zero field. Under the limiting process (3.19) the Eqns (3.12), (3.13) are to be replaced by

$$i\hbar s \hat{f}_{\mathrm{d}} + \hat{C}_{\mathrm{d}} = \hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}} \hat{f}_{\mathrm{d}} + \hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}} \hat{f}_{\mathrm{nd}} \qquad \ldots\ldots (3.22)$$

$$i\hbar s \hat{f}_{\mathrm{nd}} = \hat{\mathscr{W}}^{\mathrm{nd}}{}_{\mathrm{d}} \hat{f}_{\mathrm{d}} + \hat{\mathscr{H}}^{\mathrm{nd}}{}_{\mathrm{nd}} \hat{f}_{\mathrm{nd}}. \qquad \ldots\ldots (3.23)$$

The term $i\hbar s \hat{f}_{\mathrm{nd}}$ is of higher order than the other terms in the second equation but it cannot be discarded as it later appears in a limiting form for a delta function. The discussion of the other higher order terms is left to the next section.

We shall solve Eqn (3.23) for $\hat{f}_{\mathrm{nd}}$ in terms of $\hat{f}_{\mathrm{d}}$. For this the integral operators $\hat{\mathscr{W}}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\hat{\mathscr{H}}^{\mathrm{nd}}{}_{\mathrm{nd}}$ are required. These are just the zero field values of $\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}$, $\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}$ which from (3.16) are non-vanishing. The kernels are

$$\hat{\mathscr{H}}^{\mathrm{nd}}{}_{\mathrm{nd}}(\mathbf{k}_1\mathbf{k}_2|\mathbf{k}_3\mathbf{k}_4) = \delta_{\mathbf{k}_1\mathbf{k}_3}\delta_{\mathbf{k}_2\mathbf{k}_4}[E_{\mathbf{k}_1} - E_{\mathbf{k}_2}] \qquad \ldots\ldots (3.24)$$

and

$$\hat{\mathscr{W}}^{\mathrm{nd}}{}_{\mathrm{d}}(\mathbf{k}_1\mathbf{k}_2|\mathbf{k}_3\mathbf{k}_3) = \langle \mathbf{k}_1|W|\mathbf{k}_2\rangle\delta_{\mathbf{k}_2\mathbf{k}_3} - \langle \mathbf{k}_1|W|\mathbf{k}_2\rangle\delta_{\mathbf{k}_1\mathbf{k}_3}. \qquad \ldots\ldots (3.25)$$

For Eqn (3.22) $\hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}}$ will also be needed. This has the kernel

$$\hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}}(\mathbf{k}_1\mathbf{k}_1|\mathbf{k}_3\mathbf{k}_4) = \langle \mathbf{k}_1|W|\mathbf{k}_3\rangle\delta_{\mathbf{k}_1\mathbf{k}_4} - \langle \mathbf{k}_4|W|\mathbf{k}_1\rangle\delta_{\mathbf{k}_1\mathbf{k}_3}. \qquad \ldots\ldots (3.26)$$

Using (3.24) and (3.25) in Eqn (3.23), the solution $\hat{f}_{\mathrm{nd}}$ is easily obtained:

$$\{\mathbf{k}_1|\hat{f}|\mathbf{k}_2\} = \frac{\langle \mathbf{k}_1|W|\mathbf{k}_2\rangle[\{\mathbf{k}_2|\hat{f}|\mathbf{k}_2\} - \{\mathbf{k}_1|\hat{f}|\mathbf{k}_1\}]}{i\hbar s - [E_{\mathbf{k}_1} - E_{\mathbf{k}_2}]}. \qquad \ldots\ldots (3.27)$$

This checks the statement that $\hat{f}_{\mathrm{nd}} \sim \lambda_w \hat{f}_{\mathrm{d}}$. Together with (3.26), (3.27) gives the last term in Eqn (3.22):

$$\sum_{\mathbf{k}_3\mathbf{k}_4} \hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}}(\mathbf{k}_1\mathbf{k}_1|\mathbf{k}_3\mathbf{k}_4)\{\mathbf{k}_3|\hat{f}|\mathbf{k}_4\} = \sum_{\mathbf{k}_3} |\langle \mathbf{k}_1|W|\mathbf{k}_3\rangle|^2[\{\mathbf{k}_3|\hat{f}|\mathbf{k}_3\} - \{\mathbf{k}_1|\hat{f}|\mathbf{k}_1\}]$$
$$\left\{\frac{1}{E_{\mathbf{k}_3} - E_{\mathbf{k}_1} - i\hbar s} - \frac{1}{E_{\mathbf{k}_3} - E_{\mathbf{k}_1} + i\hbar s}\right\}. \qquad \ldots\ldots (3.28)$$

The importance of retaining the small imaginary terms $i\hbar s$ in the denominators is now apparent. Recognizing now that these are of smaller order than the other terms, the factor becomes properly ordered in the limit $s \to 0$. In this limit it is $2\pi i\delta(E_{\mathbf{k}_3} - E_{\mathbf{k}_1})$. Then the right-hand side of (3.28) becomes:

---

† The restriction $\lambda_H \to 0$ is not required for the high field approach.

$$\hat{\mathscr{W}}^{\mathrm{d}}{}_{\mathrm{nd}}\hat{f}_{\mathrm{nd}} = 2\pi i \sum_{\mathbf{k}_3} |\langle \mathbf{k}_1|W|\mathbf{k}_3\rangle|^2[\{\mathbf{k}_3|\hat{f}|\mathbf{k}_3\} - \{\mathbf{k}_1|\hat{f}|\mathbf{k}_1\}]\delta(E_{\mathbf{k}_3} - E_{\mathbf{k}_1}). \qquad \ldots\ldots (3.29)$$

Using (3.29) Eqn (3.22) becomes an equation for $\hat{f}_{\mathrm{d}}$ alone. The inhomogeneous term $\hat{C}_{\mathrm{d}}$ and the integral operator $\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}$ of this equation can be put into very simple forms. To zero order in λ_w the inhomogeneous term is

$$\{\mathbf{k}_1|C|\mathbf{k}_2\}_{w=0} = \int\!\!\int d^3\mathbf{r}_1\, d^3\mathbf{r}_2 \exp(i\epsilon yX)(-e\mathbf{\mathfrak{E}})\,.\,\langle \mathbf{r}_1|[\rho_0(\mathscr{H}_0), \mathbf{r}]|\mathbf{r}_2\rangle \psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_2}(\mathbf{r}_2). \qquad \ldots\ldots (3.30)$$

Now

$$\exp(i\epsilon yX)\langle \mathbf{r}_1|[\rho_0(\mathscr{H}_0), \mathbf{r}]|\mathbf{r}_2\rangle = -\mathbf{r}\exp(i\epsilon yX)\langle \mathbf{r}_1|\rho_0(\mathscr{H}_0)|\mathbf{r}_2\rangle.$$

Writing this to the leading order in λ_H we therefore have for $\hat{C}_{\mathrm{d}}$

$$\{\mathbf{k}_1|\hat{C}|\mathbf{k}_1\} = \int\!\!\int d^3\mathbf{r}_1\, d^3\mathbf{r}_2 e\mathbf{\mathfrak{E}}\,.\,\mathbf{r}\langle \mathbf{r}_1|\rho_0(\mathscr{H}_{0_{H=0}})|\mathbf{r}_2\rangle \psi_{\mathbf{k}_1}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}_1}(\mathbf{r}_2). \qquad \ldots\ldots (3.31)$$

Using the properties of the Bloch functions (3.31) can be reduced to

$$\{\mathbf{k}_1|\hat{C}|\mathbf{k}_1\} = ie\mathbf{\mathfrak{E}}\,.\,\frac{\partial}{\partial \mathbf{k}_1} f_0(\mathbf{k}_1, \mathbf{k}_1) \qquad \ldots\ldots (3.32)$$

where

$$f_0(\mathbf{k}_1, \mathbf{k}_1) = \langle \mathbf{k}_1|\rho_0(\mathscr{H}_{0_{H=0}})|\mathbf{k}_1\rangle. \qquad \ldots\ldots (3.33)$$

The form of $\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k}_1\mathbf{k}_1|\mathbf{k}_3\mathbf{k}_3)$ is derived in the Appendix, where it is shown that $\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}$ is identical with $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$, that is $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$ only contains terms linear in the magnetic field, and

$$\sum_{\mathbf{k}_3} \hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k}_1\mathbf{k}_1|\mathbf{k}_3\mathbf{k}_3)\{\mathbf{k}_3|\hat{f}|\mathbf{k}_3\} = -\frac{ie}{\hbar c}\left(\frac{\partial E_{\mathbf{k}_1}}{\partial \mathbf{k}_1} \wedge \mathbf{H}\right)\cdot\frac{\partial}{\partial \mathbf{k}_1}\{\mathbf{k}_1|\hat{f}|\mathbf{k}_1\}. \qquad \ldots\ldots (3.34)$$

This has the form of the usual Lorentz force acting on a charged particle moving with velocity $\mathbf{v} = \hbar^{-1}\partial E_{\mathbf{k}}/\partial \mathbf{k}$.

The equation obtained by inserting the detailed forms (3.29), (3.32) and (3.34) of the kernels and inhomogeneous term into (3.22) contains the square modulus of the matrix element $\langle \mathbf{k}_1|W|\mathbf{k}_3\rangle$ of the interaction of an electron with all the impurities. Kohn and Luttinger (1957) obtained a similar result in their treatment of the zero field equation and were able to show that this collision term could be reduced to its usual form provided there were no correlations between the positions of the impurities. Then the collision term (3.29) can be written in its customary form

$$i\hbar \sum_{\mathbf{k}_3} [W_{\mathbf{k}_1\mathbf{k}_3}\{\mathbf{k}_3|\hat{f}|\mathbf{k}_3\} - W_{\mathbf{k}_3\mathbf{k}_1}\{\mathbf{k}_1|\hat{f}|\mathbf{k}_1\}]$$

where $W_{\mathbf{k}_1\mathbf{k}_3}$ is the probability per unit time that in the absence of the field the electron should make a transition from the Bloch state $\mathbf{k}_1$ to the state $\mathbf{k}_3$. Recognizing that for the physically interesting rates at which the field could be applied s is in fact very much less than the inverse of the relaxation time, we may discard the term $i\hbar s\{\mathbf{k}_1|\hat{f}|\mathbf{k}_1\}$ in the detailed form of Eqn (3.22) and the final equation is obtained:

$$e\mathfrak{E}\cdot\frac{1}{\hbar}\frac{\partial}{\partial\mathbf{k}}f_0(\mathbf{k},\mathbf{k})+\frac{e}{c}\left(\frac{1}{\hbar}\frac{\partial E_{\mathbf{k}}}{\partial\mathbf{k}}\wedge\mathbf{H}\right)\cdot\frac{1}{\hbar}\frac{\partial}{\partial\mathbf{k}}\{\mathbf{k}|\hat{f}|\mathbf{k}\}$$
$$+\sum_{\mathbf{k}'}[W_{\mathbf{k}'\mathbf{k}}\{\mathbf{k}|\hat{f}|\mathbf{k}\}-W_{\mathbf{k}\mathbf{k}'}\{\mathbf{k}'|\hat{f}|\mathbf{k}'\}]=0. \qquad \ldots\ldots(3.35)$$

This is the usual Boltzmann equation (Jones and Zener 1934, Peierls 1931, 1932).

§ 4. CORRECTIONS TO THE BOLTZMANN EQUATION

In this section we shall investigate the corrections that appear when the magnetic field and scattering potential are included to higher order than that required to give the Boltzmann equation (3.35), and in this way deduce the conditions under which this equation is valid.

We shall solve the exact equations (3.12), (3.13) for f_{d} and f_{nd} in ascending powers of λ_H and λ_w. We assume that

$$f_{\mathrm{d}}=f_{\mathrm{d}}^{(-2)}+f_{\mathrm{d}}^{(-1)}+f_{\mathrm{d}}^{(0)}+\ldots \qquad \ldots\ldots(4.1)$$

$$f_{\mathrm{nd}}=f_{\mathrm{nd}}^{(-1)}+f_{\mathrm{nd}}^{(0)}+\ldots \qquad \ldots\ldots(4.2)$$

where

$$f_{\mathrm{d}}^{(\mathrm{n})}\sim\lambda_w^{\mathrm{n}}\text{ function of }(\lambda_H/\lambda_w) \qquad \ldots\ldots(4.3)$$

and $\hat{f}$ becomes $f_{\mathrm{d}}^{(-2)}$ in the limit $s\to 0$. λ_s has here been treated as small compared with λ_w, and from now on s is only retained to define the path of integration near the poles caused by the energy denominators, as in the derivation of (3.29). This procedure is a valid one as long as s is sufficient to fix the sign of the imaginary part of the energy denominators. If in higher order the energy denominator is modified in the following manner:

$$\frac{1}{i\hbar s-\Delta}\to\frac{1}{i\hbar s+i\alpha\hbar\omega-\Delta}$$

where α is real and about unity, but of unknown sign, the path is not defined unless $\hbar\omega\lesssim\hbar s$. Since we here want $\lambda_s\ll\lambda_w$ we would then require $\omega\tau\ll 1$. It will be seen however that such a situation does not arise.

By writing f_{d} as a power series in λ_H and λ_w we have eliminated any part of f_{d} which may have the form $\exp(-\pi^2 kT/(\hbar\omega))$, for this cannot be expanded in powers of λ_H. Such a term is expected to account for the de Haas–Schubnikov oscillations of the conductivity, which therefore cannot be treated by this method.

All inhomogeneous terms and integral operators are expanded in the same way. For example

$$C_{\mathrm{d}}=C_{\mathrm{d}}^{(0)}+C_{\mathrm{d}}^{(1)}+\ldots \qquad \ldots\ldots(4.4)$$

while

$$\mathscr{W}\equiv\mathscr{W}^{(1)}\equiv\hat{\mathscr{W}};\qquad \mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}\equiv\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}{}^{(2)}\equiv\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}. \qquad \ldots\ldots(4.5)$$

Then the first three equations for the successive parts of f_{d} can be shown to be

$$C_{\mathrm{d}}^{(0)}=\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}{}^{(2)}f_{\mathrm{d}}^{(-2)}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}{}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}{}^{(1)}f_{\mathrm{d}}^{(-2)}, \qquad \ldots\ldots(4.6)$$

$$C_{\mathrm{d}}^{(1)}=\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}^{(2)}f_{\mathrm{d}}^{(-1)}$$

$$+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\left[\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(-1)}+\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(-2)}\right] \qquad \ldots\ldots(4.7)$$

$$C_{\mathrm{d}}^{(2)}=\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}^{(2)}f_{\mathrm{d}}^{(0)}$$

$$+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\left[\begin{array}{l}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(0)}-C_{\mathrm{nd}}^{(1)}+\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(2)}\dfrac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(-2)}\\[2ex] +\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(1)}\dfrac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\left\{\begin{array}{l}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(-1)}\\ +\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(1)}\dfrac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\\ \qquad\times\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(-2)}\end{array}\right\}\end{array}\right]. \qquad \ldots\ldots(4.8)$$

Equation (4.6) is the Boltzmann equation (3.35). The higher order equations can be simplified by a convenient choice of the zero point of potential, and by the use of the diagonal singularity property (2.1). For $\langle\mathbf{k}|W|\mathbf{k}\rangle=\int W(\mathbf{r})\,d^3\mathbf{r}$ can be chosen to be zero. $C_{\mathrm{d}}^{(1)}$ contains this as a factor and is then zero. The diagonal singularity property can be used to eliminate any term containing

$$\ldots\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}\ldots$$

which written in detail is

$$\ldots\sum_{\mathbf{k}_1\mathbf{k}_2}\langle\mathbf{k}|W|\mathbf{k}_1\rangle\left\{\frac{\delta_{\mathbf{k}'\mathbf{k}_2}-\delta_{\mathbf{k}_1\mathbf{k}_2}}{i\hbar s-(E_{\mathbf{k}_1}-E_{\mathbf{k}'})}+\frac{\delta_{\mathbf{k}_1\mathbf{k}_2}-\delta_{\mathbf{k}\mathbf{k}_2}}{i\hbar s-(E_{\mathbf{k}_1}-E_{\mathbf{k}})}\right\}\langle\mathbf{k}_1|W|\mathbf{k}'\rangle\ldots$$

where $\mathbf{k}\neq\mathbf{k}'$. This factor vanishes because of (2.1). The inhomogeneous term of Eqn (4.7) therefore vanishes and we may take $f_{\mathrm{d}}^{(-1)}$ equal to zero. Eqn (4.8) then simplifies to

$$I_{w}^{(2)}+I_{H}^{(2)}=\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}^{(2)}f_{\mathrm{d}}^{(0)}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(0)} \qquad \ldots\ldots(4.9)$$

where the two parts of the inhomogeneous term are

$$I_{w}^{(2)}=C_{\mathrm{d}}^{(2)}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}C_{\mathrm{nd}}^{(1)}, \qquad \ldots\ldots(4.10)$$

$$I_{H}^{(2)}=-\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(2)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}^{(1)}f_{\mathrm{d}}^{(-2)}. \qquad \ldots\ldots(4.11)$$

Since $C_{\mathrm{nd}}^{(1)}$ depends only on the scattering perturbation the second part of $I_{w}^{(2)}$ is independent of the magnetic field. $C_{\mathrm{d}}^{(2)}$ also has this property, for the part of $C_{\mathrm{d}}^{(2)}$ due to the magnetic field is

$$[C_{\mathrm{d}}^{(2)}(\mathbf{k})]_{\mathrm{field}}=ie\mathfrak{E}\cdot\frac{\partial}{\partial\mathbf{k}}f_{H}^{(2)}(\mathbf{k}) \qquad \ldots\ldots(4.12)$$

where

$$f_H{}^{(2)}(\mathbf{k})=\epsilon\left[\frac{i}{2}\langle\mathbf{k}|y\rho_0x-x\rho_0y|\mathbf{k}\rangle-\hbar\left\langle\mathbf{k}\right|\frac{\partial\rho_0}{\partial\mathscr{H}_0}v_yx\left|\mathbf{k}\right\rangle\right]_{H=0,\,W=0} \qquad \ldots\ldots(4.13)$$

the two parts of which cancel for the one-band model. Hence $I_W{}^{(2)}$ is a correction due to the scattering only, and is given in detail by Kohn and Luttinger. $I_H{}^{(2)}$ contains all the corrections caused by the magnetic field. A detailed analysis shows that

$$\begin{aligned}I_H{}^{(2)}(\mathbf{k})=2i\mathscr{R}\sum_{\mathbf{k}_1}\langle\mathbf{k}|W|\mathbf{k}_1\rangle\frac{1}{i\hbar s-(E_{\mathbf{k}_1}-E_{\mathbf{k}})}\frac{e}{\hbar c}\mathbf{H}\,.\left(\frac{\partial E_{\mathbf{k}_1}}{\partial\mathbf{k}_1}-\frac{\partial E_{\mathbf{k}}}{\partial\mathbf{k}}\right)\wedge\left[\left(\frac{\partial}{\partial\mathbf{k}_1}-\mathbf{J}(\mathbf{k}_1)\right)\right.\\ \left.-\left(\frac{\partial}{\partial\mathbf{k}}-\mathbf{J}(\mathbf{k})\right)\right]\frac{1}{i\hbar s-(E_{\mathbf{k}_1}-E_{\mathbf{k}})}\langle\mathbf{k}_1|W|\mathbf{k}\rangle[f^{(-2)}(\mathbf{k})-f^{(-2)}(\mathbf{k}_1)]\end{aligned} \qquad \ldots\ldots(4.14)$$

where $\mathbf{J}(k)$ is defined by Eqn (A 5) of the Appendix.

In order to investigate the accuracy of the conductivity derived from the Boltzmann equation it is necessary to solve Eqns (4.6), (4.9) for $f_{\mathrm{d}}{}^{(-2)}$, $f_{\mathrm{d}}{}^{(0)}$ and estimate the ratio of the current components caused by a given electric field:

$$\frac{j_\mu{}^{(0)}}{j_\mu{}^{(-2)}}=\frac{\displaystyle\int\frac{\partial E_{\mathbf{k}}}{\partial k_\mu}f_{\mathrm{d}}{}^{(0)}\,d^3\mathbf{k}}{\displaystyle\int\frac{\partial E_{\mathbf{k}}}{\partial k_\mu}f_{\mathrm{d}}{}^{(-2)}\,d^3\mathbf{k}}. \qquad \ldots\ldots(4.15)$$

The solution of the equations requires a knowledge of the inverse operator

$$\left[\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}{}^{(2)}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}{}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}{}^{(1)}\right]^{-1}.$$

This we know explicitly for a simple case, and our detailed arguments from now on concern this case though they may be applicable generally.

We consider the simple case where the energy surfaces are spherical. Here $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}{}^{(2)}$ is a simple multiple of the z component of the angular momentum operator and if the scattering is spherically symmetric depending only on the angle of scattering, it is advantageous to expand the transition probability per unit time in terms of spherical harmonics:

$$W_{\mathbf{k}\mathbf{k}'}=W(\Theta)=\sum_l\frac{w_l}{2l+1}\mathrm{P}_l(\cos\Theta) \qquad \ldots\ldots(4.16)$$

where Θ is the angle between $\mathbf{k}$ and $\mathbf{k}'$. Then one can show that the harmonic Y_{lm} is an eigenfunction of the integral operator, with eigenvalue $i\hbar(\frac{1}{2}m\omega+w_l-w_0)$:

$$\left[\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}{}^{(2)}+\mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}{}^{(1)}\frac{1}{i\hbar s-\mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(0)}}\mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}{}^{(1)}\right]Y_{lm}=i\hbar(\tfrac{1}{2}m\omega+w_l-w_0)Y_{lm}. \qquad \ldots\ldots(4.17)$$

Hence the solutions of Eqns (4.6), (4.9) are in this case easily obtained in terms of the expansions of the inhomogeneous terms in spherical harmonics. The corresponding contributions to the current are

$$j_\mu{}^{(r)}=\frac{e\hbar}{m}\sum_{lm}\frac{k_{\mu lm}I_{lm}{}^{(r+2)}}{\frac{1}{2}m\hbar\omega+i\hbar(w_l-w_0)} \qquad r=-2,\,0 \qquad \ldots\ldots(4.18)$$

where

$$I_{lm}^{(r)} = \sum I^{(r)} Y_{lm}, \qquad \ldots\ldots (4.19)$$

$$k_{\mu_{lm}} = \sum k_\mu Y_{lm}. \qquad \ldots\ldots (4.20)$$

$I^{(0)}$ is given by Eqn (3.23) and since $I^{(2)}$ consists of the two parts $I_w^{(2)}$ and $I_H^{(2)}$ we split $j_\mu^{(0)}$ into corresponding parts $j_{\mu_w}^{(0)}$ and $j_{\mu_H}^{(0)}$. We consider in turn the ratio of each of these to $j_\mu^{(-2)}$, using dimensional arguments.

(i) $j_{\mu_w}^{(0)}/j_\mu^{(-2)}$

$$= \frac{\displaystyle\sum_{lm}\sum_{k} \frac{k_{lm} Y_{lm}}{\frac{1}{2} i m\hbar\omega + i\hbar(w_l - w_0)} \left\{ C_{\mathrm{d}}^{(2)} + \mathscr{W}^{\mathrm{d}}{}_{\mathrm{nd}}{}^{(1)} \frac{1}{i\hbar s - \mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(0)}} C_{\mathrm{nd}}^{(1)} \right\}}{\displaystyle\sum_{lm}\sum_{k} \frac{k_{lm} Y_{lm} ie\mathbf{\mathfrak{E}}\,.\,(\partial/\partial\mathbf{k}) f_0(E_{\mathbf{k}})}{\frac{1}{2} i m\hbar\omega + i\hbar(w_l - w_0)}}. \qquad \ldots\ldots (4.21)$$

This ratio differs only by the terms $\frac{1}{2}im\hbar\omega$ in the denominators from a correction evaluated by Chester and Thellung (1959) for the field-free case. It is easy to verify that there are no singular points in the summation in $j_{\mu_w}^{(0)}$ and that the sum converges at large energies. The only fast-varying factors in the sum are energy denominators, and derivatives of Fermi functions. We replace the latter by their values at absolute zero, with errors of the order kT/ζ. We now write all wave vectors in terms of the Fermi wave number. Then

$$\frac{j_{\mu_w}^{(0)}}{j_\mu^{(-2)}} = \frac{\hbar/\tau}{\zeta} \frac{\sum_z \sum_{z'} \phi_1(z, z')\alpha(z, \omega, \tau)}{\sum_z \phi_2(z)\alpha(z, \omega, \tau)} \qquad \ldots\ldots (4.22)$$

where

$$\alpha(z, w, \tau) = \sum_{lm} \frac{z_{lm} Y_{lm}}{m\hbar\omega + \hbar(w_l - w_0)} \qquad \ldots\ldots (4.23)$$

and ϕ_1 and ϕ_2 are functions of the dimensionless variables z, z'. τ is some mean value of the relaxation times $\tau_l = (w_l - w_0)^{-1}$. The dependence of α on ω or τ can be factored out when either $\omega\tau \ll 1$ or $\omega\tau \gg 1$ and the ratio of the currents is then of the order $(\hbar/\tau)/\zeta$ since each of the integrals over z, z' then yields a number about unity. For intermediate values of $\omega\tau$ the integrals in the numerator and denominator of (4.22) are different functions of $\omega\tau$. These functions are slowly varying and because of their similar limiting behaviour their ratio is never likely to differ appreciably from one.

(ii) We may write the ratio of $j_{\mu_H}^{(0)}$ to $j_\mu^{(-2)}$ in the following way:

$$\frac{j_{\mu_H}^{(0)}}{j_\mu^{(-2)}} = \left[\sum_{lm}\sum_{k} \frac{ie\mathbf{\mathfrak{E}}\,.\,(\partial/\partial\mathbf{k}) f_0 Y_{lm} k_{lm}}{\frac{1}{2} i m\hbar\omega + i\hbar(w_l - w_0)} \right]^{-1}$$

$$\times \sum_{\substack{lm\\l'm'}} \sum_{\substack{k\\k'}} \frac{ie\mathbf{\mathfrak{E}}\,.\,(\partial/\partial\mathbf{k}) f_0 Y_{lm}(k) Y_{lm}(k')}{\frac{1}{2} i m\hbar\omega + i\hbar(w_l - w_0)} \mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}{}^{(1)} \frac{1}{i\hbar s - \mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(0)}} \mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(2)} \frac{1}{i\hbar s - \mathscr{H}^{\mathrm{nd}}{}_{\mathrm{nd}}{}^{(0)}}$$

$$\times \mathscr{W}^{\mathrm{nd}}{}_{\mathrm{d}}{}^{(1)} \frac{k_{l'm'} Y_{l'm'}}{\frac{1}{2} i m'\hbar\omega + i\hbar(w_{l'} - w_0)}. \qquad \ldots\ldots (4.24)$$

Again we approximate the derivatives of Fermi functions by their values at absolute zero. Introducing dimensionless variables leads to

$$\frac{j_{\mu_H}^{(0)}}{j_\mu^{(-2)}} = \frac{\hbar\omega}{\zeta} \frac{\hbar}{\tau} \frac{\sum_{zz'} \phi_3(z, z')\alpha(z', \omega, \tau)\beta(z, z', \omega, \tau)}{\sum_z \phi_2(z)\alpha(z, \omega, \tau)} \qquad \ldots\ldots (4.25)$$

where

$$\beta = \sum_{lm} \frac{Y_{lm}(z)Y_{lm}(z')}{m\hbar\omega + \hbar(w_1 - w_0)}. \qquad \ldots\ldots(4.26)$$

In the limits $\omega\tau \gtrless 1$ it is possible to factor out the dependence of α, β on ω, τ and the ratio (4.25) becomes approximately $(\hbar/\tau)/\zeta$ for $\omega\tau \gg 1$, and approximately $\hbar\omega/\zeta$ for $\omega\tau \ll 1$. A slowly varying function of $\omega\tau$ with this limiting behaviour is $\hbar\omega/\zeta(1+\omega\tau)^{-1}$ and the ratio should differ little from this value.

The correction $j_\mu^{0} = j_{\mu_w}^{(0)} + j_{\mu_H}^{(0)}$ is therefore small compared with $j_\mu^{(-2)}$ provided $\hbar\omega$, $\hbar/\tau \ll \zeta$. However, we expect $j_\mu^{(-2)}$ to differ appreciably from the total current if $\hbar\omega \gtrsim kT$ because of the inability of the expansion method to treat the de Haas–Schubnikov terms in the conductivity. The Boltzmann equation therefore only gives a good approximation to the conductivity if (1.3) is satisfied.

§ 5. CONCLUSION

It has been shown that in the presence of a magnetic field the Boltzmann equation for a simple distribution function can be derived by a weak coupling approach which proceeds from the equation of motion of the quantum mechanical density matrix. The analysis was made convenient by the use of a representation in which it was expected on the grounds of invariance arguments that the diagonal elements of the density matrix would be much larger than the off-diagonal elements. Thus the analysis is similar to the treatment of the field-free problem where it was possible to use the momentum representation. The representation we have employed is of the Wigner type and the diagonal elements of the density matrix in this representation are all that are required for computing the average values of the three operators j_x, j_y, j_z. It is remarkable that the Boltzmann equation satisfied by this distribution function is identical with that derived by Jones and Zener (1934) on the basis of wave-packet analysis. We have therefore clarified the usual idea that individual electrons can be regarded as localized in **k**-space, and that the Lorentz force equation is valid for them.

At no point in the analysis is it necessary to assume $\omega\tau < 1$ and the corrections estimated in §4 are all small provided $\hbar\omega$, $\hbar/\tau \ll \zeta$, $\hbar\omega \lesssim kT$. Thus the application of the Boltzmann equation for arbitrary $\omega\tau$, required in the recent theories of the linear law, has been justified. Of the remaining limitations on the magnetic field, $\hbar\omega \lesssim kT$ ensures that the border region of the Fermi distribution extends over several energy levels, and $\hbar\omega \ll \zeta$ implies that states with high quantum numbers are occupied. These conditions remove any quantum effects associated with the magnetic field.

ACKNOWLEDGMENTS

The author wishes to express his sincere appreciation of the guidance and encouragement provided by Professor R. E. Peierls who suggested the problem, and to thank Dr. G. V. Chester for his constant help during the course of this work.

The award of a research studentship by the Department of Scientific and Industrial Research is also gratefully acknowledged.

APPENDIX

The Evaluation of $\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}$

The term in (3.10) giving $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k};\mathbf{k}|\mathbf{k}_1;\mathbf{k}_1)$ contains the matrix element in configuration space of $\mathscr{H}_0$:

$$\langle\mathbf{r}_1|\mathscr{H}_0|\mathbf{r}_3\rangle=\frac{1}{2m}\left\{-\hbar^2\frac{\partial^2}{\partial\mathbf{r}_1{}^2}-\frac{2e\hbar}{ic}\mathbf{A}(\mathbf{r}_3)\,.\,\frac{\partial}{\partial\mathbf{r}_1}+\frac{e^2}{c^2}A^2(\mathbf{r}_1)+2mV_0(\mathbf{r}_1)\right\}\delta(\mathbf{r}_1-\mathbf{r}_3) \qquad \ldots\ldots(\mathrm{A}\,1)$$

where V_0 is the lattice potential. Inserting this expression into (3.10) and performing partial integrations with respect to $\mathbf{r}_1$:

$$\begin{aligned}\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k};\mathbf{k}|\mathbf{k}_1;\mathbf{k}_1)&=\mathscr{J}\frac{1}{m}\int d^3\mathbf{r}_1\,d^3\mathbf{r}_2\,d^3\mathbf{r}_3\,\delta(\mathbf{r}_1-\mathbf{r}_3)\\&\times\left\{-\hbar^2\left[\frac{\partial}{\partial\mathbf{r}_1}+\left(\frac{i\epsilon}{2}\right)\mathbf{d}_{12}\right]^2-\frac{2e\hbar}{ic}Hx_1\left[\frac{\partial}{\partial y_1}+i\epsilon X_{12}\right]+\frac{e^2H^2}{c^2}x_1{}^2+2mV_0(\mathbf{r}_1)\right\}\\&\times\psi_{\mathbf{k}}{}^*(\mathbf{r}_1)\psi_{\mathbf{k}}(\mathbf{r}_2)\psi_{\mathbf{k}_1}(\mathbf{r}_3)\psi_{\mathbf{k}_1}{}^*(\mathbf{r}_2)\end{aligned} \qquad \ldots\ldots(\mathrm{A}\,2)$$

where $\mathbf{d}_{12}$ is the vector with components $(y_{12}, 2X_{12}, 0)$ produced by the action of the differential operators on the phase factors $\{\exp[y_{12}X_{12}-y_{32}X_{32}]\}$. The phase factors can be replaced by unity after the differentiation since $[y_{12}X_{12}-y_{32}X_{32}]$ vanishes when $\mathbf{r}_1=\mathbf{r}_3$. The term in (A 2) independent of the magnetic field can be written as the zero field limit of $2\mathscr{J}\langle\mathbf{k}|\mathscr{H}_0|\mathbf{k}_1\rangle\delta_{\mathbf{k}\mathbf{k}_1}$ which vanishes. The term proportional to H^2 is a linear combination of terms like $\mathscr{J}\langle\mathbf{k}|x^2|\mathbf{k}_1\rangle\delta_{\mathbf{k}_1\mathbf{k}}$ and terms like $\mathscr{J}|\langle\mathbf{k}|y|\mathbf{k}_1\rangle|^2$. Both types vanish. Hence $\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}$ contains only the term linear in the magnetic field. This can be reduced to

$$\begin{aligned}\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k};\mathbf{k}|\mathbf{k}_1;\mathbf{k}_1)&\equiv\hat{\mathscr{H}}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k};\mathbf{k}|\mathbf{k}_1;\mathbf{k}_1)\\&=\frac{eH}{mc}\left\{\begin{array}{l}\langle\mathbf{k}|p_y|\mathbf{k}_1\rangle\langle\mathbf{k}_1|x|\mathbf{k}\rangle-\langle\mathbf{k}|x|\mathbf{k}_1\rangle\langle\mathbf{k}_1|p_y|\mathbf{k}\rangle\\-\langle\mathbf{k}|p_x|\mathbf{k}_1\rangle\langle\mathbf{k}_1|y|\mathbf{k}\rangle+\langle\mathbf{k}|y|\mathbf{k}_1\rangle\langle\mathbf{k}_1|p_x|\mathbf{k}\rangle\end{array}\right\}\end{aligned} \qquad \ldots\ldots(\mathrm{A}\,3)$$

where $\mathbf{p}$ is the momentum operator. Now

$$\langle\mathbf{k}|\mathbf{r}|\mathbf{k}_1\rangle = i\frac{\partial}{\partial\mathbf{k}}\delta_{\mathbf{k}\mathbf{k}_1} + i\mathbf{J}(\mathbf{k})\delta_{\mathbf{k}\mathbf{k}_1} \qquad \text{......(A 4)}$$

where

$$\mathbf{J}(\mathbf{k}) = \int u_{\mathbf{k}}^*(\mathbf{r})\frac{\partial}{\partial\mathbf{k}}u_k(\mathbf{r})\,d^3\mathbf{r} \qquad \text{......(A 5)}$$

and the diagonal matrix elements of the velocity operator can be written simply as

$$\langle\mathbf{k}|\mathbf{v}|\mathbf{k}\rangle = \frac{1}{\hbar}\frac{\partial E(\mathbf{k})}{\partial\mathbf{k}} \qquad \text{......(A 6)}$$

(Jones and Zener 1934, Karplus and Luttinger 1954). The contribution of $\mathbf{J}$ to the right-hand side of (A 3) vanishes identically leaving

$$\sum_{\mathbf{k}_1}\mathscr{H}^{\mathrm{d}}{}_{\mathrm{d}}(\mathbf{k};\mathbf{k}|\mathbf{k}_1;\mathbf{k}_1)\{\mathbf{k}_1|f|\mathbf{k}_1\} = -\frac{ie}{\hbar c}\left(\frac{\partial E_{\mathbf{k}}}{\partial\mathbf{k}}\wedge\mathbf{H}\right)\cdot\frac{\partial}{\partial\mathbf{k}}\{\mathbf{k}|f|\mathbf{k}\}. \qquad \text{......(A 7)}$$

The Possibility of Negative Resistance Effects in Semiconductors

By B. K. RIDLEY and T. B. WATKINS
Mullard Research Laboratories, Salfords, Nr. Redhill, Surrey

MS. received 22nd February 1961

Abstract. The possibility of obtaining negative resistance effects in a new way in semiconductors is discussed. The principle of the method is to heat carriers in a high mobility sub-band with an electric field so that they transfer when they have a high enough 'temperature' to a higher energy low mobility sub-band. The conditions required for negative resistance are discussed generally and more specific conditions are obtained for some simple cases of spherical and ellipsoidal bands by solving the Boltzmann equation. It is shown that the most favourable case is when the sub-bands are sufficiently separated in energy for the emission of optical phonons to be the dominant mechanism for energy relaxation in both sub-bands. Ge–Si alloys and some III–V compounds may have suitable sub-band structures in the conduction bands. The case of p-type uniaxially strained silicon appears to be marginal in the region where the current is proportional to the square root of the electric field. The electrical instability of a crystal with a differential negative resistance is briefly discussed and it is pointed out that some sort of 'electrical domain' formation may establish itself and inhibit the observation of negative resistance. Side effects which can influence the condition for negative resistance such as specimen heating, which is advantageous, and impact ionization, which is deleterious, are also discussed.

§ 1. Introduction

It has recently been proposed by Krömer (1958) that certain energy band structure properties giving rise to a negative effective mass may be used to obtain negative resistance effects in semiconducting crystals. The chief difficulty appears to be finding a means of making a sufficiently large proportion of the carriers have negative mass.

In this paper the possibility of using other band structure properties to produce negative resistance effects is considered. The approach taken is to study means of varying the average effective mass of the carriers.

The conduction and valence bands in semiconductors consist of a number of sub-bands, and for normal conduction only the sub-bands with lowest carrier energy are effective. The next highest sub-band may be separated from the lowest sub-band by a large fraction of an electron volt. Sub-bands with very much smaller separation in energy can sometimes be produced by the effects of strain. For example, in germanium the conduction band has four sets of ellipsoidal constant energy surfaces in the [111] direction in k space, while the valence band is doubly degenerate at $k=0$, the two bands giving light and heavy holes. In both cases a strain will produce separate sets of sub-bands. In the conduction band two valleys go down and two rise in energy, and in the valence band the degeneracy is removed and two sub-bands separated in energy result.

According to the curvature of the bands and the direction of the applied electric field the carriers in the sub-bands will have different resultant effective masses. The average effective mass and hence the conductance of the crystal will depend on the relative populations of each sub-band, and this will be a function of carrier temperature. This may be varied with an applied electric field, and in what follows we shall see that under certain conditions it may be possible to use this effect to make the semiconducting crystal exhibit negative resistance effects.

§ 2. THE VARIATION OF CURRENT WITH FIELD

Let us consider the conduction band to consist of two sub-bands which may be represented in the (ϵ, k) diagram, as shown in Fig. 1. The lower band is denoted 'a' and the upper 'b'. The energies of the minima are $\epsilon_{\mathrm{a,\,b}}$ and their energy difference E. Their effective density of states are $N_{\mathrm{a,\,b}}$. We assume that the k direction is along a principal axis which is parallel to the electric field F and the effective masses and mobilities are $m_{\mathrm{a,\,b}}$ and $\mu_{\mathrm{a,\,b}}$. The numbers of electrons per cubic centimetre in the bands are $n_{\mathrm{a,\,b}}$. The conductivity is then given by

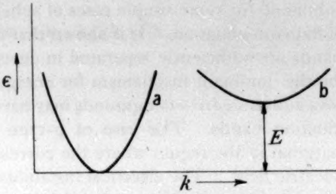

Fig. 1. Two sub-bands in a semiconductor.

$$G = e(\mu_{\mathrm{a}} n_{\mathrm{a}} + \mu_{\mathrm{b}} n_{\mathrm{b}}). \qquad \ldots\ldots (1)$$

When a sufficiently high electric field is applied to the crystal the electrons are accelerated and their effective temperature rises above the lattice temperature, and in general we must also expect the lattice temperature to increase. The effect of this will be not only to alter the mobilities but also to alter the electron densities in the bands. The incremental variation of conductivity with field may be written

$$\frac{dG}{dF} = e\left(\mu_{\mathrm{a}} \frac{dn_{\mathrm{a}}}{dF} + \mu_{\mathrm{b}} \frac{dn_{\mathrm{b}}}{dF}\right) + e\left(n_{\mathrm{a}} \frac{d\mu_{\mathrm{a}}}{dF} + n_{\mathrm{b}} \frac{d\mu_{\mathrm{b}}}{dF}\right)$$

or, putting $n_{\mathrm{a}} + n_{\mathrm{b}} = n$, where n is constant, and taking $\mu_{\mathrm{a,\,b}} \propto F^p$,

$$\frac{dG}{dF} = e(\mu_{\mathrm{a}} - \mu_{\mathrm{b}}) \frac{dn_{\mathrm{a}}}{dF} + e(\mu_{\mathrm{a}} n_{\mathrm{a}} + \mu_{\mathrm{b}} n_{\mathrm{b}}) \frac{p}{F}. \qquad \ldots\ldots (2)$$

Since the current density

$$J = GF$$

and

$$\frac{dJ}{dF} = G + F \frac{dG}{dF},$$

the condition for negative resistance is

$$-\frac{dG}{dF} \Big/ \frac{G}{F} > 1$$

or, from Eqns (1) and (2) with $f = n_b/n_a$,

$$\left[\left(\frac{\mu_a-\mu_b}{\mu_a+f\mu_b}\right)\left(-\frac{F}{n_a}\frac{dn_a}{dF}\right)-p\right]>1. \qquad \ldots\ldots(3)$$

In the next section we will examine the conditions for negative resistance by solving the Boltzmann equation for particular simple cases to gain a more detailed insight into the effect. Here we wish to limit ourselves to some general observations concerning the inequality expressed above.

The field exponent p is a function of the scattering mechanism and should be negative and large. This makes impurity scattering quite undesirable since when this is dominant the mobility rises with increasing field and thus p is positive. When lattice scattering is dominant, however, p is negative and will depend on the lattice and carrier temperatures. When the lattice temperature remains constant there are three distinct regions in the current–voltage relationship for hot electrons at low lattice temperatures ($\lesssim 20$°K).

(i) The $F^{1/2}$ region where acoustic phonon collision scattering is dominant, $p = -0{\cdot}5$.

(ii) The $F^{1/5}$ region where the emission of acoustic phonons is the dominant scattering mechanism, $p = -0{\cdot}8$ (e.g. Stratton 1957, Conwell and Brown 1960).

(iii) The F^0 region where optical phonon scattering is dominant, $p = -1{\cdot}0$. We see immediately that any contribution from the first term of Eqn (3) in region (iii) will give negative resistance. Such a contribution will arise when electrons become hot enough to spill over into the upper band, providing the upper band has a lower mobility.

(iv) Another case may be considered in which the lattice temperature is allowed to increase with field. To see the effect of this we imagine a one band case in which the lattice temperature is predominantly determined by the heat produced per unit volume Q, due to the current, but is still small compared with the electron temperature, so that

$$T \propto QF \propto^2 \mu.$$

In the $F^{1/2}$ region $\mu \propto F^{-1\,2}T^{-3/4}$ (Eqn (7); also Yamashita and Watanabe 1954), so $\mu \propto F^{-8/7}$, that is, $p = -8/7$, giving negative resistance without any contribution from the band structure. This is an extreme case, but it illustrates that Joule heating is generally advantageous to negative resistance.

The first bracket in Eqn (3) is straightforward—we must have $\mu_a > \mu_b$. Electrons must begin in a low mass band and transfer to a high mass band when they are heated by the field. The maximum value of this term is unity, i.e. when $\mu_a \gg \mu_b$.

The second bracket is not so easy to deal with. It represents the rate with field at which electrons transfer to the upper band and this will depend upon differences between the bands of effective density of states, electron temperature, and the energy gap between the sub-bands. To obtain an idea of its value let us assume a common electron temperature T_e and a Maxwell–Boltzmann distribution. If we have $T_e \propto F^q$ then

$$-\frac{F}{n_a}\frac{dn_a}{dF} = -q\frac{T_e}{n_a}\frac{dn_a}{dT_e}.$$

If E is the band separation it may be shown that with $f = (N_b/N_a)\exp(-E/kT_e)$

$$-\frac{T_e}{n_a}\frac{dn_a}{dT_e} = \frac{f}{1+f}\left(\log\frac{N_b}{N_a} - \log f\right),$$

where $N_{a,b}$ are the effective densities of states, which has a maximum value when

$$\log\frac{N_b}{N_a} - \log f = 1 + f.$$

As an example, let us consider the $F^{1/2}$ region and take the first bracket to be unity. Although the distribution is not Maxwellian let us nevertheless take our electron temperature to have the same dependence on the field as is obtained in the actual case, namely $T_e \propto F$. Thus q is also unity. Since $p = -0{\cdot}5$ we must have $f > 0{\cdot}5$ and $-(T_e/n_a)(dn_a/dT_e)$ at a maximum to obtain negative resistance. For the limiting case of $f = 0{\cdot}5$, $N_b/N_a \sim 2{\cdot}25$ and $E = 1{\cdot}5kT_e$. Such requirements are not obviously impracticable. The condition for E is not very sensitive to the ratio N_b/N_a. When $N_b/N_a = 1$, $f = 0{\cdot}3$ and $E = 1{\cdot}3kT_e$. The more detailed calculations of the next section show that negative resistance, if possible, occurs at values of kT_e which are somewhat less than the band separation, in agreement with this estimate.

§ 3. NEGATIVE RESISTANCE IN PARTICULAR CASES

To clarify ideas it is worth while to consider a particularly simple model of two spherical energy bands displaced from one another by an energy E at $k = 0$ (Fig. 2), the lower band having the lower effective mass. Such a situation is unlikely to occur naturally but if the spherical bands are replaced by suitably oriented ellipsoidal bands we come nearer to a practically realizable state, e.g. uniaxially strained p-type germanium. But to continue with the simple case, we assume that the dominant scattering is due to the interaction with a fully excited distribution of longitudinal acoustic phonons and that the matrix element governing interband transitions is of the same form as that governing intraband transitions. The first assumption means that we are dealing with conditions which in a single band would give rise to the $F^{-1/2}$ factor in the mobility law for hot electrons.

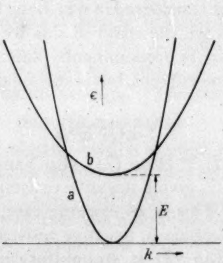

Fig. 2. Two spherical sub-bands with minima at $k = 0$.

The Boltzmann equation for the lower band is

$$\left(\frac{\partial f_a}{\partial t}\right)_{\text{field}} + \left(\frac{\partial f_a}{\partial t}\right)_{\text{intra}} + \left(\frac{\partial f_a}{\partial t}\right)_{\text{inter}} = 0$$

and a similar equation exists for the upper band. The individual terms can be obtained in the usual way by expanding the electronic distribution function f_a in spherical harmonics and taking the phonon energy to be small compared with the electron energy. Only the first two terms of the spherical harmonic expansion need be used, i.e.

$$f_\mathrm{a}=f_{\mathrm{a}0}+f_{\mathrm{a}1}\cos\theta$$

where θ is the angle between k and the electric field F. After some manipulation we obtain the energy and momentum relaxation equations:

$$\frac{2}{3}\frac{(eF)^2}{m_\mathrm{a}}\frac{\epsilon}{S_\mathrm{a}\epsilon^{1/2}+S_\mathrm{bi}(\epsilon-E)^{1/2}}\frac{d^2f_{\mathrm{a}0}}{d\epsilon^2}+\left[\frac{2}{3}\frac{(eF)^2}{m_\mathrm{a}}\frac{1-\frac{1}{2}S_\mathrm{bi}E/\epsilon^{1/2}(\epsilon-E)^{1/2}}{S_\mathrm{a}\epsilon^{1/2}+S_\mathrm{bi}(\epsilon-E)^{1/2}}\right.$$
$$\left.+\frac{2m_\mathrm{a}c^2}{kT}S_\mathrm{a}\epsilon^{3/2}\right]\frac{df_{\mathrm{a}0}}{d\epsilon}+\frac{4m_\mathrm{a}c^2}{kT}S_\mathrm{a}\epsilon^{1/2}f_{\mathrm{a}0}+[S_\mathrm{bi}(\epsilon-E)^{1/2}(f_{\mathrm{b}0}-f_{\mathrm{a}0})+\mathrm{O}(2)]=0,\quad \epsilon>E \qquad \ldots\ldots(4)$$

and

$$f_{\mathrm{a}1}=-\frac{2^{1/2}eF}{m_\mathrm{a}^{1/2}}\frac{\epsilon^{1/2}}{S_\mathrm{a}\epsilon^{1/2}+S_\mathrm{bi}(\epsilon-E)^{1/2}}\frac{df_{\mathrm{a}0}}{d\epsilon},\quad \epsilon>E \qquad \ldots\ldots(5)$$

where ϵ is the energy measured from the bottom of the lower band,

$$S_\mathrm{a}=\frac{\mathscr{E}_\mathrm{a}^{\,2}(2m_\mathrm{a})^{3/2}kT}{2\pi\rho c^2\hbar^4},\qquad S_\mathrm{bi}=\frac{\mathscr{E}_\mathrm{i}^{\,2}(2m_\mathrm{b})^{3/2}kT}{2\pi\rho c^2\hbar^4},$$

$\mathscr{E}_\mathrm{a}$ and $\mathscr{E}_\mathrm{i}$ are deformation potentials associated with intraband and interband scattering respectively, ρ is the density and c is the velocity of the acoustic waves. O(2) stands for second-order interband scattering terms which cannot be neglected in general but with which we will not be concerned in the approximations to follow. Two other similar equations occur for the upper band but these are omitted for brevity. It may be noted that the mean free path, which is the factor multiplying $eFdf_{\mathrm{a}0}/d\epsilon$ in Eqn (5), is dependent on electron energy, for energies greater than E.

3.1. *Intraband Scattering Dominant*

To find $f_{\mathrm{a}0}$ and $f_{\mathrm{b}0}$ we must solve two coupled second-order differential equations. We can simplify the problem, however, by taking the case of weak interband scattering and assuming that the distribution functions are determined solely by the electric field and intraband scattering. This is analogous to having a high thermal resistance between the bands so that the electrons in the lower band will differ in 'temperature' from those in the upper band. The solutions are now straightforward and we obtain

$$f_{\mathrm{a}0}=A\exp(-\alpha_\mathrm{a}\epsilon^2)\text{ and }f_{\mathrm{a}1}=-2^{1/2}\frac{eF}{m_\mathrm{a}^{1/2}S_\mathrm{a}}\frac{df_{\mathrm{a}0}}{d\epsilon} \qquad \ldots\ldots(6)$$

and

$$f_{\mathrm{b}0}=B\exp[-\alpha_\mathrm{b}(\epsilon-E)^2]\text{ and }f_{\mathrm{b}1}=-2^{1/2}\frac{eF}{m_\mathrm{b}^{1/2}S_\mathrm{b}}\frac{df_{\mathrm{b}0}}{d(\epsilon-E)},$$

where

$$\alpha_\mathrm{a}=\frac{3\,\mathscr{E}_\mathrm{a}^{\,4}m_\mathrm{a}^{\,5}kT}{\pi^2\rho^2c^2\hbar^8}\frac{1}{(eF)^2},$$

and similarly for α_b.

To obtain the constants A and B we evoke the particle balance equations

$$n_\mathrm{a}+n_\mathrm{b}=n,\ dn_\mathrm{a}/dt=0,$$

where n is the total density of conduction electrons and n_a, n_b are the densities in the two bands. In terms of the distribution functions these equations become

$$A\,\frac{4\pi(2m_{\mathrm{a}})^{3/2}}{h^3}\int_0^\infty \epsilon^{1/2}\exp(-\alpha_{\mathrm{a}}\epsilon^2)\,d\epsilon + B\,\frac{4\pi(2m_{\mathrm{b}})^{3/2}}{h^3}$$

$$\times\int_0^\infty (\epsilon-E)^{1/2}\exp[-\alpha_{\mathrm{b}}(\epsilon-E)^2]\,d(\epsilon-E) = n$$

$$-A\int_E^\infty \epsilon^{1/2}(\epsilon-E)^{1/2}\exp(-\alpha_{\mathrm{a}}\epsilon^2)\,d\epsilon + B\int_E^\infty \epsilon^{1/2}(\epsilon-E)^{1/2}\exp[-\alpha_{\mathrm{b}}(\epsilon-E)^2]\,d\epsilon = 0.$$

In the latter equation we have neglected the second-order interband terms. This is permitted since $f_{0\mathrm{a}} \neq f_{0\mathrm{b}}$. Solving these equations for A and B gives us the explicit distribution functions from which the current–field relationship can be deduced in the usual way. The electron densities are given by

$$\frac{n_{\mathrm{a}}}{n} = \frac{1}{1+\beta r^3\gamma^{9/4}}, \quad \frac{n_{\mathrm{b}}}{n} = \frac{\beta r^3\gamma^{9/4}}{1+\beta r^3\gamma^{9/4}}$$

where $\gamma = m_{\mathrm{a}}/m_{\mathrm{b}}$, $r = \mathscr{E}_{\mathrm{a}}/\mathscr{E}_{\mathrm{b}}$,

$$\beta = \frac{\displaystyle\int_1^\infty [x(x-1)]^{1/2}\exp(-\alpha_{\mathrm{a}}E^2x^2)\,dx}{\displaystyle\int_0^\infty [x(x+1)]^{1/2}\exp(-\alpha_{\mathrm{b}}E^2x^2)\,dx}.$$

They depend upon the field through β, which derives from the interband scattering and increases in value as the field increases. Thus as the field rises electrons spill over into the upper band. The current–field relationship is

$$J = neF\mu_{\mathrm{a}}\,\frac{1+\beta r^4\gamma^{7/2}}{1+\beta r^3\gamma^{9/4}}, \qquad \ldots\ldots (7)$$

where J is the current density and the mobility μ_{a} is given by

$$\mu_{\mathrm{a}} = \frac{2^{1/2}\pi}{3^{3/4}\Gamma(3/4)}\,\frac{e^{1/2}\rho^{1/2}\hbar^2c^{3/2}}{\mathscr{E}_{\mathrm{a}}m_{\mathrm{a}}^{5/4}(kT)^{3/4}}\,\frac{1}{F^{1/2}}.$$

Equation (7), in dimensionless form, is plotted in Fig. 3 for various values of the ratio of effective masses assuming equal deformation potentials. Negative resistance is just evident for $\gamma = 0{\cdot}4$ and is well established for $\gamma = 0{\cdot}2$.

When we turn to the more realistic case of ellipsoidal bands we realize that three different masses arise in our equations. One is the density of states effective mass $(m_{\parallel}m_{\perp}m_{\perp})^{1/3}$ which appears in, for example, S_{a} in Eqn (4), a second average mass appears in the mc^2/kT terms in the same equation, and the third is the mass in the direction of the field (the mass in the $(eF)^2/m_{\mathrm{a}}$ terms in Eqn (4)). In the spherical band case the ratio of each of these masses contributes to produce negative resistance. To be now more pessimistic let us consider the case of two identical ellipsoids oriented such that their major axes are at right angles to one another and the major axis of the upper band is parallel to the electric field. This is close to the condition of the valence band in uniaxially strained p-type germanium or silicon near $k = 0$. Since the ellipsoids are identical the average masses are the same and we have to rely on the ratio $m_{\perp}/m_{\parallel}$, i.e. the ratio of masses in the direction of the field, to give us negative resistance. Under the same conditions as before we obtain for the current

$$J = neF\mu_{\mathrm{a}}\,\frac{1+\beta\gamma^{3/2}}{1+\beta\gamma^{3/4}},$$

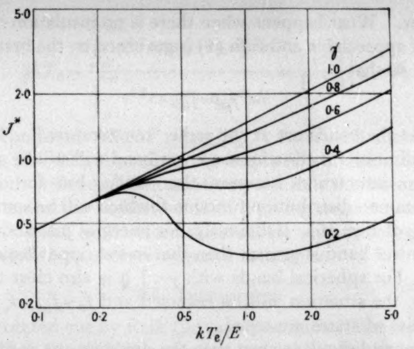

Fig. 3. Variation of current with voltage for two spherical sub-bands with minima at $k=0$, where E is the energy separation at $k=0$ and $\frac{3}{2}kT_{\rm e}$ is the mean electron kinetic energy in the lower band. The dominant scattering mechanism is assumed to be collisions with longitudinal acoustic phonons with the same deformation potential operative for both bands.

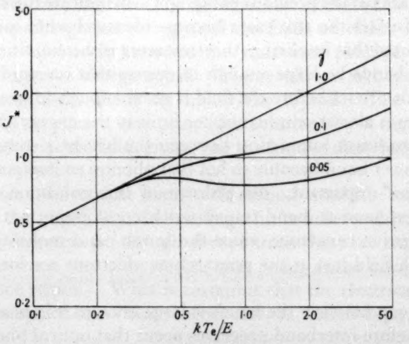

Fig. 4. Variation of current with voltage for two identically shaped ellipsoidal sub-bands with minima at $k=0$ and their major axes mutually perpendicular. The electric field is parallel to the major axis of the upper band. E is the energy separation at $k=0$ and $\frac{3}{2}kT_{\rm e}$ is the mean electron kinetic energy in the lower band. The dominant scattering mechanism is assumed to be collisions with longitudinal acoustic phonons with the same deformation potential operative for both bands.

where now $\gamma = m_\perp/m_\parallel$ and $\mu_{\rm a}$ is the same as before except that $m_{\rm a}^{5/4}$ is replaced by $m_\perp^{3/4}\bar{m}^{1/2}$ where $\bar{m}$ is an average mass. In dimensionless form this is plotted in Fig. 4 and the conditions for negative resistance are shown to be much more stringent.

3.2. *General Remarks*

The case just considered has been one in which the bands developed independent distribution functions, just as though they had been thermally insulated from one another. What happens when there is no insulation? The interband scattering is now appreciable and Eqn (4) is governed by the first-order interband scattering terms so that

$$f_{a0}=f_{b0},$$

which means that the bands are at the same 'temperature'. Thus for energies below E the distribution function for the lower band will still be given by Eqn (6), since there is no interaction between the bands, but for energies above E there will be a common distribution function f_0 which will be some sort of mixture of the f_{a0} and f_{b0} of Eqn (6). Obviously, for energies just above E the density of states in the lower band is greater than that in the upper band, and $f_0 \sim f_{a0}$ for any mass ratio. For spherical bands with $\gamma < 1$ it is also clear that well above a critical energy ϵ_c the situation will be reversed and $f_0 \sim f_{b0}$; ϵ_c is the energy at which the densities of states are equal.

This case is more difficult to treat than the previous one and no attempt to do so will be made here, concerned as we are primarily with the principles behind this method of achieving negative resistance. However, there is probably very little difference in behaviour between the two cases under steady state conditions since the steady state densities of electrons in the bands are mainly governed by the densities of available states and not by the rate of transition from one band to the other. The remarks of the previous paragraph also indicate the similarity between the two cases. In fact the two cases become identical when $\gamma \ll 1$.

It should be noted that implicit in this treatment is the condition that the energy gap between the bands be large enough to ensure that no significant interaction between the bands occurs before the field is great enough to heat the upper band electrons. There is also an implicit upper limit to the energy gap defined by the condition that significant interaction between the bands is completed before the electrons in the lower band become so hot that phonon emission or optical phonon scattering becomes important. Breakdown of this condition over the critical range of field when band-to-band transitions become important can enhance the possibility of negative resistance, since the lower band mobility begins to drop more rapidly with field just at the point where electrons are lost from the lower band.

If the energy gap between the bands is large enough it is possible to make the electrons so hot before interband processes occur that optical phonons are excited and the drift velocity saturates with field. Since the saturation drift velocity is inversely proportional to the square root of the effective mass in the direction of the field (see, for example, Reik, Risken and Finger 1960), the condition for negative resistance is just $\gamma < 1$, a condition which is certainly a practical one. What is not so easy to obtain is the large energy gap.

At low lattice temperatures the scattering of hot electrons can be by emission of acoustic phonons ($J \propto F^{1/5}$). Conditions for negative resistance in this range will lie between those for the optical phonon range and the $F^{1/2}$ range.

3.3. *The Band Separation and Lattice Temperature*

It was mentioned in § 3.2 that the band separation had to be enough to allow the upper band electrons to become hot before appreciable interaction between the bands occurred. The critical field F_c for the upper band is given by $F_c \sim c/\mu_{0b}$ where μ_{0b} is the low field mobility. Defining an electron temperature T_e for the lower band by

$$\tfrac{3}{2}kT_{\mathrm{e}} = \frac{\displaystyle\int_0^\infty \epsilon^{3/2}\exp(-\alpha_{\mathrm{a}}\epsilon^2)\,d\epsilon}{\displaystyle\int_0^\infty \epsilon^{1/2}\exp(-\alpha_{\mathrm{a}}\epsilon^2)\,d\epsilon} = \frac{\Gamma(5/4)}{\Gamma(3/4)}\alpha_{\mathrm{a}}^{-1/2},$$

we obtain the condition $kT_{\mathrm{e}}/kT \gtrsim \tfrac{1}{3}\mu_{0\mathrm{a}}/\mu_{0\mathrm{b}}$. Interband interaction becomes important when $E \sim 3kT_{\mathrm{e}}$, therefore the required condition is $E/kT \gtrsim \mu_{0\mathrm{a}}/\mu_{0\mathrm{b}}$. For spherical bands with equal deformation potentials this becomes $E/kT \gtrsim \gamma^{-5/2}$. For 'insulated' bands the highest value of γ giving negative resistance was 0·4, hence $E/kT \gtrsim 10$. $10kT$ is therefore the smallest separation between the bands for which it is possible to observe negative resistance.

§ 4. INSTABILITY

It has been pointed out by Reik (private communication) that a crystal under conditions in which it exhibited negative resistance should be electrically unstable. At any point in the crystal a random fluctuation of carrier density can produce a momentary space charge which, in the direction of the particle current, decreases the electric field on one side and increases the field on the other. When the resistance is positive a smaller current flows into the space charge region than that which flows out, and consequently the space charge decays and a uniform field is established once more. The reverse will occur when the resistance is negative, the space charge increasing until the fields on either side of it are high and low enough respectively to make the resistance positive and the currents into and out of the space charge equal. The result is a stable situation but with markedly inhomogeneous fields set up in the crystal. The process is like a separating out of two phases, one phase characterized by a higher electric field, the other by a lower electric field, giving rise to a kind of electrical domain structure throughout the crystal.

A consequence of electrical domain formation would be to reduce or, more likely, eliminate the possibility of obtaining a finite differential negative resistance in the current–voltage curve, though abrupt transitions are not ruled out. It is also possible that some sort of hysteresis may occur as the field is cycled over the negative resistance region. What is certain is that the electrical state of a crystal with negative resistance bears close theoretical, as well as experimental, scrutiny.

§ 5. DISCUSSION

Although we have discussed the conditions for negative resistance in two-band models only, it is obvious that what has been said can apply equally well to a single band if above an energy E from the band minimum the effective mass increases fairly suddenly to a new value. The single band in this case becomes very similar to two bands, one vertically above the other in energy, so we can limit our discussion to two-band models.

The requirements of a material to show negative resistance may be broadly divided into two categories, one containing intrinsic and one containing extrinsic properties. The intrinsic requirements concern the band structure and the scattering mechanisms in the material. It is apparent from what has gone before that the band structure should be such that hot electrons (or holes) move sufficiently quickly from a high mobility state to a low mobility state as the field is increased.

The higher energy band should therefore have a high density of states or, if ellipsoidal, at least have a very high effective mass in the field direction relative to the lower band.

It is possible that uniaxially strained p-type germanium or silicon has the necessary structure. Under uniaxial strain the degeneracy of the 'light' and 'heavy' valence bands at $k=0$ is removed and two ellipsoids with their major axes at right angles to one another appear separated in energy at $k=0$ (Fig. 5).

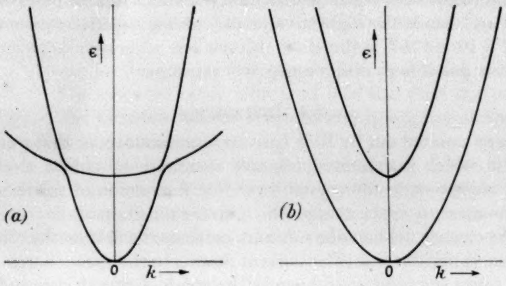

Fig. 5. Schematic (ϵ, k) diagram for the valence bands in uniaxially strained germanium; (*a*) for k parallel to the strain, (*b*) for k perpendicular to the strain.

Holes becoming hot will tend to move from the lower ellipsoid into the 'heavier' upper ellipsoid. Hensel and Feher (1960) have measured inverse-mass parameters in silicon for strains in the [001] and [111] directions; so taking their interpretation of the band structure as being reasonable and assuming that the ellipsoids actually intersect one another in the strain direction, we can make an estimate of the possibility of negative resistance. For the lower energy ellipsoid with the strain in the [111] direction $m_\perp/m=0{\cdot}401$ and $m_\parallel/m=0{\cdot}128$, where $m_\perp$ is the mass perpendicular to the direction of the strain, and $m_\parallel$ is the mass parallel to the direction of the strain. For the upper ellipsoid $m_\perp/m=0{\cdot}166$ and $m_\parallel/m=1{\cdot}408$. The density of states effective masses are $0{\cdot}274m$ and $0{\cdot}339m$ respectively, giving an effective mass ratio of 0·806. This value coupled with the ratio of masses in the field direction of 0·091 when the field is in the same direction as the strain means that marginal negative resistance effects may be observable in the $F^{1/2}$ region. The condition for the energy separation is $E \gtrsim 13kT$. For strains of the order of 10^{-3}, and assuming a rate of band separation of about 10ev per unit strain, the lattice temperature must be about 12°K or less. At these temperatures the $F^{1/5}$ region will be reached rapidly by the holes in the lower ellipsoid and this can enhance the negative resistance. The case of p-type silicon uniaxially strained in the [111] direction therefore appears to be marginal as far as the band structure goes.

Since negative resistance occurs most easily when the carriers are scattered by optical phonons, it is useful to consider materials which have naturally occurring sub-band separations of ~0·03 ev and greater since such separations are difficult to produce by strain. (Strain, however, can be used to modify a natural energy gap.) Such separations occur in the conduction valleys in the III–V compounds and also in Ge–Si alloys. These materials are therefore well worth investigating.

Given a promising band structure we must look critically at the scattering mechanism. First of all, impurity scattering must be negligible so that the density of ionized impurities must be kept low (an 'extrinsic' condition). More serious is the fact that the ratio of the deformation potentials and/or optical scattering constants of the two bands is important (e.g. Eqn (7)) since this affects the mobility difference between the bands. It is advantageous to have a lower acoustical deformation potential and a higher optical scattering constant for the lower band.

The extrinsic requirements concern the carrier density in the main. Certainly any process which increases the density as the field is increased jeopardizes the achievement of negative resistance. Impact ionization and injection from the contacts are two such processes. Ohmic contacts are certainly desirable. Impact ionization of shallow impurities can occur at quite low fields in germanium at 4°K, but how near to complete ionization one gets at high fields is not well known. If saturation in the ionization can be obtained before the negative resistance region occurs, or if the electrons are mainly thermally ionized already, the effect of impact ionization should not be serious. Alternatively, the onset of ionization can be delayed to higher fields by replacing shallow level impurities by impurities having a level near the middle of the band. This may mean that at the low working temperature conduction via the band is negligible compared with impurity conduction, in which case it would be essential to optically excite enough of the electrons in the impurity level to the lower band to ensure normal conduction. The case of hot photoelectrons has not been studied yet, but the use of light to generate electrons obviously complicates matters since the steady state density of electrons depends upon the trapping time which will be governed by the mean velocity of the electrons and hence the electric field. If the capture cross section is independent of electron energy then the trapping time will decrease as the electrons become hotter and hence the density of electrons will go down. Not only would this be an advantage for negative resistance, as hitherto envisaged, it would mean that negative resistance would occur in a single simple band at fields high enough to evoke optical scattering. Most of the measured cross sections, however, decrease with increasing temperature (see, for example, Lax 1959). If this is taken as an indication of how the cross section varies with electron energy the tendency will be to inhibit negative resistance.

It must not be forgotten that a rise in lattice temperature with increasing field is advantageous. Since a trend in this direction is inevitable anyway it is gratifying that its effect is in the right direction.

§ 6. CONCLUSIONS

It has been shown that negative resistance effects can occur in a semiconductor if a suitable band structure is available, and that the conditions which determine the suitability of a band structure are not so severe as to make it improbable that the effect will be observed in some existing semiconductors. In fact, the main hurdle to be jumped may not be the discovery of a suitable band structure but rather the elimination of the effects of impact ionization. The existence of a negative resistance region in the current-voltage characteristic of a crystal may give rise to interesting effects due to electrical instability.

ACKNOWLEDGMENTS

We would like to express our thanks to Professor H. B. G. Casimir, Dr. H. J. G. Meyer, Dr. H. G. Reik, and Mr. K. Tweedale for many invigorating discussions and also to Drs. J. Ross MacDonald and R. Stratton of Texas Instruments for pointing out an error in the earlier work. Mrs. E. Keeble's assistance with the calculations was invaluable.

LETTERS TO THE EDITOR

The Effect of Absorption in the β Filter on the Mean Wavelength of X-ray Emission Lines

The effect of absorption on the mean wavelength of x-ray emission lines has been investigated theoretically by Wilson (1958). This note describes an experimental investigation of the effect of absorption in the β filter on the mean wavelength for the case of copper K_α radiation.

The investigation was carried out using a Philips PW 1050/30 diffractometer, together with the recording apparatus of Pike and Hughes (1959). The diffractometer was used with 4° divergence and anti-scatter slits, two sets of Söller slits with an angular aperture of 4·5°, a 0·1 mm receiving slit and North American Philips Type 62019 Geiger counters as detectors.

Measurements were made on the 321 line of a tungsten specimen, firstly with no filter and then with three normal β filters placed in the diffracted beam from the specimen. The specimen of tungsten was obtained in connection with the International Lattice Parameter Project (Parrish 1960). The 321 line was recorded in steps of 0·02° (2θ) over an angular range of 3·6° (2θ). The position of the centroid of the line thus detected was calculated for four angular ranges by a method previously described (Pike and Wilson 1959).

The temperature of the specimen was noted at intervals during each run and the position of the centroid corrected to 18°c, assuming the linear expansion coefficient of tungsten to be $4{\cdot}3 \times 10^{-6}$ per deg c. The actual temperatures on different days were all in the range 16–20°c. Systematic errors, introduced in resetting the diffractometer arm, were avoided, as the step scanning mechanism is such that the diffractometer arm can be, and was, reset without unlocking the gears. The effect of any variations with time was minimized by alternating the two sets of experimental conditions.

Nine measurements were made of the 321 line with no foil and eight with three foils, and the mean position of the centroid calculated in each case. The standard deviation of the mean was calculated both from the experimental results and directly from the line profile. The values calculated by the two methods were very closely similar. The results thus obtained and the corresponding values of $\Delta\lambda/\lambda$ are shown in the Table.

Results of Measurements on 321 Line of Tungsten, corrected to 18°c

Range (°2θ)	3·6	3·2	2·8	2·4
No foil				
Mean position of centroid (°2θ)	130·6121	130·6120	130·6110	130·6082
S.D. of mean (°2θ)	0·0010	0·0006	0·0005	0·0006
3 foils				
Mean position of centroid (°2θ)	130·6075	130·6063	130·6051	130·6027
S.D. of mean (°2θ)	0·0011	0·0011	0·0010	0·0008
Difference caused by insertion of foils				
Change in centroid (°2θ)	**0·0046**	**0·0057**	**0·0059**	**0·0055**
$\Delta\lambda/\lambda$ (units of 10^{-6})	**18**	**22**	**23**	**21**
S.D. of $\Delta\lambda/\lambda$ (units of 10^{-6})	**6**	**5**	**4**	**4**

For the case of absorption in the β filter, with μ varying as λ^3, Wilson (1958) gives the result

$$\frac{\Delta\lambda}{\lambda} = -\frac{3V\mu t}{\lambda} \qquad \ldots\ldots(1)$$

where V is the variance of the wavelength, μ the linear absorption coefficient and t the thickness of the filter. For the particular case investigated here the value of μt was 2·2 and the fractional change in wavelength is calculated to be $1{\cdot}8 \times 10^{-5}$, assuming the variance to be one third of the square of the separation of the α_1 and α_2 peaks. The mean of the experimentally observed values of $\Delta\lambda/\lambda$ is $2{\cdot}1 \pm 0{\cdot}4 \times 10^{-5}$, which is in good agreement with the calculated value.

No correction has been made for truncation error in these experimental results. The effect of truncation is negligible in the present application, as can been seen from the fact that $\Delta\lambda/\lambda$ remains effectively constant with variation of the range over which the centroid is calculated.

The diffractometer was purchased with the aid of a grant from the Department of Scientific and Industrial Research. The author is grateful to Professor A. J. C. Wilson for his encouragement.

Thermoelectricity in Metals at Normal Temperatures—A Query

It is believed that thermoelectric power S in metals may arise in two primary ways: first, because of electron thermal diffusion, involving essentially the electronic specific heat† so that

$$S_e \sim \frac{c_{el}}{e} \sim \frac{k}{e}\left(\frac{T}{T_0}\right) \qquad \ldots\ldots(1)$$

(cf. for example Mott and Jones 1936, Wilson 1936, 1953) where c_{el} is the electronic specific heat per conduction electron, and T_0 is the electron degeneracy temperature; secondly, due to 'phonon drag' when the lattice specific heat is primarily responsible and

$$S_g \sim \frac{c_g}{e}\,\frac{\tau_{p\text{-}p}}{\tau_{p\text{-}p}+\tau_{p\text{-}e}} \qquad \ldots\ldots(2)$$

(MacDonald 1954, Sondheimer 1956) where c_g is the lattice specific heat per conduction electron, $\tau_{p\text{-}e}$ is the phonon–electron relaxation time, and $\tau_{p\text{-}p}$ is the phonon relaxation time due to all other phonon scattering processes.

---

† We exclude specifically 'mutual electron-drag' found at low temperatures in certain metals containing transition elements as solutes (cf. for example de Vroomen, van Baarle and Cuelenaere 1960, Guénault and MacDonald 1961).

Equation (1) evidently predicts $S \propto T$ essentially at all temperatures, while, if $T \gtrsim \theta$ so that $c_g \sim k$ (assuming the order of one free electron per atom), $\tau_{p\text{-}e}$ is constant, and $\tau_{p\text{-}p} \propto T^{-1}$ arising from anharmonic lattice interactions (phonon–phonon collisions), then from Eqn (2) $S_g \propto T^{-1}$. Rough estimates (e.g. Sondheimer 1956, p. 1249, MacDonald 1961) indicate that, to quote Sondheimer: " S_g may be expected to be comparable in magnitude with S_e at ordinary temperatures ". Thus far, we would expect that neither S_g could be neglected in comparison with S_e at room temperature in typical metals nor, moreover, that the observed thermoelectric power $S_e + S_g$ would be even approximately proportional to the absolute temperature. Figs 1 and 2 are quite

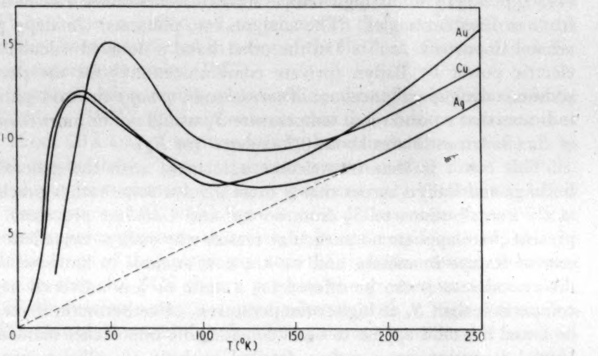

Fig. 1. Absolute thermoelectric power of ' pure ' samples of Cu, Ag and Au as a function of temperature.

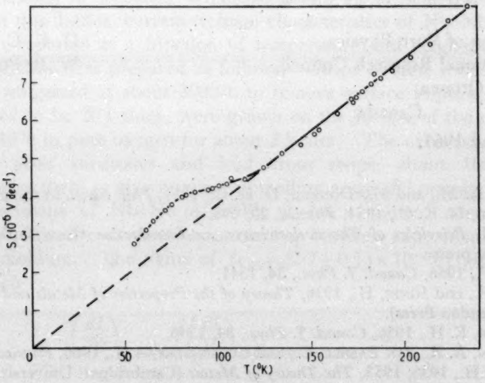

Fig. 2. Absolute thermoelectric power of ' pure ' lithium as a function of temperature. Unpublished data of J. N. Mundy.

typical of experimental results in many metals: the obvious 'hump' at lower temperatures is now generally recognized as arising from phonon drag, and indeed this contribution clearly decays progressively at higher temperatures in qualitative agreement with Eqn (2). However, in all the cases illustrated it appears experimentally that S_g has become essentially *negligible* by room temperature so that in each case the overall thermoelectric power is reasonably proportional to the absolute temperature.

Although the theoretical estimates mentioned above do *not* take specific account of *Umklapp* processes in electron–phonon scattering, one might have surmised that in conduction phenomena at high temperatures one could ignore to a first approximation the finer details of scattering processes. To quote Mott (1956, p. 1341): "At high temperatures the resistance can well be calculated from an Einstein model. The analyses into phonons, Umklapp processes, etc., are not important. . . ." On the other hand a detailed calculation of thermoelectric power by Bailyn (private communication†) for the particular case of sodium, taking specific account of *normal* and *Umklapp* electron–phonon processes, indicates that around room temperature S_g would not be more than a few per cent of S_e (Bailyn estimates about $0{\cdot}2\,\mu\text{v deg}^{-1}$ for S_g).

This result is thus in welcome agreement with the general experimental findings and Bailyn agrees that it must involve some rather precise cancellation of the contributions to S_g from *normal* and *Umklapp* processes. However, at present there appears no particular reason why such a cancellation should be a *general* feature in metals, and we are now anxious to know whether a general theoretical reason can be offered for a more or less universal neglect of S_g in comparison with S_e at higher temperatures. Furthermore, if such a reason *can* be found it would appear to be of considerable importance showing that even at 'high' temperatures a rather detailed analysis of collision processes is very essential for electron transport phenomena.

We are grateful to Drs. J. S. Dugdale and J. N. Mundy for supplying us with unpublished data on lithium (Fig. 2).

A Study of Superconducting Niobium by Electron Tunnelling

Giaever (1960) and Nicol, Shapiro and Smith (1960) have reported current–voltage characteristics of sandwiches composed of two metals separated by a thin insulating oxide film. By observing the deviation from linearity of these characteristics with one, or both, of the metals in the superconducting state, they have obtained conclusive proof that the predominant conduction mechanism is quantum mechanical tunnelling through the potential barrier afforded by the oxide. Under certain conditions, the superconductor–oxide–superconductor system resulted in a negative resistance region from which the energy gaps of the two superconductors were obtained directly. The superconducting energy gaps of Al, In and Pb have been reported and, together with the general features of the characteristics, have been interpreted in terms of the Bardeen–Cooper–Schrieffer (BCS) theory of superconductivity (1957).

With the exception of a report of tunnelling through niobium oxide by Sherrill and Edwards (1961), the requirements that the oxide be continuous at thicknesses of about 20 Å and of high resistivity have limited measurements to Al–Al_2O_3–metal sandwiches. The aluminium system suffers from the disadvantage that direct measurement of energy gaps can only be obtained below the transition temperature of Al, which for evaporated films varies from 1·2°K to 1·8°K. For most superconductors, therefore, it is not possible to explore the temperature dependence of the energy gap near the transition temperature, and it is in this region that the BCS theory predicts the greatest variation. The development of sandwiches using a superconductor with a higher transition temperature than that of Al would therefore bring about a considerable improvement.

Bulk niobium ($T_c = 9{\cdot}2°\text{K}$) and niobium oxide, have been investigated at these laboratories and found to fulfil the requirements outlined above. Their use should allow the measurement of the temperature dependence of the energy gaps of the majority of elemental superconductors up to their transition temperatures. In this Letter, current–voltage characteristics of Nb–Nb oxide–Pb sandwiches are reported as a function of temperature and magnetic field.

The sandwiches were prepared as follows. Strips of zone refined niobium were vacuum outgassed at about 2000°C to remove surface impurities. Oxide films, estimated to be 20 Å thick, were grown on the surface of the niobium by heating it to 40°C in pure oxygen for about 2 hours. The oxidized strips were mounted on glass substrates and lead cross strips, about 1000 Å thick, evaporated across them to give nominal tunnelling areas of 1 mm square.

Initial specimens of Nb–Nb oxide–Pb at 4·2°K showed current–voltage characteristics indicative of electron tunnelling between superconducting lead and normal niobium. The value of $2\epsilon_{\text{Pb}} = (2{\cdot}7 \pm 0{\cdot}1) \times 10^{-3}$ ev given by the voltage at which

$$\left(\frac{dI}{dV}\right)_{\text{normal}} \Big/ \left(\frac{dI}{dV}\right)_{\text{superconducting}} = 1,$$

obtained from this characteristic, was in good agreement with that obtained from Al–Al_2O_3–Pb sandwiches at the same temperature. The bulk niobium, however, was shown to be superconducting and the normal surface was ascribed to

the presence of impurities. When a more stringent outgassing procedure was adopted results indicated that both metal surfaces were superconducting and typical characteristics are shown in Figs 1 and 2.

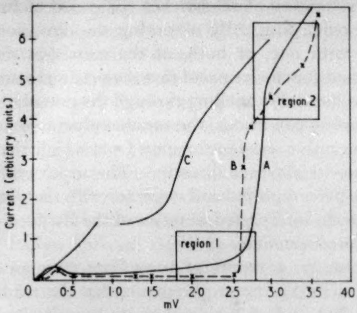

Fig. 1. Characteristic curves for Nb–Nb oxide–Pb sandwich: curve A measured at 4·18°K; curve B calculated from BCS theory ($T = 4{\cdot}2$°K); curve C measured at 6·5°K.

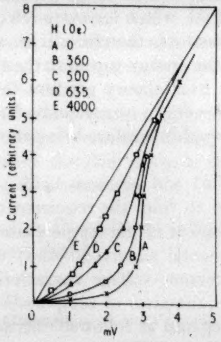

Fig. 2. Tunnel current through a Nb–Nb oxide–Pb sandwich at 4·18°K as a function of magnetic field.

Figure 1, curve A, shows the characteristic of a Nb–Nb oxide–Pb sandwich at 4·18°K. Curve B, the theoretical characteristic at 4·2°K, has been evaluated from the equation

$$I = \text{const} \int \rho_1(E)\rho_2(E-V)[f(E-V)-f(E)]\,dE, \qquad \ldots\ldots(1)$$

where ρ_1 and ρ_2 are the density of states functions for the two superconductors, f is the Fermi function, V the applied voltage and E the energy measured from the Fermi level. The density of states was calculated from the BCS function

$$\rho = \frac{n_s}{n} = \frac{E}{(E^2-\epsilon^2)^{1/2}}, \qquad \ldots\ldots(2)$$

where 2ϵ is the superconducting energy gap at 0°K and is given by

$$2\epsilon = 3{\cdot}5kT_c. \qquad \ldots\ldots(3)$$

The deviation of the experimental and theoretical curves in region 1 is assumed to be due to the presence of domains of normal and varying transition temperature niobium, i.e., the niobium surface is a non-homogeneous superconductor. The deviation in region 2 results from the methods used in the evaluation of Eqn (1). The integral is particularly sensitive to the variation of the density of states near the band edge, and when the current–voltage characteristics have been evaluated by computor it should be possible to check the validity of Eqn (2) directly.

The initial peak is not very pronounced because at 4·2°K there are few thermally excited carriers. However, preliminary values of $2\epsilon_{\mathrm{Pb}} = (2{\cdot}4 \pm 0{\cdot}3) \times 10^{-3}$ ev and $2\epsilon_{\mathrm{Nb}} = (2{\cdot}8 \pm 0{\cdot}3) \times 10^{-3}$ ev were obtained. At higher temperatures, the accuracy is considerably improved and curve C shows a characteristic obtained at 6·5°K. Experiments are in progress to measure the detailed variation of the energy gaps of lead and niobium with temperature.

Figure 2 shows the effect of a magnetic field applied parallel to the tunnelling area. The variation of characteristic shape with field is most rapid near the critical field for lead, and a value of $H_c = 630$ oersteds was obtained.

The Nb–Nb oxide–Pb sandwich would seem to be ideally suited to the detection of microwave radiation as suggested by Burstein, Langenberg and Taylor (1961). At 4·2°K it should be possible to detect radiation of wavelength less than 0·46 mm.

We would like to thank the Admiralty and the Plessey Company Ltd. for permission to publish this Letter.

The Application of Onsager's Theory to Dielectric Dispersion—A Correction

In a previous publication (Hill 1958) the behaviour of Onsager's model of a dielectric (Onsager 1936) in the region of dielectric dispersion was considered. It was pointed out that previous generalizations of Onsager's theory to this case (e.g. Cole 1938) were incorrect, because the reaction field produced by the permanent dipole moment is not dependent on the frequency of the applied field, since the motion of the dipole is of thermal origin.

Unfortunately the derivation of the equation for the high frequency case contains an error. It was assumed that the reaction field **R** remains parallel to the total moment **m**, which is not the case since

$$\mathbf{m} = \boldsymbol{\mu}_0 + \gamma \mathbf{F}$$

but

$$\mathbf{R} = \frac{(2\epsilon_0 - 1)}{2\epsilon_0 + 1} \frac{\boldsymbol{\mu}_0}{a^3} + \frac{2(\epsilon - 1)}{2\epsilon + 1} \frac{\gamma \mathbf{F}}{a^3}$$

where μ_0 is the permanent moment, γ the polarizability, $\mathbf{F}$ the internal field, ϵ_0 and ϵ the static and high frequency dielectric constants.

The couple tending to turn the molecule was therefore given incorrectly. It should be

$$\mathbf{C}=\mathbf{m}\times\mathbf{F}=g\,\frac{\mu_0\times\mathbf{E}}{1-r\gamma/a^3}$$

$$\left(g=\frac{3\epsilon}{2\epsilon+1},\quad r=\frac{2(\epsilon-1)}{2\epsilon+1}\right).$$

The final equation then becomes

$$\epsilon-\epsilon_\infty=\frac{\epsilon_0-\epsilon_\infty}{1+j\omega\tau}C_1C_2$$

where

$$C_1=\frac{\epsilon(2\epsilon_0+\epsilon_\infty)}{\epsilon_0(2\epsilon+\epsilon_\infty)}$$

as before but

$$C_2=1+\frac{6(\epsilon_\infty-1)}{(\epsilon_\infty+2)(2\epsilon_0+1)}\,\frac{\epsilon_0-\epsilon}{2\epsilon+1}$$

which is the square root of the factor previously found.

The values of C_1 and C_2 and the dielectric constants ϵ_1 and ϵ_2, obtained by applying first C_1 alone and then C_1 and C_2 together for the case $\epsilon_\infty=2\cdot5$, $\epsilon_0=12\cdot5$ previously considered, then are:

$\omega\tau$	C_1	C_2	ϵ_1	ϵ_2	ϵ_{Debye}
0	$1\cdot000-0\cdot0000j$	$1\cdot000+0\cdot0000j$	$12\cdot50-0\cdot00j$	$12\cdot50-0\cdot00j$	$12\cdot50-0\cdot00j$
0·2	$0\cdot999-0\cdot0145j$	$1\cdot000+0\cdot0059j$	$12\cdot11-2\cdot06j$	$12\cdot12-2\cdot00j$	$12\cdot11-1\cdot92j$
0·4	$0\cdot997-0\cdot0288j$	$1\cdot002+0\cdot0117j$	$10\cdot99-3\cdot69j$	$11\cdot04-3\cdot59j$	$11\cdot12-3\cdot45j$
0·6	$0\cdot993-0\cdot0425j$	$1\cdot004+0\cdot0174j$	$9\cdot61-4\cdot69j$	$9\cdot71-4\cdot58j$	$9\cdot85-4\cdot41j$
0·8	$0\cdot988-0\cdot0555j$	$1\cdot008+0\cdot0229j$	$8\cdot05-5\cdot18j$	$8\cdot39-5\cdot07j$	$8\cdot60-4\cdot90j$
1·0	$0\cdot982-0\cdot0677j$	$1\cdot012+0\cdot0281j$	$7\cdot07-5\cdot25j$	$7\cdot24-5\cdot15j$	$7\cdot60-5\cdot00j$
1·2	$0\cdot974-0\cdot0788j$	$1\cdot017+0\cdot0330j$	$6\cdot11-5\cdot10j$	$6\cdot31-5\cdot03j$	$6\cdot60-4\cdot91j$
1·5	$0\cdot962-0\cdot0935j$	$1\cdot026+0\cdot0396j$	$5\cdot03-4\cdot73j$	$5\cdot25-4\cdot69j$	$5\cdot58-4\cdot62j$
2·0	$0\cdot939-0\cdot1121j$	$1\cdot043+0\cdot0488j$	$3\cdot93-3\cdot98j$	$4\cdot16-4\cdot01j$	$4\cdot50-4\cdot00j$
3·0	$0\cdot893-0\cdot1307j$	$1\cdot081+0\cdot0600j$	$3\cdot00-2\cdot81j$	$3\cdot19-2\cdot90j$	$3\cdot50-3\cdot00j$
5·0	$0\cdot823-0\cdot1271j$	$1\cdot147+0\cdot0634j$	$2\cdot57-1\cdot64j$	$2\cdot68-1\cdot75j$	$2\cdot89-1\cdot92j$
∞	$0\cdot733-0\cdot0000j$	$1\cdot280+0\cdot0000j$	$2\cdot50-0\cdot00j$	$2\cdot50-0\cdot00j$	$2\cdot50-0\cdot00j$

The correction C_2 does not compensate so completely for C_1 as the previous calculation suggested, consequently the Cole–Cole plot consists of an arc which lies slightly outside the Debye semi-circle, the maximum loss being 3% higher than the simple Debye relation implies. The conclusion that the maximum loss occurs almost exactly at $\omega\tau=1$, where τ is the microscopic relaxation time (i.e. that the microscopic and macroscopic relaxation times are almost identical), remains unchanged.

Hyperfine Structure in Terbium Metal

The hyperfine contribution to the specific heat of terbium metal, measured by Kurti and Safrata (1958), was found to be slightly smaller than that expected from the electron paramagnetic resonance experiments of Baker and Bleaney (1958) on terbium ethyl sulphate. It was suggested that the discrepancy might be due to a reduction in the mean value of $\langle r^{-3} \rangle$ for the 4f electrons in the metal compared with the salt; however, the nuclear resonance measurements of Hervé and Veillet (1961) on the metal show that this explanation is not correct. The purpose of this Letter is to show that the discrepancy may be resolved when the electric quadrupole interaction with the terbium nucleus (^{159}Tb) is taken into account.

Terbium metal is hexagonal in structure, and the electron moments in the ferromagnetic state are directed along the hexagonal axis (the z axis). The appropriate Hamiltonian for the hyperfine structure is then

$$\mathscr{H} = a\langle J_z \rangle I_z + P\{I_z{}^2 - \tfrac{1}{3}I(I+1)\}, \qquad \ldots\ldots(1)$$

where $I = \frac{3}{2}$ and $\langle J_z \rangle$ is the time-averaged value in the ferromagnetic state. At temperatures well below the Curie point $\langle J_z \rangle$ is expected to be close to $J = 6$, a value consistent with the measured saturation moment. The electron paramagnetic resonance measurements on Tb^{3+} of Baker and Bleaney (in lanthanum ethyl sulphate) and Hutchison and Wong (1958) (in lanthanum trichloride), after allowing for crystal field effects, both give $a = 0{\cdot}0177 \pm 0{\cdot}0002\ \text{cm}^{-1} = 530 \pm 5$ Mc/s. If we write $a\langle J_z \rangle = a'$, the eigenvalues of this Hamiltonian become $\frac{3}{2}a' + P$, $\frac{1}{2}a' - P$, $-\frac{1}{2}a' - P$, $-\frac{3}{2}a' + P$; the allowed transitions are between successive values and therefore fall at $a' + 2P$, a' and $a' - 2P$, respectively. Hervé and Veillet (1961) have observed only a single transition at 3190 ± 15 Mc/s (extrapolated to $T = 0$°K); this may be identified as the central $+\frac{1}{2} \longleftrightarrow -\frac{1}{2}$ transition at a', giving very good agreement with the value $a' = 3180 \pm 30$ Mc/s (assuming $\langle J_z \rangle = 6$) expected from the paramagnetic resonance measurements on the two salts. This close agreement is remarkable, since in the metal either there is no change in $\langle r^{-3} \rangle$ or in the core polarization contribution (estimated by Baker and Bleaney as 6%) and no contribution from conduction electrons, or the changes accidentally cancel.

From the theory of Elliott and Stevens (1953), Baker and Bleaney estimated the value of P for $\langle J_z \rangle = 6$ to be $+0{\cdot}020_6\,Q$ °K, where Q is the nuclear electric quadrupole moment in barns. No experimental determination of Q exists for ^{159}Tb, but it would be expected to be of order 1 to 2 barns. From the Coulomb excitation cross section, Alder, Bohr, Huus, Mottelson and Winther (1956) deduce a value of the intrinsic quadrupole moment of $Q_0 = 6{\cdot}9$ barns, which corresponds to a value of $Q = 1{\cdot}4$ barns. This leads to a value of $P = +0{\cdot}02_9$ °K $\simeq 600$ Mc/s, which may be taken as $a'/5$ within the uncertainties of our estimate.

The nuclear specific heat given by Kurti and Safrata (1958) can be written as $CT^2/R = (24{\cdot}8 \pm 1{\cdot}2) \times 10^{-3}\ \text{deg}^2$, which is noticeably smaller than that of $(29{\cdot}1 \pm 0{\cdot}6) \times 10^{-3}$ obtained from the electron paramagnetic resonance and nuclear magnetic resonance data when P is ignored, and the specific heat is evaluated only as far as the T^{-2} term. A general series expansion for the specific heat is†

$$\frac{C}{R} = \sum_{n=2}^{\infty} c_n T^{-n}, \qquad \ldots\ldots(2)$$

---

† We have given the formulae for the specific heat in some detail as they can be used in a number of other cases, both nuclear and electronic.

where
$$c_n = n(n-1)\left\{b_n - \tfrac{1}{2}\sum_{p=1}^{n-1} b_{n-p}\,b_p + \tfrac{1}{3}\sum_{p=1}^{n-2}\sum_{q=1}^{n-2} b_{n-p-q}\,b_p\,b_q + \text{etc.}\right\}$$
$$b_p = \frac{(-1)^p\langle W^p\rangle}{p\,!}. \qquad \ldots\ldots(3)$$

Here $\langle W^p\rangle$ is the mean of the pth powers of the energy levels, measured in temperature units. If the origin is chosen to make $\langle W\rangle = 0$, considerable simplification is obtained and the leading coefficients are (first in general and second for ^{159}Tb):

$$c_2 = \langle W^2\rangle = \tfrac{5}{4}a'^2 + P^2$$
$$c_3 = -\langle W^3\rangle = -3a'^2P$$
$$c_4 = \frac{1}{2\,!}(\langle W^4\rangle - 3\langle W^2\rangle^2) = -\left(\frac{17}{16}a'^4 + P^4\right)$$
$$c_5 = -\frac{1}{3\,!}(\langle W^5\rangle - 10\langle W^3\rangle\langle W^2\rangle) = \frac{25}{6}a'^4P + \frac{10}{3}a'^2P^3$$
$$c_6 = \frac{1}{4\,!}(\langle W^6\rangle - 15\langle W^2\rangle\langle W^4\rangle - 10\langle W^3\rangle^2 + 30\langle W^2\rangle^3) = \frac{65}{96}a'^6 - \frac{15}{4}a'^4P^2 + \frac{2}{3}P^6.$$

The presence of P in the first term appears to accentuate the discrepancy, since for $P = a'/5$ the first term increases to $30{\cdot}1 \times 10^{-3}$, but the higher terms are by no means negligible in the relevant temperature range, which was about 0·6 to 1·0°K. Substitution of our values for a' and P gives

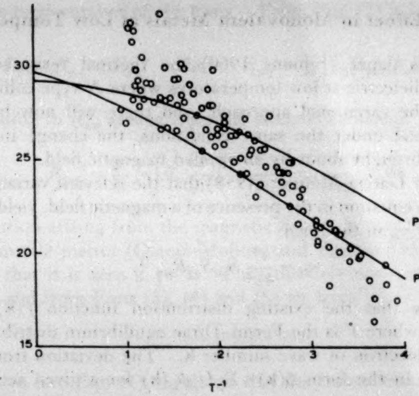
$$\frac{CT^2}{R} = (30{\cdot}1 - 2{\cdot}13T^{-1} - 0{\cdot}58T^{-2} + 0{\cdot}071T^{-3} + 0{\cdot}0067T^{-4}) \times 10^{-3} \qquad \ldots\ldots(4)$$

the mean value of which over the temperature range 0·6 to 1·0° is $26{\cdot}3 \times 10^{-3}$, which agrees well with the value given by Kurti and Safrata (1958).

At this point we received a preprint from Heltemes and Swenson (1961), giving details of their specific heat measurements on terbium metal down to 0·25°K. They have kindly allowed us to publish these data, which are shown as a plot of CT^2/R against T^{-1} in the Figure. Near 1°K the points lie rather higher than the results of Kurti and Safrata, through a reduced estimate for other contributions. This uncertainty is least at the lowest temperatures, where the specific heat is noticeably smaller than that calculated from the nuclear magnetic resonance results, assuming $P = 0$. At this temperature a series expansion is no longer sufficiently accurate, and the following (exact) expression has been used

$$\begin{aligned}\frac{CT^2}{R} = \Bigg\{&(\tfrac{1}{2}a'^2 + 2P^2)\cosh\frac{2a'}{T} + (2a'^2 + 2P^2)\cosh\frac{a'}{T} \\ &-2a'P\sinh\frac{2a'}{T} - 4a'P\sinh\frac{a'}{T} + \tfrac{1}{4}a'^2\left[9\exp\left(\frac{-2P}{T}\right) + \exp\left(\frac{2P}{T}\right)\right]\Bigg\} \\ &\times\left\{\exp\left(\frac{-P}{T}\right)\cosh\frac{3a'}{2T} + \exp\left(\frac{P}{T}\right)\cosh\frac{a'}{2T}\right\}^{-2}. \qquad \ldots\ldots(5)\end{aligned}$$

The two curves drawn are for $P = 0$ and for $P = 0{\cdot}02$°K, which gives the best fit at $T = 0{\cdot}3$°K. The fit is not so good elsewhere, though the discrepancy is not perhaps outside the experimental error, but there appears to be definite evidence for a quadrupole interaction whose size is of the order assumed.



Plot of CT^2/R against T^{-1} for terbium metal. The experimental points are from Heltemes and Swenson (1961), and near 1°K lie higher than the data of Kurti and Safrata (1958) through a difference in the estimates for contributions from non-nuclear effects (the uncertainty in these may amount to 2 or 3 units in the ordinate). The full curves are calculated from the nuclear magnetic resonance data of Hervé and Veillet (1961), with $P=0$ and 0·02°K respectively.

Work is planned to measure the specific heat of the metal down to lower temperatures, and the quadrupole interaction in a terbium salt by means of ENDOR. In the metal it may be possible to determine the quadrupole interaction by nuclear magnetic resonance, but Dr. R. A. Kamper (private communication) has suggested that transitions at $a' \pm 2P$ are likely to be broadened by strains, especially as the nuclei observed in this method are those in the domain walls; a more promising experiment would be to use the Mössbauer method. The quadrupole interaction should be of particular interest, since P varies as $\{3\langle J_z^2\rangle - J(J+1)\}$, and should be a somewhat different function of temperature from a', which varies as $\langle J_z\rangle$. This may give an indication of the contribution from electrons other than 4f (for example, s-electrons might contribute to a' but not to P). It should be noted also that the axis of the quadrupole interaction is primarily determined by the direction of the spontaneous magnetization, and only indirectly by the crystal field. Such nuclear electric quadrupole interactions should exist in all rare earth metals which exhibit spontaneous magnetization, whether ferromagnetic or antiferromagnetic.

The Hall Effect in Monovalent Metals at Low Temperatures

In a previous paper (Simons 1960) the thermal resistance tensor was considered for a dielectric at low temperatures where N-type collision processes predominate. The variational approach used there will now be employed to obtain, for a metal under the same conditions, the change in the electrical resistance tensor brought about by an applied magnetic field.

It is shown by Garciá-Moliner (1958) that the relevant variational principle for the Boltzmann equation in the presence of a magnetic field, yields the electrical conduction tensor σ_{ij} in the form

$$\sigma_{ij}=\frac{e^2}{4\pi^3}S_{pi}S_{qj}R_{pq}{}^{-1}. \qquad \ldots\ldots(1)$$

Here we suppose that the existing distribution function $f(\mathbf{k})$ is given by $f=F-(\partial F/\partial E)\phi$, where F is the Fermi–Dirac equilibrium distribution and E is the energy of an electron of wave number $\mathbf{k}$. The deviation from equilibrium $\phi(\mathbf{k})$ is expanded in the form $\phi(\mathbf{k})=\Sigma_p U_p\phi_p(\mathbf{k})$ for a given set of $\phi_p(\mathbf{k})$ and

$$R_{pq}=\sum_t\int L_t[\phi_p]_t[\phi_q]_t\,\mathbf{dk}+\frac{e}{\hbar c}H\int\phi_p\frac{\partial F}{\partial E}\left(v_2\frac{\partial}{\partial k_3}-v_3\frac{\partial}{\partial k_2}\right)\phi_q\,\mathbf{dk} \qquad \ldots\ldots(2)$$

where $[\phi]_t$ is the linear combination of ϕ's relevant to the tth type of electron collision process and L_t is the corresponding collision operator. H is the magnetic field, applied along the x axis, and $\mathbf{v}$ is the velocity of an electron,

$$S_{pi}=\int\frac{\partial F}{\partial E}\phi_p v_i\,\mathbf{dk}. \qquad \ldots\ldots(3)$$

We now wish to apply these results to a metal in which both electron scattering and phonon scattering are dominated by electron–phonon N processes. A necessary condition for this to be so, is that the Fermi surface should not touch the surface of the first Brillouin Zone, since if this were the case, U processes of a frequency comparable with that of the N processes would occur at any temperature. This means that we are immediately restricted to a consideration of monovalent metals. For these, it is then necessary that the temperature should be sufficiently low, so that the frequency of 3-particle U processes of the type electron + phonon ⇌ electron is negligibly small. Assuming that the amount of impurity scatter and the effect of the magnetic field is also much less than the contribution of the N processes, we may then adequately represent $\phi(\mathbf{k})$ by a linear combination of the three independent resolutes of $\mathbf{k}$; that is,

$$\phi_p(\mathbf{k})=k_p, \quad p=1,\,2,\,3 \qquad \ldots\ldots(4)$$

(Ziman 1956). This is so, since the effect of N processes acting alone is to impress this form on the distribution function $\phi(\mathbf{k})$, and to produce a similar displacement of the phonon distribution function. In the absence of other scattering processes the collision integral and the resistivity will then vanish (Peierls 1955). The presence of such processes will lead to a non-zero resistivity, but if they are much less frequent than N processes, the change in the distribution function from the form given by Eqn (4) will be very small, and may be neglected for present purposes. Substituting from Eqn (4) into Eqn (3), it is readily shown by an approach similar to that of Simons (1960) that

$$S_{pi}=-4\pi^3\hbar^{-1}N\delta_{pi}, \qquad \ldots\ldots(5)$$

where N is the total number of electrons. From Eqn (2) it is seen that

$$R_{pq}=R_{pq}'+R_{pq}'' \quad \text{where} \quad R_{pq}'=\sum_t \int L_t[k_p]_t[k_q]_t\,\mathbf{dk}$$

is the contribution to R_{pq} arising from the electron collisions, and

$$R_{pq}''=\frac{e}{\hbar c}H\int k_p\frac{\partial F}{\partial E}\left(v_2\frac{\partial}{\partial k_3}-v_3\frac{\partial}{\partial k_2}\right)k_q\,\mathbf{dk} \qquad \ldots\ldots(6)$$

is the contribution arising from the magnetic field. It may be shown that R_{pq}'' is an antisymmetric matrix (Garciá-Moliner and Simons 1957), and from Eqn (6) it is clear that it is zero if $q=1$. Thus the only non-zero components are $R_{23}''=-R_{32}''$, and from Eqns (3), (4) and (5) we have

$$R_{32}''=4\pi^3 eHN/\hbar^2 c. \qquad \ldots\ldots(7)$$

Substituting this into Eqn (1), it follows that the resistance tensor $r_{ij}(=\sigma_{ij}^{-1})$ is given by $r_{ij}=r_{ij}'+r_{ij}''$, where r_{ij}' is the resistance tensor in the absence of an applied magnetic field, and

$$r_{ij}''=\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -\gamma \\ 0 & \gamma & 0 \end{bmatrix} \quad \text{with } \gamma=H/Nec.$$

Since the magnetic field is applied along the x axis, we see that this form for r_{ij}'' implies the absence of any magnetoresistance. In fact, it is clear that the only non-zero change in the resistance tensor arises when the magnetic field, electric field and current are mutually perpendicular. This is just the condition for the Hall effect, and it is seen from the above results that the Hall coefficient is given by $R=1/Nec$. This is, of course, the same result as is given by the elementary theory of the Hall effect, but there it is derived subject to certain assumptions, among which are the following: (i) an effective mass exists, (ii) the electron gas is degenerate, (iii) an isotropic relaxation time exists. Since for real metals, these approximations may be somewhat in error, experimental deviations from the $R=1/Nec$ result would not have been unexpected. However, we now see that if experiments are performed at low temperatures with low magnetic field on monovalent metals of increasing degree of purity, we might reasonably expect the results to tend to $R=1/Nec$, independent of the crystal orientation with respect to the magnetic field.

The Magnetic Susceptibility of Manganese Zinc Fluoride Solid Solutions

The change in the antiferromagnetic transition resulting from the dilution of the magnetic ion has been the subject of considerable theoretical investigation (see references in Baker, Lourens and Stevenson 1961). All models predict that the Néel temperature will fall rapidly with dilution, and that no long range order will exist if the concentration of the magnetic ion is less than a certain value. There is little experimental evidence, but early work by Bizette and Tsai (1943) on MnO–MgO and FeO–MgO suggests such behaviour, and recently Baker, Lourens and Stevenson (1961) have reported on the disappearance at low temperatures of the nuclear magnetic resonance line of manganese zinc fluoride mixed crystals. From this they deduce the dependence of the Néel temperature on concentration. The variation is in qualitative agreement with the predictions of Sato, Arrott and Kikuchi (1959) for a model in which the local fluctuations in the density of magnetic ions are accounted for. It may be noted, however, that the agreement is much more complete with the results obtained from a model in which every magnetic ion is surrounded by a density of magnetic ions equal to the average density.

The variation in magnetic susceptibility in magnetically dilute systems will not give a particularly satisfactory measure of the Néel temperature, as the maximum in the susceptibility may be ill defined. However, the susceptibility variation below the Néel temperature, as predicted by different models, is widely different. Measurements on MnF_2–ZnF_2 down to 90°K have already been published by Corliss, Delabarre and Elliott (1950). In the present work the measurements were extended below the Néel temperatures where the influence of the ordering process is marked.

The preparation and analysis of the single crystal specimens has already been described (Finlayson *et al.* 1960). A fine powder was prepared for this experiment and immobilized by paraffin wax in a small silica cup suspended by a silica rod from a Sucksmith balance (Finlayson, Llewellyn and Smith 1959). Thermal contact between specimen and thermometer was maintained by introducing a few millimetres of helium into the sample chamber. Correction was made for the deflection of the silica cup, and the absolute value of the susceptibility was obtained by calibration of the balance with a water sample. The diamagnetic correction for the zinc and fluorine ions is less than the experimental error, and has not been included.

In the higher temperature region, the reciprocal susceptibility varies linearly with temperature (Figure) and can be represented by

$$\chi_M = \frac{C_M}{T+\Delta}$$

where Δ is the asymptotic Néel temperature. The magneton values p_B can be obtained from

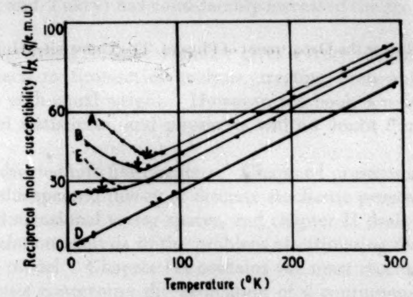
$$p_B = 2{\cdot}828\sqrt{C_M},$$

and values of both p_B and Δ are given in the Table.

Specimen	C_M	Δ	p_B
MnF_2	4·37	100	5·91
$Mn_{0·87}Zn_{0·13}F_2$	4·36	80	5·90
$Mn_{0·61}Zn_{0·39}F_2$	4·23	58	5·88
$Mn_{0·11}Zn_{0·89}F_2$	4·19	8·0	5·86

These data agree with the results of Corliss, Delabarre and Elliott (1950) in giving a value of p_B rather lower than the free ion value of 5·92 for a $^6S_{5/2}$ state. Also the asymptotic Néel temperature is proportional to the concentration of the manganese ion.

It can be seen from the Figure that the linear section of the $(1/\chi, T)$ plot extends to lower temperatures as the concentration is reduced. Below this section a minimum in the inverse susceptibility is found for the higher concentrations and this corresponds with the temperature (indicated by arrow on graph) at which the nuclear magnetic resonance line disappears (Baker, Lourens and Stevenson 1961). For the medium concentration a departure from linearity is found 20° above the temperature at which the resonance line disappears, and there is no minimum in the inverse susceptibility at any temperature. For the lowest concentration there is no departure from a linear variation over the temperature range investigated.



Inverse molar susceptibility variation with absolute temperature: A, experimental curve for MnF_2; B, experimental curve for $Mn_{0·87}Zn_{0·13}F_2$; C, experimental curve for $Mn_{0·61}Zn_{0·39}F_2$; D, experimental curve for $Mn_{0·11}Zn_{0·89}F_2$; E, calculated curve for $Mn_{0·61}Zn_{0·39}F_2$.

A broadening of the minimum in dilute antiferromagnetics has been found by other workers (Bizette and Tsai 1943, Bizette 1946). However, the absence of a minimum in the intermediate concentration curve would not be expected from the simplest models. Thus, the treatment given by Sato *et al.* (1959), which gives a qualitative prediction of the variation of the Néel temperature with concentration, leads to a clearly defined minimum in the inverse susceptibility (see Figure).

It can be seen, therefore, that susceptibility measurements below the Néel temperature provide a useful test of the adequacy of any model of the ordering processes in a dilute antiferromagnetic.

REVIEWS OF BOOKS

Time Series Analysis, by E. J. HANNAN. Pp. vi + 152. (London: Methuen; New York: John Wiley, 1960.) 21*s*.

The history of time-series analysis may be traced back to two distinct sources. On the one hand, the statistician's approach via autocorrelation analysis has proved useful in the analysis of, for example, econometric data. Here, the object is to fit a ' finite-parameter ' model (i.e. an autoregressive or moving-average scheme) to the data in order to make short term predictions. Physicists and engineers, however, have developed the method of spectral analysis to investigate problems in, for example, communication engineering and noise in electronic circuits. In recent years the development of the theory of stationary stochastic processes has provided a common meeting ground for these two approaches. In fact, in the light of such results as the Wiener–Khintchine theorem, autocorrelation and spectral analysis are seen to be complimentary concepts, and the statistical approach to spectral analysis (commencing with the work of Bartlett and Tukey) has considerably increased the scope and usefulness of this method.

In his monograph, Professor Hannan gives a very elegant account of the statistical approach to time-series analysis, treating both autocorrelation and spectral analysis with equal weight. However, the book is written primarily for the mathematical statistician, and physicists will no doubt find the style rather formal.

The work is divided into five chapters. Chapter I presents a fairly theoretical introduction to the spectral theory of discrete stochastic processes, based on the theory of finite dimensional vector spaces, and chapter II deals with the application of autocorrelation analysis to the problem of estimating the parameters of a finite parameter model. Chapter III contains the most recent developments in time-series analysis concerning the estimation of a continuous spectral density function. The author discusses the work of Grenander and Rosenblatt and Parzen on the statistical errors of spectral estimates, but due, no doubt, to restrictions of space, the very important problem of practical analysis is only briefly outlined. However, it should be pointed out that, given only a sample record, the problem of constructing an estimate of a continuous spectrum which has a prescribed error and prescribed resolvability is still unsolved. From the point of view of the physicist or engineer, this is perhaps the most important aspect of spectral analysis, and one which requires urgent theoretical investigation.

In chapter IV the author considers a variety of problems under the heading ' Hypothesis testing and confidence intervals '. The situation is roughly that one wishes to test whether an empirical autocorrelation function (i.e. a ' correlogram ') or spectrum is consistent with an assumed model of the original time-series. Most of the standard ' goodness of fit ' tests for the correlogram are neatly presented, and recent work on similar types of tests for the spectrum is also included. A brief discussion is presented of the problem of ' mixed spectra ', i.e. estimating the spectrum of a process which contains a number of sine waves with different amplitudes and frequencies (corresponding to spectral ' lines ') superimposed on a component with a purely continuous spectrum. This is, perhaps, the most difficult problem in statistical spectral analysis, and one which also requires further theoretical investigation.

The final chapter deals with regression analysis and the elimination of non-stationary trends, and contains some of the author's own original work on time-series analysis. It should be noted that most of the theoretical distributions which arise in this type of analysis usually involve the covariance structure of the residual process. However, in many practical applications this covariance structure is unknown. The chapter concludes with an investigation of the effects of trend removal on the analysis of the residual process.

On the whole, the author is to be highly complimented on achieving a truly comprehensive survey of time-series analysis in such short space. The book may be confidently recommended both to physicists who are familiar with the practical side of spectral analysis and wish to acquaint themselves with the mathematical theory, and to mathematical statisticians who wish to be brought up to date with the statistical analysis of time series. M. B. PRIESTLEY.

Variational Principles in Dynamics and Quantum Theory, 2nd Edn, by W. YOURGRAU and S. MANDELSTAM. Pp. xi + 180. (London: Sir Isaac Pitman, 1960.) 32*s*. 6*d*.

The first edition of this little book which appeared in 1955 was highly praised for its soundness as philosophy as well as physics (see, for example, Professor Salam's review in this journal, 1955, A, **68**, 659). This new edition which has been revised and enlarged retains the original character. We are presented not merely with formal mathematics but with a critical analysis of the ideas underlying the formulation of variational principles in physics.

Several additions have been made. Two postscripts, resulting from correspondence with Professor Schrödinger, deal with the fine-structure formula and with the correct replacements of curvilinear coordinates by operators in quantum mechanics. There is a new Appendix on the application of variational methods to chemical reactions. By far the most important addition is a new chapter on the Feynman and Schwinger principles in quantum mechanics. Instead of the Hamiltonian formalism, these principles employ a Lagrangian formulation directly. This chapter gives a lucid account of the Feynman principle (including a very clear discussion of integrals over paths), its classical limit and its relationship to the Schwinger principle and to the conventional formulation of quantum mechanics. The Feynman and Schwinger principles have played a prominent part in the development of quantum field theory. A readable account of these ideas represents a most worth-while addition to this excellent book. F. MANDL.

Nuclear Photodisintegration, by J. S. LEVINGER. Pp. viii + 144. (Oxford: University Press, 1960.) 15*s*.

Workers in the field of nuclear photodisintegration who have awaited eagerly the publication of this work by J. S. Levinger, who has made so many theoretical contributions to the development of the subject, will not be disappointed. The author leads into the theory by analogy with the atomic photoeffect, the transition probabilities here being calculated by perturbation theory. The experimental physicist will be able to follow this treatment including the derivation of the dipole 'sum-rules' which occupies the first 36 pages of the book. The dispersion theory application to the nuclear photoeffect is also indicated in this first chapter.

Subsequent chapters deal with the photodisintegration of the deuteron (12 pages), sum-rule calculations (16 pages), discrete transitions (12 pages), total cross section for photon absorption discussed from the point of view of various models (20 pages) and a final chapter of 30 pages on the products of photodisintegration.

The experimental work is not discussed in detail although the difficulties associated with the use of continuous bremsstrahlung spectra are indicated.

The main features of the nuclear photoeffect are discussed in terms of several different models. Many of them are model-independent and it is clear that more precise detail in the experimental measurements is needed. Thus, structure in the ' giant resonance ' is now beginning to emerge and much more should be known about this in the near future.

It is perhaps a pity that the flair that the author obviously possesses of explaining theoretical calculations in simple terms was curbed by the limited size of the book, but the 130 pages of text collect much information not elsewhere available in a single publication and despite the compression the experimentalist will find the theoretical treatment invaluable. E. H. BELLAMY.

High Energy Nuclear Physics, by W. O. LOCK. Pp. xi + 190. (London: Methuen; New York: John Wiley, 1960.) 18*s*.

There has been a growing demand during the last few years for a book to serve as an introduction to nuclear physics below 1 GeV for the research student. This small but compact book easily fills this demand and, more importantly, should give the student a genuine appreciation of the subject.

The introductory chapters set the level of the book by using mathematical equations together with reasoning to show the physical concepts behind the common glibly used symbols. In the following chapters on scattering and photoproduction of pions the experimental results are analysed theoretically and explained phenomenologically, the result again producing a genuine understanding of the topics. Nucleon–nucleus and nucleon–nucleon interactions are then discussed and finally the two sections combined in the production of pions in nucleon–nucleon collisions.

Of course there are complaints: in such a small book some arguments must be curtailed and some results omitted, but surely energies below 1 GeV are not called high nowadays! Here, in effect, is the one main fault: the book is badly dated in the middle of 1959. To take two examples: the discussion of the Panofsky ratio implies that a discrepancy between theory and experiment needs further investigation, and the section on p–p scattering at 310 MeV gives five phase-shift solutions; whereas at that time the discrepancy was reasonably well explained and only two phase-shift solutions remained. However, these and other points can easily be removed in the next edition, and one hopes that this will not be long delayed. R. T. TAYLOR.

Soviet Research in Geophysics, Vol. 3, *Microstructure and Macrostructure*, by B. N. IVAKIN. Pp. xiii + 113. (New York: Consultants Bureau, 1960.) $ 6.00.

The volume *Microstructure and Macrostructure of Elastic Waves* can be gauged for both form and content and on the first count it must be rated negatively. The volume is a translation of a monograph, No. 39, of the *Transactions of the Geophysical Institute of the Academy of Science*, from the original Russian into English. The quality of the translation is, at best, amateurish and the author's work has suffered because of the abuse by the translator. We have all seen examples in the popular literature of the raw output to be expected from machine translation devices; this volume has many of these properties. I do not know if the monograph in question has been subject to machine or manual translation but it shows the lack of both literary and scientific editing. As an example, the following quotation is offered (page 5): " In the latter case†, the wave properties of waveguides have some asymptotic state to which the wave properties of a waveguide fed by an abruptly connected source with a periodic (e.g. sinusoidal) form of oscillations tends."

This is not the first example of a published translation from the Russian; we have a right to expect greater literacy and less literality. We also expect a use of proper English scientific terminology.

Ivakin considers the problem of the multiple reflections of sinusoidal waves from a multiply layered or one-dimensional, continuously inhomogeneous medium. His special device is to convert all the quantities involved, reflection coefficients, propagation constants, etc., into terms encountered in electrical engineering, a discipline where the problem has been discussed in the literature. He treats the problem by describing a series of transmission lines with different lengths and characteristic impedances. A number of examples are solved. The people most concerned with multiple reflections from one-dimensional media having many layers, the petroleum exploration geophysicists, are now able to synthesize seismograms corresponding to impulsive excitation of layered media using computing machinery. The Ivakin scheme is good and well known to electrical engineers; the problem of sinusoidal excitation is not particularly pertinent to current geophysics. There are more significant works in the Russian geophysical literature appropriate to the early translations into English.

Readers interested in a more sophisticated treatment of reflections in multiply layered media, including the difficult problems of oblique incidence, should refer to the recent translation of the Russian volume *Waves in Layered Media* by Brekhovskikh; this has been done in comparatively good scientific and grammatical English. L. KNOPOFF.

Ionization Phenomena in Gases, by GORDON FRANCIS. Pp. vii + 300. (London: Butterworths Scientific Publications, 1960.) 60*s*.

The rapid progress that has been made since the end of the last war in the study of gas discharges, particularly at very high current densities, and the growing importance in so many fields of physics of the plasma state of matter has made clear the need for a monograph that discusses developments in this field from a modern standpoint. Dr. Francis has succeeded in writing a book that should fill this need admirably. The subject matter is well chosen, particular attention being devoted to those topics that are most rapidly developing and of greatest current interest. A great deal of it has not previously been brought together into a monograph. The elucidation of the physical principles underlying the phenomena observed in ionized gases is maintained as the primary aim of the book and is not allowed to become obscured with technical detail.

After a short and scarcely necessary introductory chapter on atomic structure and spectral notation, which this reviewer found the least satisfactory part of the book, a very condensed chapter follows on fundamental physical processes of importance in the gas discharge. A short but lucid chapter on the applications

† Steady state oscillations.

of the similarity principle follows. Alternating and high frequency discharges are treated in considerable detail in chapter 4. This chapter possibly goes into somewhat greater detail than is the case in the other chapters, but since this is a field in which the author has made important contributions he can be forgiven for being a little expansive. After a short chapter on the upper atmosphere an interesting account of high current discharges, including the pinched discharge and applications to thermonuclear reactions, follows. The final chapter contains a useful account of plasma oscillations and waves.

In his preface the author states that the book is intended mainly for those finishing their degrees or about to begin research, but there is no doubt that many who are already active workers in plasma physics or related topics will find the book of value. A high standard is maintained throughout on the technical side of the production. E. H. S. BURHOP.

Resonance Absorption in Nuclear Reactors, by L. DRESNER. Pp. x + 131. (Oxford, London, New York, Paris: Pergamon Press, 1960.) 40*s*.

In early discussions of the feasibility of self-sustaining chain reactions based on natural uranium fuel, it was recognised that the unknown extent of resonance absorption introduced an important uncertainty. Although it was known that resonance absorption could be reduced by lumping the uranium, little quantitative discussion appeared in the open literature until the first Geneva Conference in 1955. At this stage it became apparent that Western and Russian physicists had approached the topic from fundamentally different viewpoints.

The Conference therefore stimulated further and more penetrating study of the subject in which Dr. Dresner has played an important part. His monograph provides a comprehensive survey of the present position and is of particular value to the newcomer to the field, since care has been taken to derive important results from first principles with a clear indication of the assumptions involved. The theory of resonance absorption in homogeneous media is first developed and then generalized to cover other situations of practical interest. This includes a discussion of the wide and narrow resonance approximations in heterogeneous systems formed from relatively isolated lumps, regular lattices or fuel clusters. More study is evidently required on clusters since no improvement on Hellstrand's semi-empirical method has yet been devised. The value of the work is enhanced by the inclusion of chapters on relevant topics in slowing down and transport theory, a historical introduction and a critical comparison of the theory with experimental data. It is apparent that present understanding of the subject is such that it is entirely feasible to calculate resonance escape probabilities from the measured resonance parameters.

One small criticism must be made. On page 89 there appears the following statement, which might prove misleading to a reader unfamiliar with water-moderated reactor calculations: " In practical examples of tight lattices such as occur with hydrogeneous moderation the Dancoff correction is relatively small, the surface being decreased by the order of 5%." It is quite true that the mutual shielding of a single pair of fuel pins will be approximately 5%, but in a conventional square lattice each fuel pin has 8 near neighbours. The Dancoff correction therefore amounts to 40–50% of the effective surface and gives rise to very significant changes in the resonance integral, resonance escape probability and effective reproduction constant.

The book can be thoroughly recommended in view of the importance of the subject matter and the absence of comparable works; it should be studied carefully by all interested in low-enrichment reactor physics. D. HICKS.

Imperfections in Crystals, by H. G. VAN BUEREN. Pp. xviii + 676. (Amsterdam: North-Holland, 1960.) 110*s*.

This book is about atomic defects such as dislocations, vacancies, interstitials and F-centres, in crystals. Despite the intense interest now being shown in these defects by metallurgists and solid state physicists it is surprising that, until this book appeared, there existed no published introductory account of the whole field of crystal imperfections; only special accounts of particular parts such as dislocation theory or radiation damage. The author is to be congratulated on having recognized this gap; on having realized the exceptional timeliness of the present moment for such a book, when the basic theory has become stable and so much direct evidence for the structure and properties of the defects has appeared; and on having filled the gap with such a pleasant and useful book.

The treatment throughout is fairly elementary and this, together with the readable style, should make the book useful for students of physics and metallurgy who are interested in this branch of solid-state theory. The complete and impartial review of all the various contributions to the subject, including some that have undeservedly been forgotten in much of the recent research work, will also make the book valuable as a work of reference to more advanced readers.

The range of topics covered is extremely wide and complete. To take some examples, work hardening and alloy hardening of metals, creep, recrystallization, observations of lattice defects, radiation damage, diffusion and phase changes, internal friction, nuclear resonance, scattering of electrons and electromagnetic waves by defects, fatigue and fracture, optical and electrical properties of non-metallic crystals, and movements of lattice defects in non-metallic crystals. Naturally the treatment in most places is introductory rather than definitive but nevertheless it is rarely superficial; and on topics which touch on the author's own research interests, for example the dislocation structure and plastic properties of silicon and germanium, it is quite authoritative.

This book can be strongly recommended to those who seek a readable, thorough, and reliable introduction to this branch of solid-state physics and physical metallurgy. A. H. COTTRELL.

Cartesian Tensors: an Introduction, by G. TEMPLE. Pp. vii + 92. (London: Methuen; New York: John Wiley, 1960.) 12*s*. 6*d*.

Anything written by Professor Temple is expected to be interesting and provocative. But we need not always agree with his own reasons for finding his material interesting. Here he gives an account of cartesian tensors defined as invariant multilinear functions of direction. He considers this definition to give ' a new unity to the subject '. However, the unity is rather formal at this level; I think that it does not compensate for the severe limitations of cartesian tensors compared with general tensors. I always find that students learn general tensor calculus very quickly. It appeals to them because of its naturalness and usableness, whereas I believe they would find this treatment of cartesian tensors to be artificial in itself and to be confusing when they proceed to general tensors. Professor Temple says that his book is for first-year students; I think it is likely rather that lecturers preparing courses in tensor calculus will find it useful on account of some of its more subsidiary topics such as isotropic tensors (chapter VI) and spinors (chapter VII) of which such simple accounts are probably not available elsewhere. Also, anyone who knows a little about tensor calculus in general will find the 'Bourbaki treatment' given by Temple to be entertaining for its own sake. The reader must be warned, however, that he has to do some of his own proof-correcting! W. H. MCCREA.

Nuclear Fusion—The Second Geneva Series on the Peaceful Uses of Atomic Energy, edited by W. P. ALLIS. Pp. viii + 488. (New York, London: Van Nostrand, 1960). 94*s*.

In this book Professor Allis has brought together a number of selected papers on thermonuclear research delivered at the International Conference at Geneva in 1958. He has grouped them into chapters, each preceded by a short explanation, a page or two long, of the principles concerned. He has cut the papers, sometimes considerably. The result is rather surprisingly successful as an exposition of the state of the subject at the time of Geneva. It would, however, be hard reading for anyone hitherto unacquainted with the subject, but if he has read, for example, Spitzer's admirable little book in Interscience Tracts, or its equivalent, he will find this book most helpful. Partly because of the self-contained character of the individual papers it is convenient for reference.

G. P. THOMSON.

Royal Society Mathematical Tables, Vol. 7, *Bessel Functions*, Part III, *Zeros and Associated Values*, edited by F. W. J. OLVER. Pp. ix + 79. (London: Cambridge University Press, 1960.) 50*s*.

New methods have been developed in the presentation of this book of tables of Bessel Functions which is the third in the series of three undertaken by the Royal Society of the Mathematical Tables Committee. In an interesting introduction the new method is described and its debt to the present day automatic electronic computing machine acknowledged.

Annual Reports on the Progress of Chemistry, Vol. LVI, 1959. Pp. xiv + 476. (London: The Chemical Society, 1960.) 40*s*.

Among the articles contained in Volume LVI of the *Annual Reports on the Progress of Chemistry* 1959 are some which will interest physicists; these include The physical properties of some simple fluids, by J. S. Rowlinson, and Nuclear magnetic resonance, by J. A. Pople.

Full reviews of the volume will be found in the various chemical journals.

Solid State Physics, Vol. 11, edited by F. SEITZ and D. TURNBULL. Pp. xvi + 438. (New York: Academic Press, 1960.) 89*s*. 6*d*.

This, the eleventh volume of the series *Solid State Physics*, edited by F. Seitz and D. Turnbull, contains the following articles: Semiconducting properties of gray tin; Physics at high pressure; The effects of elastic deformation on the electrical conductivity of semiconductors; Imperfection ionization energies in CdS-type materials by photoelectronic techniques; Cyclotron resonance. It contains also a cumulative subject index for Volumes 1–10. A list of articles planned for future volumes is also given and covers some thirty further articles by a wide range of well-known authors.

Neutron Detection, by W. D. Allen. Pp. viii + 260. (London: Newnes, 1960.) 45*s*.

Dr. Allen has packed an amazing amount of information about the methods of detecting neutrons into 250 pages. Obviously he was unable to go into considerable detail in a book of this size, but each technique which he mentions carries references, and an extensive bibliography is included at the back for good measure.

My objection (and it is a small one) is that he has stuck so closely to his title. I should like to have seen a few more numbers quoted in the section on neutron sources, for example, a graph of the deuteron–triton cross section as a function of energy, and energy–angle graphs or nomograms for the neutrons arising from this process, and from other common processes for neutron production. More details on the shielding of neutron detectors also would have been acceptable. Finally, far more useful range–energy curves exist than that given in appendix IX(a), for research workers using nuclear emulsions to detect neutrons.

I recommend this book to anyone working in the field of neutron physics, and also to experimenters who are bothered by neutron backgrounds.

W. H. R. F. MUIRHEAD.

Stochastic Processes, Problems and Solutions, by L. Takács. Pp. xi + 137, (London: Methuen; New York: John Wiley, 1960.) 18*s*.

This book is one of the first of a new series of monographs on applied probability and statistics, edited by M. Bartlett. It is not a textbook in the usual sense of the word but rather a collection of problems and their solutions for readers who are already familiar with probability theory. The fundamental notions and theorems of the theory of stochastic processes which are needed for dealing with the special problems are only given in a condensed but precise and lucid form. The complete solutions of all the problems are given and the ways to find them are clearly indicated though, of course, not in all mathematical detail.

The first two chapters of the book deal with Markov chains and Markov processes which are stochastic sequences or processes in which the future behaviour of a system depends only on its present state but not on its past. The third chapter is devoted to non-Markovian processes, in particular to stationary, recurrent (or regenerative) and secondary processes. Most of the theorems and problems of this chapter have not been treated in other books, and a considerable part of them is the result of the author's own scientific work.

The problems are chosen from a wide field of pure and applied science and engineering, like random walk and Brownian motion, nuclear processes and their recording, cosmic rays, birth and death processes, problems of renewals (e.g. of machine parts), theory of queues and waiting times, linear prediction of stochastic series, etc.

The book will be of great interest and value to all those mathematically minded scientists who work on phenomena which have stochastic features.

The Scattering of Low-energy [illegible]ronium by Hydrogen Atoms

By P. A. FRA[illegible]R

Department of Physics, University of Western Ontario, London, Canada

Communicated by Sir Harrie Massey; *MS. received 7th December* 1960

Abstract. When ortho-positronium collides with a hydrogen atom not only may it be scattered, but there is also the possibility of conversion of the ortho-positronium to para-positronium by electron exchange. The total elastic cross section and the conversion cross section have been calculated for positronium kinetic energies 0 to 9·8 ev, for the $l=0$ partial wave only. A particular choice of trial wave function explicitly satisfying the Pauli principle and a variational argument lead to integro-differential equations, with no 'ordinary force', from which the phase shifts have been obtained by a numerical method. The cross sections are very strongly energy dependent: the total cross section ranges from $192\pi a_0^2$ at zero energy to $2{\cdot}92\pi a_0^2$ at 6·8 ev, while the (conversion)/(total) ratio ranges from 0·176 to 0·070 over these energies. These ratios are well below the value 1/4 expected at high energies from the Born approximation. The total cross section results of Massey and Mohr for this problem using Born approximation were $230\pi a_0^2$ at zero energy and $25\pi a_0^2$ at 6·8 ev, with the (conversion)/(total) ratio 1/4.

§ 1. INTRODUCTION

MASSEY AND MOHR (1954) have surveyed, using Born approximation methods, the processes involved in the fate of positrons slowed down in atomic hydrogen gas. These processes included the formation of positronium and the slowing down of ortho-positronium and the ortho–para conversion by collisions with the hydrogen. This paper reports a more detailed calculation of the cross sections for elastic collisions of slow ortho-positronium with hydrogen atoms and for the quenching of ortho-positronium by electron exchange and conversion to para-positronium in collisions with hydrogen atoms. It is assumed throughout that the positronium has a stable existence; that is, that its life time against spontaneous decay by annihilation is long enough to make the notion of a collision meaningful. Further, the possibility of annihilation of the positron with the atomic electron during the collision has been neglected in this calculation (Deutsch 1953, p. 148). Only s-scattering has been considered, and at the low energies of interest (generally $< 5{\cdot}1$ ev) the neglect of higher order partial waves should not be serious. Spin–orbit effects have been neglected (Massey and Mohr 1954).

§ 2. SCATTERING AND CONVERSION CROSS SECTIONS

The Schroedinger equation for the system of ortho-positronium and the hydrogen atom is (assuming infinite mass for the proton):

$$H\Psi = E\Psi \qquad \ldots\ldots(1)$$

where

$$H=-\nabla_p^2-\nabla_1^2-\nabla_2^2-\frac{2}{r_{1p}}-\frac{2}{r_{2p}}-\frac{2}{r_1}-\frac{2}{r_2}+\frac{2}{r_p}+\frac{2}{r_{12}}.$$

$\mathbf{r}_1$ and $\mathbf{r}_2$ are the position vectors of the two electrons, $\mathbf{r}_p$ that of the positron. Units in which $\hbar=1$, $m_e=\frac{1}{2}$ and $e^2=2$ are used; in this system, similar to atomic units, the unit of length is a_0 (the Bohr radius) and the unit of energy is the binding energy of the hydrogen atom, 13·6 ev. Writing

$$\boldsymbol{\sigma}_1=(\mathbf{r}_1+\mathbf{r}_p)/2; \quad \boldsymbol{\rho}_1=(\mathbf{r}_1-\mathbf{r}_p),$$

the 'positronium portion' of the Hamiltonian (the positron and electron 1, say) may be written

$$-\nabla_p^2-\nabla_1^2-\frac{2}{r_{1p}}\equiv-\tfrac{1}{2}\nabla_{\sigma_1}^2-2\nabla_{\rho_1}^2-\frac{2}{\rho_1}.$$

The positronium ground state wave function $\phi(\rho_1)$ binding energy $\frac{1}{2}$, satisfies

$$\left(-2\nabla_{\rho_1}^2-\frac{2}{\rho_1}\right)\phi(\rho_1)=-\tfrac{1}{2}\phi(\rho_1) \qquad \ldots\ldots(2)$$

$$\phi(\rho_1)=\left(\frac{1}{8\pi}\right)^{1/2}\exp(-\rho_1/2) \qquad \text{(normalized).}$$

The ground state hydrogen atom wave function $\psi(r_2)$, binding energy 1, satisfies

$$\left(-\nabla_{r_2}^2-\frac{2}{r_2}\right)\psi(r_2)=-\psi(r_2) \qquad \ldots\ldots(3)$$

$$\psi(r_2)=\left(\frac{1}{\pi}\right)^{1/2}\exp(-r_2) \qquad \text{(normalized).}$$

It is convenient to write

$$E=\tfrac{1}{2}k^2-\tfrac{3}{2} \qquad \ldots\ldots(4)$$

where $\frac{1}{2}k^2$ is the kinetic energy of the positronium; k is the magnitude of the momentum.

Solutions $\Psi^{(-)}(\mathbf{r}_p,\mathbf{r}_1,\mathbf{r}_2)$ and $\Psi^{(+)}(\mathbf{r}_p,\mathbf{r}_1,\mathbf{r}_2)$ of (1) are sought, respectively antisymmetric and symmetric in the electron coordinates $\mathbf{r}_1$ and $\mathbf{r}_2$, with asymptotic forms ($\sigma_1\to\infty$)

$$\Psi^{(+)}\sim\left(\exp(ik\sigma_{1z})+F(\theta_1)\frac{\exp(ik\sigma_1)}{\sigma_1}\right)\phi(\rho_1)\psi(r_2),$$

$$\Psi^{(-)}\sim\left(\exp(ik\sigma_{1z})+G(\theta_1)\frac{\exp(ik\sigma_1)}{\sigma_1}\right)\phi(\rho_1)\psi(r_2), \qquad \ldots\ldots(5)$$

where θ_1 is the scattering angle (the angle the positronium position vector $\boldsymbol{\sigma}_1$ makes with the z axis). We do not consider the possibility of excitation of the positronium or hydrogen atoms, which is of course impossible below $\frac{1}{2}k^2=0{\cdot}375$ (5·1 ev). The differential elastic scattering cross section. ncluding the ortho–para conversion, is given by

$$\sigma(\theta)=\tfrac{3}{4}|G|^2+\tfrac{1}{4}|F|^2.$$

The differential cross section for the ortho–para conversion or the differential quenching cross section is given by

$$\sigma_p(\theta)=\tfrac{1}{16}|G-F|^2$$

as may be seen as follows:

The system of three spin $\frac{1}{2}$ particles forms quartet or doublet states. With the quartet spin functions, which are, in particular, symmetric in the spin coordinates of the electrons, must be associated $\Psi^{(-)}$. There is no possibility of ortho–para conversion in a quartet state.

The doublet states may be divided into two classes: those symmetric in the spins of the electrons and those antisymmetric in these spins. For the case $m=\frac{1}{2}$ these may be taken to be

$$\chi_{1/2}{}^{1/2}(\mathrm{p}, \overline{1,2}) = \frac{1}{\sqrt{6}}\left\{-2\beta(\mathrm{p})\alpha(1)\alpha(2)+\alpha(\mathrm{p})\alpha(1)\beta(2)+\alpha(\mathrm{p})\beta(1)\alpha(2)\right\},$$
$$\chi_{1/2}{}^{1/2}(\mathrm{p}, \widetilde{1,2}) = \frac{1}{\sqrt{2}}\left\{\alpha(\mathrm{p})\alpha(1)\beta(2)-\alpha(\mathrm{p})\beta(1)\alpha(2)\right\};$$

where the bar over 1 and 2 denotes symmetric, and the tilde denotes antisymmetric. Together with the $m=-\frac{1}{2}$ states, these form a complete set of doublet states.

The linear combination

$$\Psi = \frac{\sqrt{3}}{2}\Psi^{(+)}(\mathrm{p},1,2)\chi_{1/2}{}^{1/2}(\mathrm{p},\widetilde{1,2})+\tfrac{1}{2}\Psi^{(-)}(\mathrm{p},1,2)\chi_{1/2}{}^{1/2}(\mathrm{p},\overline{1,2})$$

satisfies the Pauli principle, and also corresponds to an incoming wave of ortho-positronium alone. For the doublet spin functions may be written

$$\chi_{1/2}{}^{1/2}(\mathrm{p},\widetilde{1,2}) = \frac{\sqrt{3}}{2}\sqrt{\frac{2}{3}}\left\{\chi_1{}^1(\mathrm{p},1)\beta(2)-\frac{1}{\sqrt{2}}\chi_1{}^0(\mathrm{p},1)\alpha(2)\right\}-\frac{1}{2}\chi_0{}^0(\mathrm{p},1)\alpha(2),$$
$$\chi_{1/2}{}^{1/2}(\mathrm{p},\overline{1,2}) = \frac{\sqrt{3}}{2}\chi_0{}^0(\mathrm{p},1)\alpha(2)+\frac{1}{2}\sqrt{\frac{2}{3}}\left\{\chi_1{}^1(\mathrm{p},1)\beta(2)-\frac{1}{\sqrt{2}}\chi_1{}^0(\mathrm{p},1)\alpha(2)\right\},$$

where $\chi_1{}^1(\mathrm{p},1)$ and $\chi_1{}^0(\mathrm{p},1)$ are triplet functions of the positron and electron spins, and $\chi_0{}^0(\mathrm{p},1)$ is the singlet function of these spins. Thus Ψ has the asymptotic form

$$\begin{aligned}\Psi \sim \phi(\rho_1)\psi(r_2)\Bigg\{&\left[\exp(ik\sigma_{1z})+(\tfrac{3}{4}F+\tfrac{1}{4}G)\frac{\exp(ik\sigma_1)}{\sigma_1}\right]\\ &\times\sqrt{\frac{2}{3}}\left\{\chi_1{}^1(\mathrm{p},1)\beta(2)-\frac{1}{\sqrt{2}}\chi_1{}^0(\mathrm{p},1)\alpha(2)\right\}\\ &+\frac{\sqrt{3}}{4}(G-F)\frac{\exp(ik\sigma_1)}{\sigma_1}\chi_0{}^0(\mathrm{p},1)\alpha(2)\Bigg\},\end{aligned}$$

which explicitly describes a plane wave of unit amplitude of ortho-positronium incident on hydrogen atoms with a scattered wave, in the doublet eigenstate

$$\sqrt{\frac{2}{3}}\left\{\chi_1{}^1(\mathrm{p},1)\beta(2)-\frac{1}{\sqrt{2}}\chi_1{}^0(\mathrm{p},1)\alpha(2)\right\},$$

together with an outgoing wave of para-positronium of amplitude $\sqrt{3}(G-F)/4$.

Taking into account the quartet scattering we have then that

$$\begin{aligned}\sigma(\theta) &= \tfrac{1}{6}[4|G|^2+2\{|\tfrac{3}{4}F+\tfrac{1}{4}G|^2+\tfrac{3}{16}|G-F|^2\}]\\ &= \tfrac{3}{4}|G|^2+\tfrac{1}{4}|F|^2,\end{aligned}$$

as could have been expected; and clearly the part of the total scattering that corresponds to conversion is

$$\sigma_{\mathrm{p}}(\theta)=\tfrac{1}{16}|G-F|^2.$$

This result has also been obtained by Field (1958) in connection with the essentially similar problem of the conversion of ground state hydrogen atoms in a hyperfine triplet state to the hyperfine singlet state by electron collisions. Ferrell (1958) has made similar considerations.

s-scattering alone is considered in this paper. The s-parts of $F(\theta)$ and $G(\theta)$ are respectively

$$\frac{1}{k}\exp(i\eta^+)\sin\eta^+ \quad\text{and}\quad \frac{1}{k}\exp(i\eta^-)\sin\eta^-$$

where η^+ and η^- are the s-phase-shifts obtained from wave functions $\Psi^{(+)}$ and $\Psi^{(-)}$ respectively. Considering then that it is sufficient to consider $l=0$ scattering alone, the total scattering and conversion cross sections (integrated over 4π) are

$$\sigma = \frac{4\pi}{k^2}\{\tfrac{3}{4}\sin^2\eta^- + \tfrac{1}{4}\sin^2\eta^+\}, \qquad \ldots\ldots(6)$$

$$\sigma_{\mathrm{p}} = \frac{4\pi}{k^2}\frac{1}{16}\{\sin^2\eta^- + \sin^2\eta^+ - 2\sin\eta^+\sin\eta^-\cos(\eta^- - \eta^+)\}. \qquad \ldots\ldots(7)$$

For zero energy

$$\frac{\tan\eta^+}{k} \to -A^+ \quad\text{and}\quad \frac{\tan\eta^-}{k} \to -A^-$$

where A^+ and A^- are scattering lengths. The cross sections become

$$\sigma = 4\pi\{\tfrac{3}{4}(A^-)^2 + \tfrac{1}{4}(A^+)^2\}$$

$$\sigma_{\mathrm{p}} = 4\pi\tfrac{1}{16}\{A^- - A^+\}^2.$$

§ 3. The Spatial Wave Functions

Wave functions $\Psi^{(-)}(\mathbf{r}_{\mathrm{p}}, \mathbf{r}_1, \mathbf{r}_2)$ and $\Psi^{(+)}(\mathbf{r}_{\mathrm{p}}, \mathbf{r}_1, \mathbf{r}_2)$, respectively antisymmetric and symmetric in $\mathbf{r}_1$ and $\mathbf{r}_2$, and satisfying asymptotic conditions (5), are to be found. The exact wave functions have the property that

$$I^{(\pm)} = \int d\boldsymbol{\sigma}_1\, d\boldsymbol{\rho}_1\, d\mathbf{r}_2 \Psi^{(\pm)}(H-E)\Psi^{(\pm)} = 0.$$

If $\Psi^{(\pm)}$ be taken as having asymptotic form (writing $a^\pm$ for $\tan\eta^\pm$)

$$\Psi^{(\pm)} \sim \phi(\rho_1)\psi(r_2)\frac{1}{\sigma_1}[\sin\, k\sigma_1 + a^\pm\cos k\sigma_1],$$

that is considering only the $l=0$ parts† and also changing the amplitude at infinity, then for variations $\delta\Psi^{(\pm)}$, with

$$\delta\Psi^{(\pm)} \sim \phi(\rho_1)\psi(r_2)(\delta a^\pm)\frac{\cos k\sigma_1}{\sigma_1},$$

about the exact solution,

$$[\delta I^{(\pm)} - 4\pi k(\delta a^\pm)] = 0. \qquad \ldots\ldots(8)$$

---

† Throughout this paper only s-scattering is considered; higher order partial waves could of course be considered by similar means, but at the expense of complicating the presentation.

The approximate calculation of $\Psi^{(\pm)}$ is based on the following considerations. Form trial functions

$$\Psi_t^{(\pm)}(\mathbf{r}_p, \mathbf{r}_1, \mathbf{r}_2) = \phi(\rho_1)\psi(r_2)\frac{1}{\sigma_1}f^{(\pm)}(\sigma_1) \pm \phi(\rho_2)\psi(r_1)\frac{1}{\sigma_2}f^{(\pm)}(\sigma_2) \qquad \ldots\ldots(9)$$

which have explicitly the appropriate symmetries, and where

$$f^{(\pm)}(\sigma) \underset{\sigma\to\infty}{\sim} \sin k\sigma + a_t^{\pm}\cos k\sigma$$

with

$$f^{(\pm)}(0) = 0.$$

Form

$$I_t^{(\pm)} = \int d\boldsymbol{\sigma}_1\, d\boldsymbol{\rho}_1\, d\mathbf{r}_2 \Psi_t^{(\pm)}(H-E)\Psi_t^{(\pm)} \qquad \ldots\ldots(10)$$

and calculate $\delta I_t^{(\pm)}$ for variations $\delta f^{(\pm)}(\sigma)$ with

$$\delta f^{(\pm)}(\sigma) \sim (\delta a_t^{\pm})\cos k\sigma. \qquad \ldots\ldots(11)$$

The calculation of $\delta I_t^{(\pm)}$ is fairly straightforward and certainly lengthy and is outlined in appendix A. It is found that

$$\tfrac{1}{2}[\delta I_t^{(\pm)} - 4\pi k(\delta a_t^{\pm})] = \int d\boldsymbol{\sigma}_1 \frac{\delta f^{(\pm)}(\sigma_1)}{\sigma_1}\left\{(-\nabla_{\sigma_1}^{\,2} - k^2)\frac{f^{(\pm)}(\sigma_2)}{\sigma_2} \pm \int d\boldsymbol{\sigma}_2 K(\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2)\frac{f^{(\pm)}(\sigma_2)}{\sigma_2}\right\} \qquad \ldots\ldots(12)$$

with

$$\begin{aligned} K(\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2) = (4)^3 \int d\mathbf{r}_p \phi(2|\boldsymbol{\sigma}_1 - \mathbf{r}_p|)\psi(|2\boldsymbol{\sigma}_1 - \mathbf{r}_p|)\phi(2|\boldsymbol{\sigma}_2 - \mathbf{r}_p|)\psi(|2\boldsymbol{\sigma}_2 - \mathbf{r}_p|) \\ \times\left\{-k^2 - 5 + \frac{2}{|2\boldsymbol{\sigma}_1 - \mathbf{r}_p|} + \frac{2}{|2\boldsymbol{\sigma}_2 - \mathbf{r}_p|} + \frac{4}{r_p}\right. \\ + \frac{2}{|\boldsymbol{\sigma}_1 - \boldsymbol{\sigma}_2|} - \frac{2(2\boldsymbol{\sigma}_1 - \mathbf{r}_p).(\boldsymbol{\sigma}_1 - \mathbf{r}_p)}{|2\boldsymbol{\sigma}_1 - \mathbf{r}_p||\boldsymbol{\sigma}_1 - \mathbf{r}_p|} \\ \left. - \frac{2(2\boldsymbol{\sigma}_2 - \mathbf{r}_p).(\boldsymbol{\sigma}_2 - \mathbf{r}_p)}{|2\boldsymbol{\sigma}_2 - \mathbf{r}_p||\boldsymbol{\sigma}_2 - \mathbf{r}_p|}\right\}. \qquad \ldots\ldots(13) \end{aligned}$$

It is noted that $K(\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2)$ is symmetric in $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$.

The requirement that

$$\delta I_t^{(\pm)} - 4\pi k(\delta a_t^{\pm}) = 0$$

leads to integro-differential equations for $f^{(\pm)}(\sigma)$:

$$\frac{1}{\sigma_1}\left\{\frac{d^2 f^{(\pm)}(\sigma_1)}{d\sigma_1^{\,2}} + k^2 f^{(\pm)}(\sigma_1)\right\} = \pm \int d\boldsymbol{\sigma}_2 K(\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2)\frac{f^{(\pm)}(\sigma_2)}{\sigma_2}. \qquad \ldots\ldots(14)$$

Writing

$$\Psi_t^{(\pm)} = \Psi^{(\pm)} + \Delta\Psi^{(\pm)},$$

to first order in $\Delta\Psi^{(\pm)}$ (the 'error' in $\Psi_t^{(\pm)}$), one obtains from (8)

$$I_t^{(\pm)} = 4\pi k(\Delta a^{\pm})$$

where

$$a_t^{\pm} = a^{\pm} + \Delta a^{\pm}.$$

A presumably better approximation to $a^{\pm}$ is thus given by

$$a_1{}^{\pm} = a_t{}^{\pm} - \frac{I_t{}^{(\pm)}}{4\pi k}.$$

It is shown in appendix B that

$$I_t{}^{(\pm)} = 0$$

for $f^{(\pm)}(\sigma)$ satisfying (14). Thus $a_t{}^{\pm}$ is an approximation to $a^{\pm}$ accurate to second order in the difference between the trial function and the exact function. The apparent success of the exchange approximation, which employs a trial function of similar form to that above, for electron–hydrogen atom elastic scattering at low energies (Bransden *et al.* 1958, Brackmann *et al.* 1958), would suggest that the approximation used here is quite good. The most serious source of error is likely to be neglect of such virtual processes as the formation, during the impact, of H^- and a free positron or the excitation of higher states of positronium or hydrogen.

§ 4. THE KERNEL

The angle integrations in the integro-differential equations (14) may be carried out. Consider, for example, the term on the right-hand side proportional to k^2 (the subscript on **r** will now be dropped):

$$f^{(\pm)}(\sigma_1) = \int d\boldsymbol{\sigma}_2 \int d\mathbf{r}\,\phi(2|\boldsymbol{\sigma}_1 - \mathbf{r}|)\psi(|2\sigma_1 - \mathbf{r}|)\phi(2|\boldsymbol{\sigma}_2 - \mathbf{r}|)\psi(|2\boldsymbol{\sigma}_2 - \mathbf{r}|)\frac{f^{(\pm)}(\sigma_2)}{\sigma_2}$$

with

$$\phi(\rho) = \left(\frac{1}{8\pi}\right)^{1/2} \exp\left(-\frac{\rho}{2}\right)$$

and

$$\psi(r) = \left(\frac{1}{\pi}\right)^{1/2} \exp(-r).$$

Now

$$|\boldsymbol{\sigma} - \mathbf{r}| = (\sigma^2 + r^2 - 2\sigma r\mu)^{1/2}$$

and

$$|2\boldsymbol{\sigma} - \mathbf{r}| = (4\sigma^2 + r^2 - 4\sigma r\mu)^{1/2}$$

with

$$\mu = \frac{\boldsymbol{\sigma}\,.\,\mathbf{r}}{\sigma r}.$$

The products of exponentials may be expanded in series of Legendre polynomials:

$$(\exp[-|\boldsymbol{\sigma} - \mathbf{r}|])(\exp[-|2\boldsymbol{\sigma} - \mathbf{r}|]) = \frac{1}{\sigma r}\sum_{l=0}^{\infty}(2l+1)G_l(\sigma, r)\mathrm{P}_l(\mu)$$

with

$$G_l(\sigma, r) = \frac{\sigma r}{2}\int_{-1}^{1} d\mu\,\mathrm{P}_l(\mu)(\exp[-|\boldsymbol{\sigma} - \mathbf{r}|])(\exp[-|2\boldsymbol{\sigma} - \mathbf{r}|]). \qquad \ldots\ldots(15)$$

With such expansions for both $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$ dependent factors, and making use of the addition theorem for the spherical harmonics, and further carrying out the angle integrations $d\Omega_{\sigma_2}$ and $d\Omega_r$ inside the summations, one obtains

$$f^{(\pm)}(\sigma_1) = \frac{2}{\sigma_1}\int_0^{\infty} d\sigma_2 \int_0^{\infty} dr\,G_0(\sigma_1, r)G_0(\sigma_2, r)f^{(\pm)}(\sigma_2).$$

The remaining terms may be similarly treated; the result is that the integro-differential equations for $f^{(\pm)}(\sigma)$ become

$$\left\{\frac{d^2}{d\sigma_1{}^2}+k^2\right\}f^{(\pm)}(\sigma_1)=\pm\int_0^\infty d\sigma_2\left\{\frac{k^2}{2}K^{(1)}(\sigma_1,\sigma_2)+K^{(2)}(\sigma_1,\sigma_2)\right\}f^{(\pm)}(\sigma_2) \qquad \ldots\ldots(16)$$

with

$$f^{(\pm)}(0)=0$$

and

$$f^{(\pm)}(\sigma_1)\underset{\sigma_1\to\infty}{\sim}\sin k\sigma_1+a^{\pm}\cos k\sigma_1,$$

$$K^{(1)}(\sigma_1,\sigma_2)=-(256)\int_0^\infty drG_0(\sigma_1,r)G_0(\sigma_2,r)$$

with $G_0(\sigma,r)$ given by (15) with $l=0$;

$$\begin{aligned}K^{(2)}(\sigma_1,\sigma_2)=(256)\int_0^\infty dr\Big\{&-\tfrac{5}{2}G_0(\sigma_1,r)G_0(\sigma_2,r)+\frac{2}{r}G_0(\sigma_1,r)G_0(\sigma_2,r)\\&+G_0(\sigma_1,r)J_0(\sigma_2,r)+J_0(\sigma_1,r)G_0(\sigma_2,r)\\&+\left(\sum_l\gamma_l(\sigma_1,\sigma_2)G_l(\sigma_1,r)G_l(\sigma_2,r)\right)\\&-G_0(\sigma_1,r)[(2\sigma_2{}^2+r^2)K_0(\sigma_2,r)-3\sigma_2rK_1(\sigma_2,r)]\\&-G_0(\sigma_2,r)[(2\sigma_1{}^2+r^2)K_0(\sigma_1,r)-3\sigma_1rK_1(\sigma_1,r)]\Big\}\end{aligned}$$

where

$$\begin{aligned}\gamma_l(\sigma_1,\sigma_2)&=\frac{1}{\sigma_2}\left(\frac{\sigma_1}{\sigma_2}\right)^l,\quad(\sigma_1\leqslant\sigma_2)\\&=\frac{1}{\sigma_1}\left(\frac{\sigma_2}{\sigma_1}\right)^l,\quad(\sigma_1\geqslant\sigma_2)\end{aligned}$$

(arising from the expansion of $1/(|\boldsymbol{\sigma}_1-\boldsymbol{\sigma}_2|)$) and where

$$\begin{aligned}J_0(\sigma,r)&=\frac{\sigma r}{2}\int_{-1}^1 d\mu\exp(-|\boldsymbol{\sigma}-\mathbf{r}|)\frac{\exp(-|2\boldsymbol{\sigma}-\mathbf{r}|)}{|2\boldsymbol{\sigma}-\mathbf{r}|}\\K_0(\sigma,r)&=\frac{\sigma r}{2}\int_{-1}^1 d\mu\frac{\exp(-|\boldsymbol{\sigma}-\mathbf{r}|)}{|\boldsymbol{\sigma}-\mathbf{r}|}\frac{\exp(-|2\boldsymbol{\sigma}-\mathbf{r}|)}{|2\boldsymbol{\sigma}-\mathbf{r}|}\\K_1(\sigma,r)&=\frac{\sigma r}{2}\int_{-1}^1 d\mu\mu\frac{\exp(-|\boldsymbol{\sigma}-\mathbf{r}|)}{|\boldsymbol{\sigma}-\mathbf{r}|}\frac{\exp(-|2\boldsymbol{\sigma}-\mathbf{r}|)}{|2\boldsymbol{\sigma}-\mathbf{r}|}.\end{aligned}$$

The $G_l(\sigma,r)$ are given by Eqn (15).

While the integrals $G_l(\sigma,r)$ etc., could be expressed as series of products of Bessel functions, it was decided to evaluate them numerically, this being a more straightforward process. These integrations were carried out on the first University College (London) Electronic Computer for a net of σ and r. The time available on the machine demanded some economy in the numerical work: the integrals were thus computed along rays of constant σ/r to cut down the time spent in the exponential sub-routine.

The net of points covered the ranges $0\leqslant\sigma\leqslant10$ and $0\leqslant r\leqslant16$, and because of the ray technique was necessarily rather sparse for large arguments. Some of the integrals could be evaluated in closed form for an irrational (σ/r) ratio,

$(\sigma/r)=(1/\sqrt{2})$, and this possibility was used to check the accuracy of the numerical procedure. It was found that the results were accurate to a fixed *decimal place*, with 5 figures accurate in the largest values. The values for large arguments were exponentially smaller and hence relatively not as accurate. However, their final contribution is small. The r-integration was subsequently carried out on a desk machine, and the results for $K^{(1)}(\sigma_1,\sigma_2)$ and $K^{(2)}(\sigma_1,\sigma_2)$, Eqn (16), are displayed in Table 1. $K^{(2)}(\sigma_1,\sigma_2)$ is made up of several contributions: the summation over l in one term was cut off at $l=6$, which was consistent with the overall accuracy of the kernel.

§ 5. SOLUTION OF THE INTEGRO-DIFFERENTIAL EQUATIONS

The integro-differential equations (16) with the conditions on the solutions may be transformed into integral equations by means of the appropriate Green's function. That is the systems

$$\left\{\frac{d^2}{d\sigma_1{}^2}+k^2\right\}f^{(\pm)}(\sigma_1)=\pm\int_0^\infty d\sigma_2 K(\sigma_1,\sigma_2)f^{(\pm)}(\sigma_2)$$
$$f^{(\pm)}(0)=0$$
$$f^{(\pm)}(\sigma)\underset{\sigma\to\infty}{\sim}\sin k\sigma+a^{\pm}\cos k\sigma \qquad \ldots\ldots(16)$$

become

$$f^{(\pm)}(\sigma)=\sin k\sigma-\int_0^\infty d\sigma' L(\sigma,\sigma')\int_0^\infty d\sigma''[\pm K(\sigma',\sigma'')]f^{(\pm)}(\sigma'') \qquad \ldots\ldots(17)$$

with

$$L(\sigma,\sigma')=\frac{1}{k}\sin k\sigma'\cos k\sigma \quad (\sigma'\leqslant\sigma)$$
$$=\frac{1}{k}\cos k\sigma'\sin k\sigma \quad (\sigma'\geqslant\sigma). \qquad \ldots\ldots(18)$$

The approximations $a^{\pm}$ to the tangents of the phase-shifts are given by

$$a^{\pm}=-\frac{1}{k}\int_0^\infty d\sigma'\sin k\sigma'\int_0^\infty d\sigma''[\pm K(\sigma',\sigma'')]f^{(\pm)}(\sigma''). \qquad \ldots\ldots(19)$$

If the range of the kernel be considered finite, the integral equations (17) may be approximated by systems of simultaneous algebraic equations, the unknowns being the values of $f^{(\pm)}$ at selected points, and the integrations approximated by standard numerical rules. This method of solution was ideally suited for the present problem where it was impractical to compute the kernel $K(\sigma',\sigma'')$ at many regularly spaced points. The $f^{(\pm)}(\sigma)$ need only be known within the range of the kernel (indeed need not be very well known where the kernel is small), for the $a^{\pm}$ may be obtained from the integrals (19). A survey of the application of this method of solution of scattering problems has been given by Fraser (1958). It has been found that use of the simple trapezoidal rule for the σ'-integration gives satisfactory results; indeed it gives better results than more refined rules blindly applied. The reason is the discontinuity in slope of the Green's function $L(\sigma,\sigma')$. Simpson's or other appropriate rules may be used for the σ''-integration. It is of course possible to use better integration rules, taking careful account of

Table 1. The Kernel Equation (16)

the discontinuityin slope of $L(\sigma,\sigma')$, but such refinement was not felt to be necessary here. The integral equation may be modified for the case of zero energy (Fraser 1958).

Appendix C gives further details of the numerical calculation as well as the results of applying the method to a similar problem solvable in closed form given by Buckingham and Massey (1941–42). Judging from the results of applying the method to the exactly solvable case it would appear that for the present problem, with the net of points shown in Table 1, the error in the cross sections is at most about 5%. In principle, at least, the method is capable of considerable refinement, but may not be practical beyond a certain stage of required accuracy. With the rather sparse and irregular net of points available in this problem it would seem ideal. The 11 simultaneous equations for each energy and symmetry were set up and solved on a Bendix G-15-D Computer.

The results of applying this numerical method to the present problem are given in tabular and graphical form in the following section.

§ 6. Results and Discussion

The s-cross sections (6) and (7) may be recast in terms of the quantities $k\cot\eta^+$ and $k\cot\eta^-$:

$$\sigma=(4\pi)\left\{\frac{3}{4}\frac{1}{k^2+k^2\cot^2\eta^-}+\frac{1}{4}\frac{1}{k^2+k^2\cot^2\eta^+}\right\} \qquad \ldots\ldots(20)$$

$$\sigma_{\mathrm{p}}=(4\pi)\frac{1}{16}\frac{(k\cot\eta^- - k\cot\eta^+)^2}{(k^2+k^2\cot^2\eta^-)(k^2+k^2\cot^2\eta^+)}. \qquad \ldots\ldots(21)$$

Table 2 presents the calculated values of $(k\cot\eta^\pm)$ and $\eta^\pm$ as functions of k^2 and k, and the cross sections σ and σ_{p} in units of $a_0{}^2$ obtained from Eqns (20) and (21). The assignment of the value π to the phase shifts at zero energy was made on the basis of the behaviour of curves of $(\eta^\pm, k)$ (Fig. 1). Results for higher

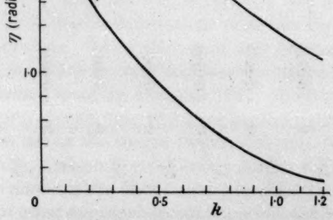

Fig. 1. The phase-shifts η^+ and η^- as functions of k.

energies than those presented here indicated that the η^+ curve crossed the axis at $k \simeq 1{\cdot}4$ while that for η^- showed no sign of crossing. The Born approximation would indicate that the phase shifts are equal and opposite at high energies. However the assignment is unimportant as the cross sections may be expressed in terms of $k \cot \eta^\pm$. (The results for $k > 1{\cdot}2$ have not been given as they were felt to be relatively inaccurate, and as the corresponding energies are well above the limit of elastic scattering alone.) Also in Table 2 are shown some cross sections obtained by interpolation.

Table 2

The total elastic cross section and the conversion cross section in units of a_0^2 (respectively σ and σ_p from Eqns (20) and (21)) and related quantities, as functions of the ortho-positronium kinetic energy: $\frac{1}{2}k^2$ in units of 13·6 ev.

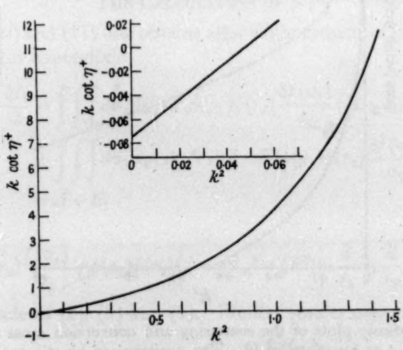

Fig. 2. $k \cot \eta^+$ as a function of k^2.

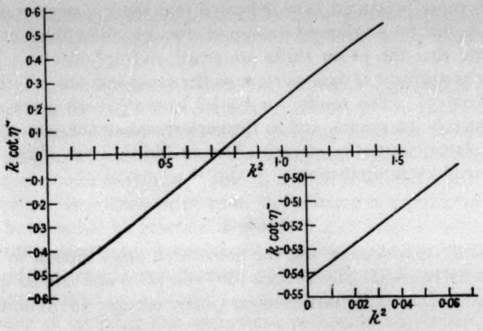

Fig. 3. $k \cot \eta^-$ as a function of k^2.

Figs 2 and 3 show the $(k \cot \eta^\pm, k^2)$ curves, with insets showing the expected straight line behaviour for very small energies. Effective ranges may be deduced from the slopes at low energies:

$$r_0^+ = 3{\cdot}00 a_0$$
$$r_0^- = 1{\cdot}44 a_0.$$

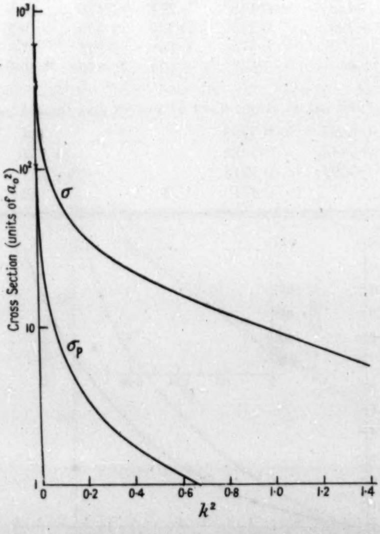

Fig. 4. Semi-logarithmic plots of the scattering and conversion cross sections σ and σ_p (in units of $a_0{}_2$) as functions of k^2. The positronium kinetic energy is $\frac{1}{2}k^2$ in units of 13·6 ev.

The cross sections (Table 2 and Fig. 4) are seen to be strongly energy dependent and very large at very low energies, as was indicated by the Born–Oppenheimer approximation results of Massey and Mohr (1954). It is interesting but probably coincidental that the Massey and Mohr value for the elastic cross section at zero energy is $230\pi a_0^2$, while the present work leads to the value $192\pi a_0^2$. The disagreement at higher energies is considerable; at $k^2 = 1$ (6·8 ev) the Massey and Mohr value is $25\pi a_0^2$ while the present work gives $2{\cdot}92\pi a_0^2$. Over the range of energies here considered the ratio of the quenching and elastic cross sections is substantially lower than the value 1/4 expected at higher energies.

A more accurate calculation of the elastic scattering of ortho-positronium by helium atoms is well in hand, and will shortly be completed. The results will be applicable to the problem of the moderation of ortho-positronium by helium gas, and the wave functions obtained will be used in a calculation of the quenching rate by annihilation on collision with the atomic electrons.

ACKNOWLEDGMENTS

The author is grateful to the National Research Council of Canada for an Overseas Post-Doctoral Fellowship (1954–56) held at University College, London, during the tenure of which this work was started, and acknowledges the partial support since that time of the Defence Research Board of Canada, The Department of Defence Production, the Geophysics Research Directorate of the U.S. Air Force Cambridge Research Center, and the National Research Council of Canada.

The author's thanks are due to Professor Sir Harrie Massey for suggesting the problem and for his continued interest throughout. He also wishes to thank Mr. W. Lawson for his help with the operation of the computer at the Physics Department of University College London, Mrs. Joyce Walton of Computing Devices of Canada for her assistance on the G-15-D, and Dr. M. A. Preston of McMaster University for making available the G-15-D at that University.

APPENDIX A

THE CALCULATION OF $\delta I_t^{(\pm)}$

From (9), (10) and (11) one obtains after slight reduction (the ± superscripts are omitted in this appendix):

$$\begin{aligned}\frac{\delta I_t}{2} &= \iiint d\boldsymbol{\sigma}_1\, d\boldsymbol{\rho}_1\, d\mathbf{r}_2 \phi(\rho_1)\psi(r_2)\frac{\delta f(\sigma_1)}{\sigma_1}(H-E)\Psi_t \\ &\quad + \iiint d\boldsymbol{\sigma}_1\, d\boldsymbol{\rho}_1\, d\mathbf{r}_2 \Psi_t(H-E)\phi(\rho_1)\psi(r_2)\frac{\delta f(\sigma_1)}{\sigma_1} \\ &= A+B.\end{aligned}$$

Now

$$(H-E)\phi(\rho_1)\psi(r_2)\frac{f(\sigma_1)}{\sigma_1} = \phi(\rho_1)\psi(r_2)\left\{(-\tfrac{1}{2}\nabla_{\sigma_1}{}^2 - \tfrac{1}{2}k^2) - \frac{2}{r_1} + \frac{2}{r_\text{p}} - \frac{2}{\rho_2} + \frac{2}{r_{12}}\right\}\frac{f(\sigma_1)}{\sigma_1},$$

where use is made of (2), (3) and (4). Similar results may be obtained for

$$(H-E)\phi(\rho_1)\psi(r_2)\frac{\delta f(\sigma_1)}{\sigma_1}$$

and for

$$(H-E)\phi(\rho_2)\psi(r_1)\frac{f(\sigma_2)}{\sigma_2}$$

with a rewriting of the Hamiltonian appropriate for electron 2 being 'in the positronium' and electron 1 'in the atom'. Further

$$\begin{aligned}\iint d\boldsymbol{\rho}_1\, d\mathbf{r}_2 \phi(\rho_1)\psi(r_2)\left\{\frac{2}{r_{\mathrm{p}}}-\frac{1}{r_1}+\frac{2}{r_{12}}-\frac{2}{\rho_2}\right\}\phi(\rho_1)\psi(r_2)\\ =\iint d\boldsymbol{\rho}_1\, d\mathbf{r}_2 \phi(\rho_1)\psi(r_2)\left\{\frac{2}{|\boldsymbol{\sigma}_1-\boldsymbol{\rho}_1/2|}-\frac{2}{|\boldsymbol{\sigma}_1+\boldsymbol{\rho}_1/2|}\right.\\ \left.+\frac{2}{|\mathbf{r}_2-\boldsymbol{\sigma}_1-\boldsymbol{\rho}_1/2|}-\frac{2}{|\mathbf{r}_2-\boldsymbol{\sigma}_1+\boldsymbol{\rho}_1/2|}\right\}\phi(\rho_1)\psi(r_2)\\ =0;\end{aligned}$$

the result corresponds to the statement that in first approximation there is no direct interaction between the positronium and the atom (Massey and Mohr 1954).

Thus

$$\begin{aligned}A=\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\{-\tfrac{1}{2}\nabla_{\sigma_1}{}^2-\tfrac{1}{2}k^2\}\frac{f(\sigma_1)}{\sigma_1}\\ \pm\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\iint d\boldsymbol{\rho}_1\, d\mathbf{r}_2\phi(\rho_1)\psi(r_2)\left\{-\tfrac{1}{2}\nabla_{\sigma_2}{}^2-\tfrac{1}{2}k^2-\frac{2}{r_2}\right.\\ \left.+\frac{2}{r_{\mathrm{p}}}-\frac{2}{\rho_1}+\frac{2}{r_{12}}\right\}\phi(\rho_2)\psi(r_1)\frac{f(\sigma_2)}{\sigma_2}\\ =C\pm D.\end{aligned}$$

Similarly

$$\begin{aligned}B=\int d\boldsymbol{\sigma}_1\frac{f(\sigma_1)}{\sigma_1}\{-\tfrac{1}{2}\nabla_{\sigma_1}{}^2-\tfrac{1}{2}k^2\}\frac{\delta f(\sigma_1)}{\sigma_1}\\ \pm\iiint d\boldsymbol{\sigma}_1\, d\boldsymbol{\rho}_1\, d\mathbf{r}_2\phi(\rho_2)\psi(r_1)\frac{f(\sigma_2)}{\sigma_2}\left\{-\tfrac{1}{2}\nabla_{\sigma_1}{}^2-\tfrac{1}{2}k^2-\frac{2}{r_1}+\frac{2}{r_{\mathrm{p}}}\right.\\ \left.-\frac{2}{\rho_2}+\frac{2}{r_{12}}\right\}\phi(\rho_1)\psi(r_2)\frac{\delta f(\sigma_1)}{\sigma_1}\\ =E\pm F.\end{aligned}$$

Making use of Green's theorem and the asymptotic forms of $f(\sigma)$ and $\delta f(\sigma)$ one may easily show that

$$E=A+2\pi k(\delta a_{\mathrm{t}}).$$

It is convenient to transform the integrations in D and F from $(\boldsymbol{\sigma}_1, \boldsymbol{\rho}_1, \mathbf{r}_2)$ space to $(\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_2, \mathbf{r}_{\mathrm{p}})$ space. The Jacobian of the transformation has the value $(4)^3$. In terms of $\boldsymbol{\sigma}_1$, $\boldsymbol{\sigma}_2$ and $\mathbf{r}_{\mathrm{p}}$:

$$\begin{aligned}\boldsymbol{\rho}_1=2(\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}});\quad \boldsymbol{\rho}_2=2(\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}})\\ \mathbf{r}_1=2\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}};\quad \mathbf{r}_2=2\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}},\end{aligned} \qquad \ldots\ldots(22)$$

and these expressions will be understood in the following.

The terms in D and F that need consideration are those involving ∇_σ^2. For D, this part is

$$(4)^3\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\int\int d\boldsymbol{\sigma}_2\,d\mathbf{r}_{\mathrm{p}}\phi(\rho_1)\psi(r_2)\phi(\rho_2)\psi(r_1)\{-\tfrac{1}{2}\nabla_{\sigma_2}{}^2\}\frac{f(\sigma_2)}{\sigma_2}$$
$$=(4)^3\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\int\int d\boldsymbol{\sigma}_2\,d\mathbf{r}_{\mathrm{p}}\frac{f(\sigma_2)}{\sigma_2}\{-\tfrac{1}{2}\nabla_{\sigma_2}{}^2\}\phi(\rho_1)\psi(r_2)\phi(\rho_2)\psi(r_1).$$

For F, this part may be transformed into

$$(4)^3\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\int\int d\sigma_2\,d\mathbf{r}_{\mathrm{p}}\,\frac{f(\sigma_2)}{\sigma_2}\{-\tfrac{1}{2}\nabla_{\sigma_1}{}^2\}\phi(\rho_1)\psi(r_2)\phi(\rho_2)\psi(r_1).$$

Now,

$$\nabla_{\sigma_1}{}^2\phi(\rho_1)\psi(r_1)=\nabla_{\sigma_1}{}^2\phi(2|\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}|)\psi(|2\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}|)$$
$$=\phi(\rho_1)\psi(r_2)\left\{5-\frac{8}{r_1}-\frac{4}{\rho_1}+4\frac{\mathbf{r}_1\cdot\boldsymbol{\rho}_1}{r_1\rho_1}\right\},$$

and similarly for $\nabla_{\sigma_2}{}^2\phi(\rho_2)\psi(r_2)$.

Combining D and F, using the intermediate results and expressing the coordinates in terms of $\boldsymbol{\sigma}_1$, $\boldsymbol{\sigma}_2$ and $\mathbf{r}_{\mathrm{p}}$ one obtains

$$D+F=\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\int d\boldsymbol{\sigma}_2K(\boldsymbol{\sigma}_1,\boldsymbol{\sigma}_2)\frac{f(\sigma_2)}{\sigma_2},$$

with $K(\boldsymbol{\sigma}_1,\boldsymbol{\sigma}_2)$ given by (13).

Finally one obtains, from $\frac{1}{2}\delta I_{\mathrm{t}}=A+B=(C+E)\pm(D+F)$,

$$\tfrac{1}{2}(\delta I_{\mathrm{t}}-4\pi k(\delta a_{\mathrm{t}}))=\int d\boldsymbol{\sigma}_1\frac{\delta f(\sigma_1)}{\sigma_1}\left\{(-\nabla_{\sigma_1}{}^2-k^2)\frac{f(\sigma_1)}{\sigma_1}\right.$$
$$\left.\pm\int d\boldsymbol{\sigma}_2K(\boldsymbol{\sigma}_1,\boldsymbol{\sigma}_2)\frac{f(\sigma_2)}{\sigma_2}\right\},$$

which is Eqn (12) of the text.

APPENDIX B

THE VANISHING OF $I_{\mathrm{t}}^{(\pm)}$

Many of the steps required to show the vanishing of $I_{\mathrm{t}}^{(\pm)}$ are similar to those in appendix A, and will not specifically be pointed out. Again the $(\pm)$ superscripts are suppressed, and the vectors are often written in their simplified form with Eqns (22) understood. In Ψ_{t}, $f(\sigma)$ now satisfy (14).

$$\frac{I_{\mathrm{t}}}{(4)^3}=\int\int\int d\boldsymbol{\sigma}_1\,d\boldsymbol{\sigma}_2\,d\mathbf{r}_{\mathrm{p}}\Psi_{\mathrm{t}}(H-E)\Psi_{\mathrm{t}}$$
$$=2\int\int\int d\boldsymbol{\sigma}_1\,d\boldsymbol{\sigma}_2\,d\mathbf{r}_{\mathrm{p}}\Psi_{\mathrm{t}}(H-E)\phi(\rho_1)\psi(r_2)\frac{f(\sigma_1)}{\sigma_1}$$
$$=2\frac{1}{(4)^3}\int d\boldsymbol{\sigma}_1\frac{f(\sigma_1)}{\sigma_1}\{-\tfrac{1}{2}\nabla_{\sigma_1}{}^2-\tfrac{1}{2}k^2\}\frac{f(\sigma_1)}{\sigma_1}$$
$$\pm\int\int\int d\boldsymbol{\sigma}_1\,d\boldsymbol{\sigma}_2\,d\mathbf{r}_{\mathrm{p}}\frac{f(\sigma_2)}{\sigma_2}\phi(\rho_2)\psi(r_1)\frac{f(\sigma_1)}{\sigma_1}\phi(\rho_1)\psi(r_2)$$
$$\times\left\{-\frac{5}{2}-\frac{1}{2}k^2+\frac{2}{r_1}+\frac{2}{\rho_1}-\frac{2}{\rho_2}+\frac{2}{r_{12}}+\frac{2}{r_{\mathrm{p}}}-\frac{2\mathbf{r}_1\cdot\boldsymbol{\rho}_1}{r_1\rho_1}\right\}.$$

Table 3. Comparison of Approximate and Exact Results for the Kernel $\mu\sigma\sigma' \exp[-b(\sigma+\sigma')]$, Eqns (24) and (25) with $b=2$, $\mu=\pm 100$.

† For this value of k, a different set of integration weights was used. This set was based largely on the 3/8 rule; for other values of k, the results using these weights were very slightly better for $\mu=100$, and rather worse for $\mu=-100$.

On replacing

$$\{-\tfrac{1}{2}\nabla_{\sigma_1}{}^2-\tfrac{1}{2}k^2\}\frac{f(\sigma_1)}{\sigma_1}$$

by

$$\pm\int d\boldsymbol{\sigma}_2 K(\boldsymbol{\sigma}_1,\boldsymbol{\sigma}_2)\frac{f(\sigma_2)}{\sigma_2}$$

from (14), one obtains, after some cancellation of terms,

$$\begin{aligned}\frac{I_{\mathrm{t}}}{(4)^3}=\mp\iiint d\boldsymbol{\sigma}_1\,d\boldsymbol{\sigma}_2\,d\mathbf{r}_{\mathrm{p}}\frac{f(\sigma_1)}{\sigma_1}\frac{f(\sigma_2)}{\sigma_2}\phi(\rho_2)\psi(r_2)\phi(\rho_1)\psi(r_1)\\ \times\left\{-\frac{1}{|2\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}|}+\frac{1}{|2\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}}|}+\frac{1}{|\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}|}-\frac{1}{|\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}}|}\right.\\ \left.+\frac{(2\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}).(\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}})}{|2\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}||\boldsymbol{\sigma}_1-\mathbf{r}_{\mathrm{p}}|}-\frac{(2\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}}).(\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}})}{|2\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}}||\boldsymbol{\sigma}_2-\mathbf{r}_{\mathrm{p}}|}\right\}.\end{aligned}$$

Thus $I_{\mathrm{t}}=0$, since the quantity in braces is antisymmetric in $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$.

APPENDIX C

THE NUMERICAL SOLUTION OF THE INTEGRAL EQUATIONS FOR $f^{(\pm)}(\sigma)$

This appendix gives further details of the numerical method of solution of the integral equations, which was briefly outlined in the text. Also, some results of applying the method to a similar problem solvable in closed form are presented. Consider the integro-differential equation, with conditions on the solution,

$$\left\{\frac{d^2}{d\sigma^2}+k^2\right\}f(\sigma)=\int_0^\infty d\sigma' M(\sigma,\sigma')f(\sigma'),$$

$$f(0)=0;\quad f(\sigma)\underset{\sigma\to\infty}{\sim}\sin k\sigma+a\cos k\sigma.$$

These may be transformed into the integral equation

$$f(\sigma)=\sin k\sigma-\int_0^\infty d\sigma' L(\sigma,\sigma')\int_0^\infty d\sigma'' M(\sigma',\sigma'')f(\sigma''),$$

with the Green's function $L(\sigma,\sigma')$ given by (18), and with

$$a=-\frac{1}{k}\int_0^\infty d\sigma'\sin k\sigma'\int_0^\infty d\sigma'' M(\sigma',\sigma'')f(\sigma'').$$

It is presumed that the kernel $M(\sigma',\sigma'')$ vanishes sufficiently fast for large argument that the integrations may be cut off at some finite value of σ. The integrals are then approximated by some numerical rule, and this procedure leads to simultaneous algebraic equations with the unknowns being the values of $f(\sigma)$ at a set of discrete points:

$$f_i=s_i-\sum_{jk}L_{ij}\beta_j' M_{jk}\alpha_k'' f_k$$

or

$$\sum_{jk}(\delta_{ik}+L_{ij}\beta_j' M_{jk}\alpha_k'')f_k=s_i \qquad \ldots\ldots(23)$$

where $f_i=f(\sigma_i)$ etc. The numbers β_j' and α_k'' are the appropriate numerical integration weights for the σ' and σ'' integrations respectively. These have been discussed in the text. Solution of (23) leads to values of f_i which are then used to compute a through

$$a = -\frac{1}{k}\sum_{jk} s_i \alpha_i M_{ij} \alpha_j f_j.$$

Buckingham and Massey (1941–42) have given the solution for the case of

$$M(\sigma, \sigma') = \mu\sigma\sigma' \exp\left[-b(\sigma+\sigma')\right]:$$

$$f(\sigma) = \sin k\sigma + a\cos k\sigma - a\left\{1 + \left(\frac{b^2+k^2}{2b}\right)\sigma\right\}\exp(-b\sigma) \quad \ldots\ldots (24)$$

with

$$\frac{1}{a} = \frac{-4b^3(b^2+k^2)^4 + \mu(-5b^6 + 15b^4k^2 + 5b^2k^4 + k^6)}{16kb^5\mu}. \quad \ldots\ldots (25)$$

The choice of $b=2$ and $\mu = \pm 100$ gives kernels $M(\sigma, \sigma')$ approximating in behaviour and magnitude the kernels of the present problem. Accordingly this soluble problem was attacked by the numerical method, and the approximate results compared with the exact ones. The set of points used was that available for the present problem:

$$\{\sigma\} = \{\tfrac{1}{4}, \tfrac{1}{2}, \tfrac{3}{4}, 1, \tfrac{5}{4}, \tfrac{3}{2}, 2, 2\tfrac{1}{2}, 3, 4, 5\}.$$

The integration weight factors used were

$$\{\beta\} = \{\tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{4}, \tfrac{1}{8}+\tfrac{1}{4}, \tfrac{1}{2}, \tfrac{1}{2}, \tfrac{1}{4}+\tfrac{1}{2}, 1, \tfrac{1}{2}\},$$

which arise from the use of the trapezoidal rule for the Green's function integration as discussed in the text, and

$$\{\alpha\} = \{\tfrac{1}{3}, \tfrac{1}{6}, \tfrac{1}{3}, \tfrac{1}{6}, \tfrac{1}{3}, \tfrac{1}{12}+\tfrac{3}{16}, \tfrac{9}{16}, \tfrac{9}{16}, \tfrac{3}{16}+\tfrac{1}{3}, \tfrac{4}{3}, \tfrac{1}{3}\},$$

which arise from the use of the $\tfrac{1}{3}$ and $\tfrac{3}{8}$ rules. Values for the point $\sigma=0$ are, of course, unnecessary.

Table 4

Values of $(\cos\eta^{\pm})\, f^{(\pm)}(\sigma)$ (for $\sigma=5$) for the positronium problem obtained (i) from the solution of the simultaneous equations and (ii) by substitution into $\sin(k\sigma+\eta^{\pm})$ of the computed phase-shifts (for $k=0$, into $\sigma - A^{\pm}$).

The results for this 'test-case' kernel are presented in Table 3 for $k=0{\cdot}5$ and 1, and are compared with the exact solutions. The method may also be formulated for $k=0$ in terms of

$$\Phi(\sigma)=\lim_{k\to 0}\left(\frac{f(\sigma)}{k}\right)$$

with

$$\Phi\sim\sigma-A,$$

A being the scattering length (Fraser 1958). The results for $k=0$ are also presented in Table 3.

Finally, as an indication of the consistency of the results of applying this method to the positronium problem, Table 4 shows values of $f^{(\pm)}(\sigma)$ (normalized to unit amplitude at infinity) for $\sigma=5$ obtained in two ways: (i) from the solution of the simultaneous equations and (ii) by substitution into the expression $\sin(k\sigma+\eta^{\pm})$, the phase-shifts being obtained from the integrals (19), or into $\sigma-A^{\pm}$ for $k=0$.

Infra-red Emission and Electroluminescence in Zinc Sulphide Phosphors

By D. W. G. BALLENTYNE
University of Hull

MS. received 8*th March* 1961

Abstract. It is shown that the infra-red emission of zinc sulphide phosphors is dependent upon the copper concentration. Infra-red emission occurs after simultaneous excitation by ultra-violet and infra-red in phosphors containing less than 5×10^{-4} g atoms Cu per mole ZnS. For greater concentrations of copper infra-red emission does not occur but such phosphors are electroluminescent.

---

§ 1. Introduction

In 1954 Garlick and Dumbleton first observed infra-red emission bands in zinc sulphide phosphors. In 1956 Browne showed that infra-red emitting phosphors belong to two classes. The infra-red emission of class I phosphors is excited by illuminating the phosphor with infra-red radiation of the correct wavelength. Class II phosphors require simultaneous excitation by ultra-violet radiation as well as infra-red. Class II phosphors were shown to contain copper impurities but the emission of class I phosphors was believed to depend upon non-stoichometry. The origin of infra-red emission can be explained by reference to Fig. 1 which shows a simple band model for a crystalline phosphor. The green and blue emissions are the emission bands usually associated with zinc sulphide phosphors. The infra-red excitation bands correspond to the transitions I and II whilst the emission bands correspond to the transitions III and IV. The difference in class I and class II phosphors depends upon the occupancy of these levels. If the levels are normally unoccupied then infra-red alone will cause the necessary electron transitions. If, however, electrons are usually present in these levels infra-red emission can only occur if holes are trapped from the valence band or generated by the direct transitions V and VI. These transitions are, of course, in the ultra-violet.

Apple and Prener (1960) have studied infra-red emission in aluminium co-activated ZnS(Cu) phosphors. The emission is greatly increased by allowing the phosphor to anneal in a high sulphur pressure thereby reducing the anion vacancies to a very low concentration. The phosphors prepared in this way are class I phosphors, and the intensity of the emission is proportional to the concentration of copper added. It was assumed that the gas–solid reaction can be represented by the equation

$$\mathrm{ZnCu}_{4\delta}{}^{0}(\mathrm{S}_1{}^{+}{}_{4\delta}) \rightleftharpoons \mathrm{ZnCu}_{4\delta}{}^{-}\mathrm{V}_{2\delta}{}^{++}(\mathrm{S}_1{}^{+}{}_{2\delta}) + \delta \mathrm{S}_2$$

where $\mathrm{V}_{2\delta}{}^{++}$ represents a sulphur vacancy doubly charged with respect to the sulphur in the solid. Cu^0 is a copper ion with a hole in the ground state which is neutral with respect to the copper for which it substitutes and Cu^- is a copper ion with the states occupied by electrons making it negatively charged with respect to zinc. This equation explains the observation that the fourth power of the brightness of emission is proportional to the sulphur pressure. The addition of aluminium to the system which can act as a singly ionized donor allows replacement of V^{++} by Al^{+} so that the charge balance is

$$Cu^{-}=V^{++}+Al^{+}.$$

It is shown that when the aluminium concentration is much smaller than the copper concentration the infra-red intensity is almost constant but as it approaches that of copper the infra-red emission should drop rapidly to zero. This behaviour is not observed and it was concluded that not all the aluminium goes into solution.

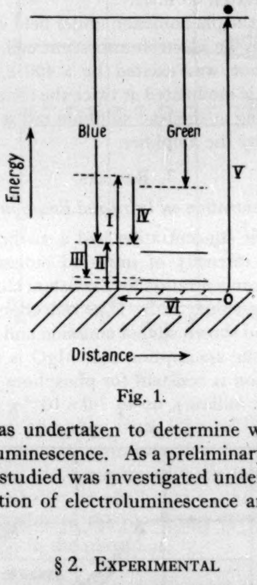

Fig. 1.

The present work was undertaken to determine whether infra-red emission occurred during electroluminescence. As a preliminary the emission of the series of phosphors previously studied was investigated under ultra-violet and infra-red excitation. The correlation of electroluminescence and infra-red emission was then investigated.

§ 2. EXPERIMENTAL

The phosphors were prepared as previously described. The zinc sulphide used was freed from gross contamination with chlorine by washing with distilled water until the filtrate gave no precipitate with silver nitrate and was then fired for two hours at 800°c in a stream of dry H_2S. The chlorine content of the final product was of the order of parts per million. The activator, copper, and the co-activator, aluminium, were added to a slurry of the zinc sulphide as the sulphates. After drying at 110°c the phosphors were fired for half-an-hour in a stream of wet hydrogen sulphide. These phosphors appear to have reached equilibrium with the surrounding atmosphere, as increasing the length of the firing time had no effect. X-ray diffraction studies show that phosphors containing less than 6×10^{-4} g atom Cu per mole ZnS are hexagonal in structure whilst phosphors with greater concentrations of copper are mixtures of the cubic and hexagonal phases, although preponderantly cubic in structure (Ballentyne 1960).

The infra-red emission was detected using a lead sulphide cell with a silicon filter. A 60 w tungsten lamp was focused on the phosphor in a holder, the construction of the holder being such that the phosphor tube could be removed and replaced at the same place in the system. The desired excitation band was isolated by filters. In three experiments a 0·700 μ, a 0·903 μ interference filter and a Wratten 29 filter were used. The form of the curves was not affected although the intensity of emission was greatest with the last filter. The ultra-violet radiation was filtered through a 2 cm $CuCl_2$ filter to remove infra-red. The emitted radiation was focused on to the lead sulphide cell through an 800 cycle chopper disk. In order to reduce reflection of the exciting radiation the emergent light passed through a Wratten 89 filter.

In order to investigate the phenomenon under field excitation of the phosphor the holder was replaced by an electroluminescent cell. The chopper disk was removed and the phosphor was excited by a 400 c/s 800 v alternating field. The fact that the emission is modulated at twice the frequency of the applied field means that the light arriving at the lead sulphide cell is modulated at the correct frequency for acceptance by the amplifier.

§ 3. RESULTS

3.1. *Effect of Copper Concentration on Infra-red Emission during Photoluminescence*

The variation of copper concentration had a marked effect on the infra-red emission. In Fig. 2 the intensity of infra-red emission in arbitrary units is plotted against the copper concentration for a constant aluminium concentration of $3{\cdot}5 \times 10^{-4}$ g atoms Al per gramme ZnS. The reflection of the exciting radiation from an MgO sample is also shown so that emission and absorption of the sample may be differentiated on the assumption that MgO is a perfect reflector. The integrated infra-red emission is constant for phosphors prepared from pure zinc sulphide (Cu < 1 part per million), up to $3{\cdot}0 \times 10^{-4}$ g atom Cu per mole ZnS. For copper concentrations above this value infra-red emission does not occur. The phosphors with these larger copper concentrations have a layer of copper sulphide precipitated on to the crystallites. In order to test whether the decrease in emission was due to the absorption of this layer, the phosphors were washed in hot 10% KCN which dissolves the excess copper sulphide. The washed phosphors still did not emit infra-red although the reflectance of the powder increased.

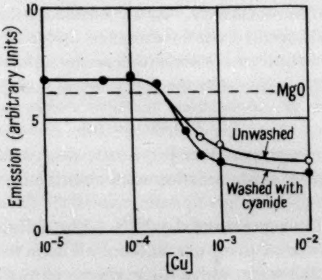

Fig. 2.

3.2. *Effect of Aluminium Concentration*

It appears from Fig. 2 that the emission of infra-red only occurs when the molar concentration of the activator is less than the molar concentration of the co-activator (see above). Experiments with variation of aluminium concentration indicates that this result is fortuitous. In Fig. 3 the effect of aluminium concentration on an emitting phosphor containing $1{\cdot}5 \times 10^{-4}$ g atom Cu per mole ZnS and a non-emitting phosphor with $1{\cdot}5 \times 10^{-3}$ g atom Cu per mole ZnS is shown. Over a large range of concentrations the effect is small but at large aluminium concentrations the intensity of both the emission and reflectance decreases. This may probably be attributed to the precipitation of increasing concentrations of Al_2O_3 oxide in the phosphors (Fröhlich 1953) due to a limit of solubility of aluminium in the phosphor.

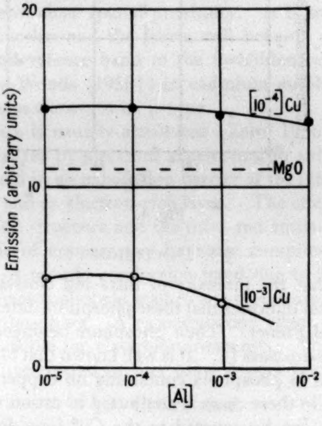

Fig. 3.

3.3. *Infra-red Emission and Electroluminescence*

In Fig. 4 the variation of electroluminescent brightness with copper concentration is given. Electroluminescence occurs in those phosphors which do not emit infra-red. The concentration of co-activator does not appear to effect the appearance of electroluminescent emission. There is a precipitation of copper sulphide on to the grains of the phosphor and the crystal structure changes from predominantly hexagonal to predominantly cubic. It has been argued that the electron-rich layer of copper sulphide is the source of electroluminescence. The fact that cyanide washed phosphors from which superficial copper sulphide has been dissolved are brighter electroluminescent phosphors seems to indicate that the copper in the bulk of the crystal is more important than the surface layer.

No infra-red emission can be detected from electroluminescent phosphors under the joint action of infra-red or ultra-violet with the electric field.

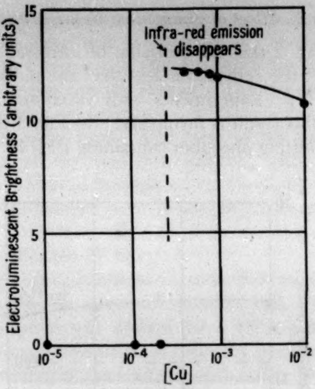

Fig. 4.

§ 4. Discussion

The observation that the intensity of infra-red emission is independent of the copper concentration indicates that these phosphors differ markedly from those prepared by Apple and Prener. Their phosphors belonged to class I whilst the phosphors studied here are class II. It is well known that blue and green emission bands can be observed in phosphors containing no copper whatsoever (Garlick 1958). The emission in these cases is attributed to cation vacancies which, after capturing an electron, can be equated to the Cu^0 ions described above. The number of cation vacancies which can be generated will depend upon the total charge equality. It can be seen that

$$Cu^- + V_C = Al^+ + V_A$$

where V_C and V_A are the anion and cation vacancies. Thus if the cation vacancies are greatly in excess of the copper centres then the emission will be virtually independent of the copper and aluminium concentrations as found above.

The discontinuity in the curve may be attributed to the precipitation of copper. Thus the solubility of copper in zinc sulphide is independent of the co-activator concentration. When copper sulphide precipitates out it causes a major change in the crystal structure of the zinc sulphide host crystal (Ballentyne 1960). Although the powder has been fired at 1100°c (above the wurtzite sphalerite transition temperature of 1024°c) the phosphor is found to be predominantly cubic in structure with a slight inclusion of the hexagonal form.

Copper sulphide is cubic in form and if we assume that the substitutional solubility of copper in zinc sulphide is low and that a concentration of interstitial copper has gradually built up, then when the concentration of copper reaches a certain level (i.e. 1 Cu for 10–20 atoms in the lattice) it causes nucleation of a new phase in which a high concentration of copper is present substitutionally in the lattice thereby modifying the crystal form. Infra-red emission due to cation vacancies is now no longer a possibility. Charge compensation of these centres by means of the aluminium co-activator is not possible and the copper ions must be uncompensated unless a large number of anion vacancies are generated.

This is not probable as the firing atmosphere is rich in free sulphur. It is possible that the copper ions are auto-compensated. Under these conditions it is possible that necessary electrons are found from the inner shell of the copper. The transitions from the normal levels into the d shell of the copper ion may account for the appearance of the red emission band. The luminescent centre will now consist of three levels whose kinetics may differ widely from the two-level centres and this may account for the disappearance of the infra-red emission. The situation can also be affected by the fact that the concentration of copper ions is so high that these are in close spatial proximity. It is to be expected that the wave functions will overlap and the levels will become continuous forming a pseudo-conduction and valence band in the forbidden region. Such an effect has been observed by Woods (1958†) in cadmium sulphide which, with high copper doping, has been shown to be p-type.

Electroluminescence is usually attributed (Zalm 1956) to impact ionization of the luminescent centres by electrons accelerated to sufficiently high energies in the large electric field in an exhaustion barrier at the interface between a semiconducting phosphor and an electron-rich layer. The effect of the concentration of copper on the crystal structure and the infra-red emission of these phosphors indicates that the role of copper may be more complicated than providing a source of electrons. A pseudo-conduction band due to the high concentration of copper atoms in the crystal could lead to a p-type material in contact with the normal n-type ZnS phosphors. A recombination effect at the p–n junction so formed may be responsible for electroluminescence. The possibility of such a mechanism is being investigated further using copper doped single crystals.

§ 5. CONCLUSION

It has been shown that infra-red emission in ZnS [Cu](Al) phosphors does not occur in the materials containing high copper concentrations. The copper concentration in these cubic materials is large and most of the ions will be uncompensated. The conditions of preparation are such that the presence of sulphur vacancies is unlikely but the inclusion of the ion can possibly be explained by autocompensation (i.e. by withdrawing an electron from an inner shell of the copper ion). The kinetics in the three-level centre so formed may well be different from the two-level centre. Under these conditions infra-red emission is not to be expected. The proximity of the copper centres may lead in fact to impurity bands whose formation may be connected with the appearance of electroluminescence. During electroluminescence processes infra-red emission was not detected.

ACKNOWLEDGMENTS

My thanks are due to Miss J. B. Bleackly for the preparation of the phosphors used in this work and to the University of Hull for the facilities for the work.

Temperature Variation of Optical Energy Gap for GaSb–InSb Alloys

By J. C. WOOLLEY and J. A. EVANS†
Department of Physics, University of Nottingham

MS. received 6*th March* 1961

Abstract. Reasonably homogeneous, polycrystalline, solid ingots of GaSb–InSb alloys have been produced by slow directional freezing techniques, as described previously. For alloys of various compositions, normal absorption measurements have been made to determine the variation of optical energy gap E_g with temperature in the range 100–800°K. It is found that alloys show a linear variation of E_g with temperature, and values of extrapolated absolute zero energy gap and energy gap temperature coefficient are obtained. These results are compared with the data from electrical measurements described previously and the question of the variation with composition of the band form of the alloys is discussed.

---

§ 1. INTRODUCTION

SINCE the results of Goryunova *et al.* (Goryunova and Fedorova 1955, Goryunova and Gorshkov 1958) and Woolley *et al.* (Woolley, Smith and Lees 1956, Woolley and Smith 1958) showed that single-phase solid solution could be obtained at all compositions of GaSb–InSb alloys, considerable work has been carried out to determine the electrical and optical properties of these alloys. On the optical side, the variation of optical energy gap E_g as a function of composition has been determined by Woolley, Evans and Gillett (1959, to be referred to as I) and by Ivanov-Omskii and Kolomiets (1959 a). Determination of electrical parameters have been made by Ivanov-Omskii and Kolomiets (1959 b, 1960) on the equimolecular alloy GaSb–InSb and by Woolley and Gillett (1960, to be referred to as II) for the complete range of alloy composition. The present work is an extension of the optical investigation described in I, and the determination of the variation of E_g with temperature allows a comparison to be made between the optical results and the electrical data given in II.

§ 2. PREPARATION OF SPECIMENS AND METHODS OF MEASUREMENT

The preparation of the ingots from which the specimens were taken for the present work has already been described in I and II, the same ingots being used for all three sets of measurements. The compounds were prepared from elements of 99·999% purity and the InSb was further purified by normal zone refining techniques. Three ingots containing (*a*) 70 mol. %, (*b*) 30 mol. % and (*c*) 10 mol. % GaSb respectively were made up and equilibrium conditions obtained by slow directional freezing. Cross sections from various points on these ingots provided specimens covering the range of composition from 0–94 mol. % GaSb, the degree of homogeneity being as described in I.

---

† Now at Standard Telephones and Cables Ltd., Footscray, Kent.

The optical measurements were made by normal transmission methods using the apparatus described in I, specimens of thickness somewhere in the range 60–160 μ being used. For measurements below room temperature the specimen holder was made of steel and the specimen attached to it with Durofix. The specimen and holder were contained in an evacuated chamber, the holder making good thermal contact with the top plate of the chamber which was of brass. This top plate formed the bottom of a metal Dewar which could be filled with liquid air or solid carbon dioxide in ether. Conduction through the brass holder enabled the specimen to be held at a steady temperature while the transmission measurements were made, the temperature of the specimen being determined by a chromel–alumel thermocouple placed close to it. The infra-red beam entered and left the chamber through arsenic trisulphide windows.

For temperatures above room temperature, the specimen was clamped at the centre of a long steel holder, and around each end of the holder was wound a small insulated tubular heating element. This holder was again mounted in an evacuated chamber and conduction along the holder enabled the specimen to be held at the required temperature, a Pt–PtRh thermocouple being used for temperature determination in this case. This system allowed measurements to be made up to temperatures of approximately 800°K.

§ 3. Results

For various alloys throughout the composition range, measurements were made of relative transmission I/I_0 as a function of wavelength at temperatures at approximately 100°K intervals from 100°K upwards. In the case of the InSb-rich alloys measurements were made up to only approximately 400°K, this limit being set by the wavelength range of the apparatus ($\sim 8\,\mu$) since for these alloys at high temperature the absorption edge had moved outside this wavelength range. Since, however, the electrical results in II had indicated no anomalous behaviour in this composition range, it was assumed that measurements up to 400°K were sufficient to allow the values of E_{0g} (the energy gap E_g at absolute zero) and β (the temperature coefficient of E_g) to be determined. For the GaSb-rich alloys, where the electrical results of II showed anomalous behaviour, measurements were made up to the temperature limit of the apparatus, which was approximately 800°K.

The method of determining E_g from the transmission data on polycrystalline specimens of unknown reflectivity is somewhat arbitrary. In I the value of λ corresponding to the energy gap was obtained by estimating the apparent onset of transmission from $(I/I_0, \lambda)$ graphs. In an attempt to obtain a more consistent set of values, particularly as specimens of different thickness were used, a different method of interpretation, described previously for other similar alloy systems (Woolley and Ray 1960, Woolley, Gillett and Evans 1960), was used in this case. The results have been plotted as $\log(I_0/I)$ against λ and some of the curves for an alloy containing 78 mol. % GaSb are shown in Fig. 1. Assuming that for specimens of thickness d the approximate equation $I = I_0 C \exp(-Kd)$ can be used for the transmitted intensity and that over the range concerned C is reasonably

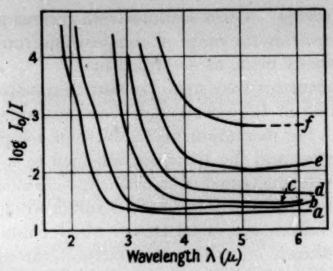

Fig. 1. Variation of log (I_0/I) with wavelength for the alloy 78 mol. % GaSb 22 mol. % InSb. Curve *a*, 103°K; curve *b*, 291°K; curve *c*, 499°K; curve *d*, 599°K; curve *e*, 685°K; curve *f*, 718°K.

independent of λ, this gives

$$\log\left(\frac{I_0}{I}\right)_E - \log\left(\frac{I_0}{I}\right)_B = \frac{K_E - K_B}{2{\cdot}303}\, d$$

where the subscript E indicates values at the wavelength λ_E, corresponding to the energy gap E_g, and the subscript B the background values. A choice of definition of λ_E was made by putting $K_E - K_B = 300\ \mathrm{cm}^{-1}$, as this choice gave a value of E_g for InSb close to the generally accepted value for the compound. Using this criterion the values of E_g obtained for the alloys were reasonably close to those quoted in I. By this method, values of E_g were obtained as a function of temperature for each specimen and these are plotted in Fig. 2. It is seen that in each case E_g is found to vary linearly with temperature over the temperature range considered, and hence E_g can be represented by the equation $E_g = E_{0g} + \beta T$.

From the results in Fig. 2 the values of E_g at 300°K have been taken for the various compositions and compared with the room temperature results given in I and also with the values quoted by Ivanov-Omskii and Kolomiets. All of these results are collected in Fig. 3. It is seen that there is good agreement over the whole range of composition between the results given in I and the present results. The values of Ivanov-Omskii and Kolomiets, however, while showing reasonable agreement in the range 0–20 mol. % GaSb, lie well below the other results over the rest of the composition range. It is to be noted that preliminary values of E_g given by Woolley, Smith and Evans (1960) for material showing some inhomogeneity tend to agree with the results of Ivanov-Omskii and Kolomiets for alloys in the range 85–100 mol. % GaSb. It is thus possible that the presence of some inhomogeneity may be responsible for the disagreement in the results in Fig. 3, but it is not possible to consider this further as Ivanov-Omskii and Kolomiets do not indicate the degree of homogeneity of their specimens.

By extrapolating the graphs in Fig. 2 to $T = 0$ a value of E_{0g} can be obtained for each composition, and the values of E_{0g} are plotted as a function of composition in Fig. 4. Also shown by the broken line in Fig. 4 are the values of E_0 determined by electrical measurements and given in II. The form of these curves is discussed below. The slopes of the lines in Fig. 2 give the values of energy gap temperature coefficient β and these are plotted as a function of composition in Fig. 5. This graph also is discussed below.

§ 4. Discussion

The electrical results given in II indicated that for compositions between 0 and 60 mol. % GaSb the behaviour of the alloys was normal and that the addition of GaSb to InSb progressively changed the value of the extrapolated energy gap E_0 without causing any changes in the general form of the band structure. The present values of E_{0g} and β shown in Figs 4 and 5 reinforce this suggestion. Over this range of composition the values of E_{0g} are in good agreement with the electrical values of E_0, particularly as the absolute values of E_g depend to some extent on the arbitrary choice of definition of E_g from the optical data. Also the value of β changes very little over this range of composition. It thus appears most probable that the band form of InSb with the conduction band minimum at 000 in *k*-space is retained by the alloys in this composition range. For the composition range 60–100 mol. % GaSb the results obtained so far have been anomalous. Thus the values of optical energy gap E_g given in I indicated the possibility of a discontinuity in the slope of the curve of E_g against composition at about 73 mol. % GaSb. The electrical data presented in II gave two values of E_0 in this composition range, a lower value E_{01} being obtained at low temperatures, and a higher value E_{02} at higher temperatures, the transition temperature T_c lying in each case in the temperature range 650–800°K. The variation of E_{01} and E_{02} with composition is shown in Fig. 4. When these values are compared with the values of E_{0g} presented here, it is seen that over the approximate composition range 60–85 mol. % GaSb E_{0g} agrees with E_{02}, but in the range 95–100 mol. % GaSb E_{0g} shows some agreement with E_{01}.

In II it was suggested that the form of the electrical results could be explained by one of two possible alternatives, i.e. the anomalous behaviour in the range 60–100 mol. % GaSb was due to either (*a*) band changes occurring in this range of composition or (*b*) ordering, possibly relatively short range, occurring in the composition range around 75 mol. % GaSb, the transition temperature T_c being in fact the ordering temperature. In order to explain the electrical results in terms of a band change, it is necessary to postulate a change in band form not only with composition, but also with temperature, in the anomalous range. Owing to the difficulties of making the detailed electrical results for each specimen fit with the idea of a change of band minimum with temperature, it was suggested that possibly ordering effects were a more likely explanation.

This view must be modified however in the light of the present results. The observed values of E_{0g} show a monotonic variation from InSb to GaSb. Bearing in mind the fact that in both InSb and GaSb the conduction band minimum occurs at 000 in *k*-space (Zwerdling *et al.* 1959, Sagar 1960, Moss 1960), it appears probable that at every composition the measured E_{0g} corresponds to a direct transition which is what is observed in the absorption measurements. The smooth variation of β in Fig. 5 supports this suggestion. Since all the optical measurements were made at temperatures below 800°K, these represent conditions below the transition temperature T_c. The lower values of E_{01} could not then correspond to a direct transition but would correspond to indirect transitions not observed in the present optical work. And since in the composition range 60–85 mol. % GaSb the high temperature electrical E_{02} corresponds with the low temperature optical E_{0g}, the idea that ordering takes place and gives two entirely different sets of conduction band minima above and below T_c seems to be ruled out.

In an explanation in terms of a band change, it is seen that since in this composition range $E_{02}=E_{0g}$, E_{02} would correspond to a direct transition. Thus here the 000 minimum would be the lowest minimum in the conduction band at temperatures down to T_c, but below this temperature some other conduction band minimum would be the lowest, resulting in indirect transition begins observed by the electrical measurements at these lower temperatures. Such an effect would occur if the minima had different temperature coefficients, and were at the same energy at the temperature T_c. There is some support for this suggestion in the form of the (log (I_0/I), λ) curves for the alloy containing 78 mol. % GaSb as shown in Fig. 1. The curves corresponding to low temperatures, i.e. below approximately 500°K, show a slight kink in the absorption edge whereas at higher temperatures no such kink was observed. Such a kink could be due to the effect of an indirect transition of lower energy than the direct transition becoming noticeable at lower temperatures. Effects of this type were observed for various alloys in the range 73–89 mol. % GaSb.

It is still not clear however how the relatively sharp discontinuities at a temperature T_c which occur in the (log (np/T^3), $1/T$) graphs (II) can be correlated with such a band change. It is of interest to note that even in this case if the values of E_{01} are explained as being due to an indirect transition to a conduction band minimum with an anomalous temperature coefficient, this effect occurs only over a limited range of composition centred on 75 mol.% GaSb which is the optimum ordering composition for these alloys. Thus some structural effect such as short range ordering could still play a part and be responsible for the anomalous values of β in this composition range.

The form of the various E_0 curves (Fig. 4) in the range 85–100 mol.% GaSb would still appear anomalous and it is not possible at this stage to account for their form. The values of β shown in Fig. 5 as a function of composition are considerably scattered about the mean line (shown broken) in this anomalous range, and it is felt that these deviations are greater than would be expected from the estimated accuracy of the determinations. The deviations may be significant and reflect the more complex behaviour of the band structure in this composition range. More detailed data are required before explanations can be attempted, and it is hoped in particular to carry out a more detailed investigation of the optical absorption edge for alloys in the range 60–100 mol.% GaSb, and to extend the temperature range of observations from the present limit to values well above T_c.

ACKNOWLEDGMENTS

The authors are indebted to Professor L. F. Bates for the facilities of his laboratory. The work described forms part of an investigation carried out for the Admiralty.

The Electrical and Magnetic Properties of the Uranium–Niobium System

By L. F. BATES and R. D. BARNARD†
Department of Physics, University of Nottingham

MS. received 3rd March 1961

Abstract. The magnetic susceptibilities and electrical resistivities of a series of γ-phase uranium–niobium alloys were measured over the temperature ranges 293–1200°K and 90–1200°K, respectively. The form of the resistivity–temperature–concentration relations is abnormal, especially at low temperatures, where negative temperature coefficients of resistivity occur in the uranium-rich alloys, and no explanation can be found in terms of localized moments on either U or Nb atoms. Comparison is made of the same properties of the γ U–Mo alloys and particular attention is directed towards the electronic band structure of niobium. A rigid band model is shown to be appropriate for dilute solid solutions of uranium and molybdenum, but such a model is not applicable to the uranium-rich γ U–Mo and the U–Nb alloys.

§ 1. Introduction

Research on the physical properties of the U–Mo and U–Nb alloys has received impetus in recent years, following the discovery by Bleiberg, Jones and Lustman (1956) that some of the metastable γ body-centred cubic alloys possess small negative temperature coefficients of resistivity below room temperature. More recently, Chandrasekhar and Hulm (1958) studied the electrical resistivity and superconductivity of a series of α (orthorhombic) and γ (body-centred cubic) binary alloys of uranium with molybdenum and niobium between 1° and 295°K. All the quenched γ alloys in the range 15–30 at. % were found to exhibit anomalous negative temperature coefficients of resistivity. Magnetic susceptibility and electrical resistivity measurements on the γ U–Mo alloys were made (Bates and Barnard 1961) over an extended temperature range in order to include the stable γ region, and it was concluded that no explanation of the results could be given in terms of localized electrons on either the molybdenum or uranium atoms.

In spite of these and other investigations (Loasby 1958, Blatt 1961, Berlincourt 1959), the origin of the unusual behaviour has not been completely explained. It was therefore thought that more light might be shed on the problem by studying the electrical and magnetic properties of the U–Nb system, where the γ phase could be retained in metastable equilibrium over a much larger composition range than in the U–Mo system. In addition, it was hoped that a comparison of the properties of the γ U–Mo and γ U–Nb alloys would provide information on the electronic structure of γ uranium, particularly on the density of states–energy distribution.

---

† Now at Research Laboratories of Electrical and Allied Industries Research Association, Leatherhead, Surrey.

No previous extensive investigation into the physical properties of the U–Nb alloys has been made, but the phase diagram of the system is well established (Pfeil, Brown and Williamson 1958). There is complete solubility above 950°C of γ uranium and niobium, although with intermediate compositions below 950°C the state exists in two body-centred forms, γ_1 and γ_2. The γ phase of samples of composition greater than 20 at. % Nb can be retained at room temperature by quenching.

§ 2. Experimental Procedure

The alloys were prepared at the Atomic Energy Research Establishment, Harwell, in an argon arc furnace from 99·9% pure uranium (see Bates and Barnard 1961), and spectroscopically standardized niobium, supplied by Johnson Matthey and Co. Ltd. The ingots were wrapped in molybdenum foil, sealed in quartz capsules under a pressure of less than 10^{-4} mm Hg, and annealed for two weeks at 1000°C. The ingots were afterwards machined to give cylinders 4 cm long and 5 mm in diameter, which were resealed, heated in the capsules, and quenched in water from 1000°C with fracture of the quartz. Microscopic inspection of the specimens kindly performed at the Atomic Energy Research Establishment, Harwell, showed for compositions above 30 at. % Nb the existence of the γ body-centred cubic phase in metastable equilibrium; but, like the alloys of similar composition in the U–Mo system, between 20 and 30 at. % Nb there was established a distorted γ body-centred tetragonal phase whose axial ratio was so close to unity that the tetragonality was not observable by X-ray techniques. In addition, the investigation showed that the alloys were not completely homogeneous despite the long time of anneal, the inhomogeneity being more marked in the 20–70 at. % Nb range of composition. No observations of the lattice parameters were made, as these were being performed concurrently at Harwell by Pfeil, Brown and Williamson (1958). The parameters were found to obey Vegard's law fairly accurately, the addition of niobium contracting the lattice of γ uranium.

The experimental arrangements for the measurement of magnetic susceptibility between 293 and 1200°K and for electrical resistivity between 90 and 1200°K together with a discussion of the experimental limitations have been described elsewhere (Bates and Barnard 1961).

Alloys in the composition range 20–80 at. % Nb were first measured in the metastable γ state with rise in temperature until the γ phase began to decompose. This was manifested by marked discontinuities in the slopes of the susceptibility–temperature and of the resistivity–temperature curves, at which juncture measurements were discontinued until further rise in temperature took the specimens into the stable γ region. Having once in these alloys established the γ phase, which is stable only at very high temperatures, it was possible to make measurements with decrease in temperature into the $\gamma_1+\gamma_2$ phase region; for precipitation of γ to $\gamma_1+\gamma_2$ is so slow that the γ phase does not decompose at temperatures near 700°C, even after several days. Above 800°C, Pfeil, Brown and Williamson (1958) reported that the transition from single phase γ to $\gamma_1+\gamma_2$ does not occur even after anneals of eight weeks duration. Each of the curves for these alloys thus had a temperature region where no observations of the γ phase could be made, but it was possible to interpolate between the observations in the metastable and stable γ regions and so estimate with reasonable accuracy the form of the curves where the γ phase was decomposing. For compositions above 80 at. % Nb, the alloys were stable in the body-centred cubic modification for all temperatures up to their melting points.

§ 3. EXPERIMENTAL RESULTS

3.1. *Magnetic Susceptibility*

The molar susceptibilities against temperature of the U–Nb alloys in both metastable and stable γ states are shown in Figs 1 and 2. In view of the inhomogeneity of some of the specimens, two values of the room temperature susceptibility were obtained for each specimen (one in the inverted position) and the mean taken as the correct value. With no specimen was a difference of more than 2% found between measurements when the specimen was inverted, to bring another portion of the specimen into the region of maximum field gradient.

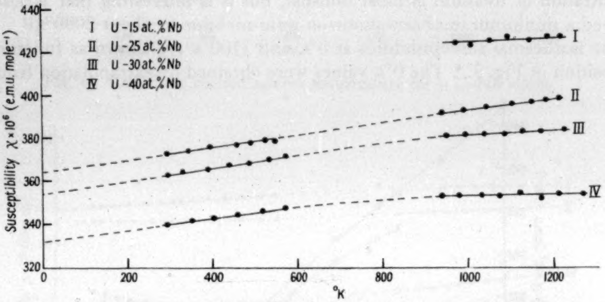

Fig. 1. Susceptibility plotted against temperature for γ U–Nb alloys.

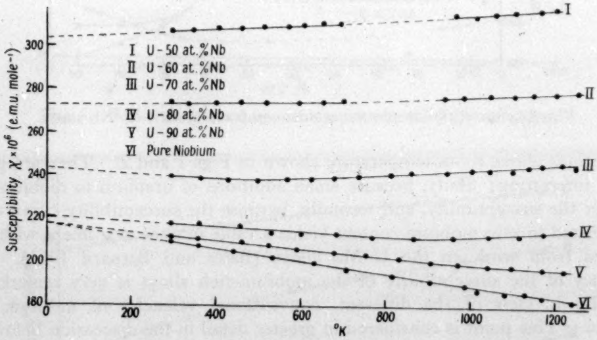

Fig. 2. Susceptibility plotted against temperature for γ U–Nb alloys.

It is clear that the addition of niobium to γ uranium gives a general reduction, not only of the magnitude of the susceptibility, but also of the temperature coefficient. The temperature coefficient of susceptibility of U–25 at. % Nb is positive, as in the U–Mo system, and gradually decreases with increasing niobium concentration until it is negative as with pure niobium. The results for pure niobium are in close agreement with those previously recorded (Kriessman 1953), the variation with temperature being fairly linear over the range of temperature investigated. The absolute value at room temperature was $2{\cdot}29 \pm 0{\cdot}02 \times 10^{-6}$ e.m.u. g^{-1}, a value rather higher than that recorded by Kriessman, but in close agreement with that recorded by Williams (1960 unpublished), viz. $2{\cdot}3 \times 10^{-6}$ e.m.u. g^{-1}.

Two of the niobium-rich alloys, U–70, 80 at. % Nb, exhibited shallow susceptibility minima at about 500°K and 900°K, respectively. This tendency for a minimum to exist and for it to shift towards higher temperatures with increasing concentration of niobium is most unusual, but it is interesting that Kriessman observed a minimum in observations on pure niobium at about 2000°K.

The isothermal susceptibilities at 0°K and 1100°K are shown as functions of composition in Fig. 3. The 0°K values were obtained by extrapolation from the observations above room temperature shown in Figs 1 and 2. They are particularly interesting; firstly, because small additions of uranium to niobium did not alter the susceptibility, and secondly, because the susceptibility curve when extrapolated to zero niobium content yields a value in close agreement with that obtained from work on the U–Mo alloys (Bates and Barnard 1961). The constancy of the susceptibility of the niobium-rich alloys is very remarkable, especially in view of the different, conventional valencies of uranium and niobium. This point is considered in greater detail in the discussion below.

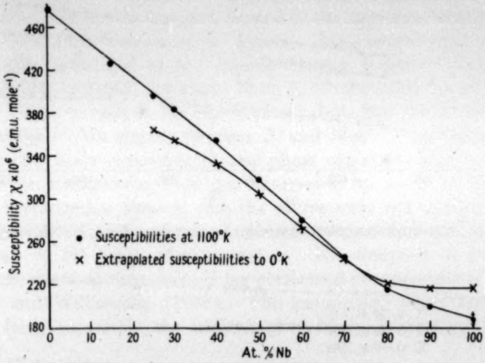

Fig. 3. Susceptibility plotted against composition for γ U–Nb alloys.

3.2. *Electrical Resistivity*

The resistivity–temperature curves for uranium-rich alloys, shown in Fig. 4, are characterized by behaviour very similar to that of uranium-rich U–Mo alloys; i.e. by a negative temperature coefficient of resistivity for the quenched alloys. Increasing concentrations of niobium reduced the magnitude of the negative temperature coefficient and the magnitude of the positive coefficient in the stable γ region. This abnormal behaviour persisted to 60 at. % Nb, Fig. 5, and then more or less normal behaviour prevailed, Fig. 6, to pure niobium.

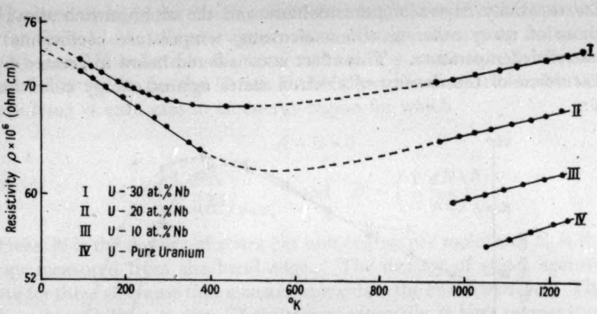

Fig. 4. Resistivity plotted against temperature for γ U–Nb alloys.

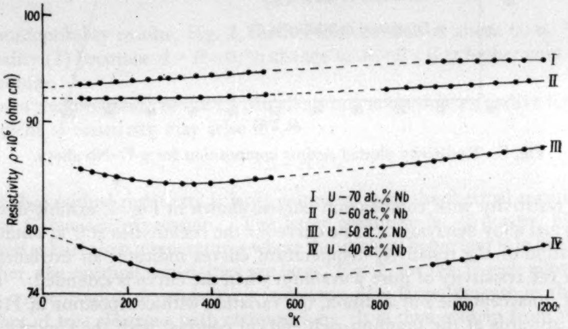

Fig. 5. Resistivity plotted against temperature for γ U–Nb alloys.

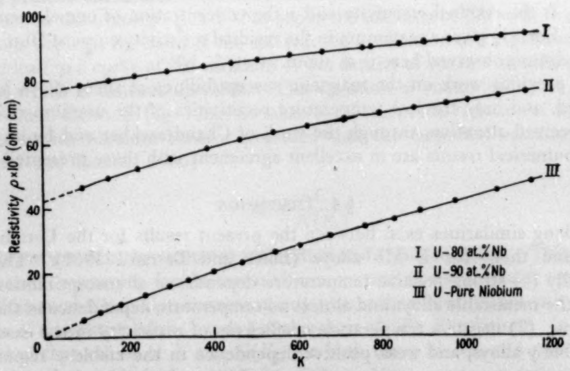

Fig. 6. Resistivity plotted against temperature for γ U–Nb alloys.

The resistivity curves of pure niobium and the niobium-rich alloys show, like those of many other transition elements, temperature coefficients which decrease with temperature. This effect is considered below in greater detail in the discussion of the density of electron states against energy curve for pure niobium.

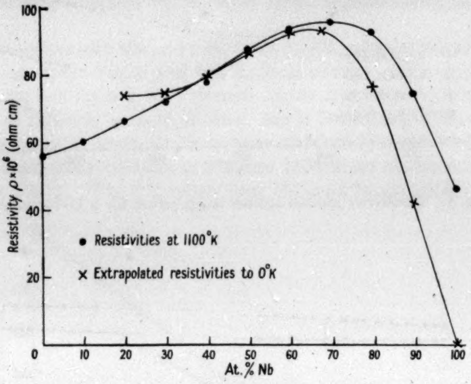

Fig. 7. Resistivity plotted against composition for γ U–Nb alloys.

The resistivity with composition curves, shown in Fig. 7, exhibit deviations from normal alloy behaviour. The curve for the resistivities at 0°K, obtained by extrapolation of the resistivity–temperature curves indicates an extremely high value for the resistivity of pure γ uranium when the curve is extended. This is, of course, unacceptable; in addition, the variation with composition at 1100°K is concave upwards at the uranium-rich end, in contrast with the concave downwards curve given by the equation

$$\rho_0 \propto x(1-x). \qquad \ldots\ldots(1)$$

Here ρ_0 is the residual resistivity and x the concentration of one element in the other. Eqn (1) gives a maximum in the residual resistivity curve at 50 at. % Nb; the maximum observed here is at about 64 at. % Nb.

No previous work on the magnetic susceptibilities of these alloys has been recorded, and only the low temperature resistivities of the uranium-rich alloys have received attention, through the work of Chandrasekhar and Hulm (1958). Their numerical results are in excellent agreement with those presented above.

§ 4. DISCUSSION

Striking similarities exist between the present results for the U-rich U–Nb alloys and those for U–Mo alloys (Bates and Barnard 1961). These are essentially (1) strong positive temperature dependence of susceptibilities in the case of the metastable alloys and almost no temperature dependence in the stable γ regions; (2) negative temperature coefficients of resistivity in the case of the metastable γ alloys, and weak positive dependence in the stable γ regions; (3) similar resistivity–concentration and susceptibility–concentration curves.

The similarities in the results would seem to indicate that an explanation like that for the γ U–Mo alloys is appropriate, although there is no indication as to why Nb and Mo behave in the same manner in γ uranium. Briefly, then, the susceptibility results for the U-rich U–Nb alloys are compatible with the Fermi surface lying in each case in an energy region for which

$$A - B > 0 \qquad \ldots\ldots(2)$$

where

$$A = \left(\frac{1}{N}\frac{d^2N}{dE^2}\right)_{E=E_0} \quad \text{and} \quad B = \left(\frac{1}{N}\frac{dN}{dE}\right)^2_{E=E_0}$$

Here, N is the density of states per unit energy per mole, and E_0 is the Fermi energy measured from the band edge. The density of states against energy curves for these alloys are thus concave upwards at the Fermi surface. The failure of the susceptibilities to give T^2 variations, especially at high temperatures, may be due to the failure of the degeneracy condition

$$E_0 \gg kT. \qquad \ldots\ldots(3)$$

The susceptibility results, Fig. 2, further indicate that at about 60 at. % Nb the inequality (2) becomes $A - B = 0$, to change to $A - B < 0$ at higher concentrations of niobium.

As in the discussion of the U–Mo alloys one notes that a negative temperature coefficient of resistivity may arise if

$$3B - A > 0, \qquad \ldots\ldots(4)$$

and if the residual resistivity is large compared with the thermal resistivity given by the Grüneisen expression. The latter condition is, of course, likely to be satisfied at fairly low temperatures where the unusual behaviour is in fact observed. Further, the residual resistivities are large, Fig. 7, for the U-rich alloys, and the weak concentration dependence is indicative of a large increase in the effective number of free electrons with composition. It is thus evident from the present discussion that the Fermi surfaces in both the U-rich U–Mo and U–Nb alloys lie in regions where the density of states–energy curves possess finite gradients of strong positive curvature.

Since in the uranium-rich U–Nb alloys the addition of Nb with five valency electrons depletes the band of the solvent, the application of a rigid band model should lead to a curve of the variation of the density of states with solute concentration which is concave upwards. The variation of susceptibility at 0°K with composition shown in Fig. 3 may be taken to represent the variation of the density of states with niobium content provided that the empirical relation (Childs, Gardner and Penfold 1960)

$$K = \frac{C}{N(E_0)} \qquad \ldots\ldots(5)$$

is valid, where K is the exchange interaction and C is a constant. This variation is concave downwards for the low niobium content alloys, and so it appears that the addition of Nb to U in concentrations greater than 20 at. % not only alters the degree of occupation of the bands but also their $(N(E), E)$ relation. It should be remarked that values of K and $N(E_0)$ for both the γ U–Mo and pure niobium obey the relation (5) fairly accurately.

In a discussion of the magnetic properties of the transition elements, Kriessman and Callen (1954) concluded that, if the Pauli susceptibility decreased with temperature, the Fermi surface was near a maximum in the density of states curve. Such susceptibility behaviour is exhibited by pure niobium, and thus little change of susceptibility should result when uranium, which enhances the degree of occupation of the bands of niobium, is added in small quantities. This argument is clearly supported by the susceptibility–composition curves shown in Fig. 3, and also by similar results on the Nb–Mo system (Matthias *et al.* 1960). Additional evidence that this band shape is correct for pure niobium was obtained by calculations of A and B from the susceptibility and resistivity data.

Values of $A-B$ and $3B-A$ were obtained from the linear regions of plots of the Pauli susceptibility against T^2 and of $\rho(E, T)/T$ against T^2, where $\rho(E, T)$ is the resistivity. That these plots should be straight lines is evident from the formulae

$$\chi_M' = 2\mu^2 N(E_0)\left[1 + \frac{\pi^2 k^2 T^2}{6}(A-B)\right]_{E=E_0} \qquad \ldots\ldots(6)$$

for the molar Pauli susceptibility χ_M' and

$$\rho(E, T) = \rho(E_0 T)\left[1 - \frac{\pi^2 k^2 T^2}{6}(3B-A)\right]_{E=E_0} \qquad \ldots\ldots(7)$$

for the resistivity, where $\rho(E_0 T)$ is the Grüneisen expression which is proportional to T in the temperature range under consideration. Above the Debye temperature (~254°K), and below 500°K, the plot of $\rho(E, T)/T$ against T^2 was linear. The values of A and B thus obtained were

$$A = \left(\frac{1}{N}\frac{d^2N}{dE^2}\right)_{E=E_0} = -2{\cdot}2\,(\mathrm{ev})^{-2}$$

and

$$B = \left(\frac{1}{N}\frac{dN}{dE}\right)^2_{E=E_0} = 9{\cdot}0\,(\mathrm{ev})^{-2}.$$

The negative value for A clearly supports the previous discussion, as this condition is essential for the Fermi surface to be near a maximum in the $(N(E), E)$ distribution. No great accuracy is claimed for these values of A and B, especially as the Pauli susceptibility was calculated on the assumption of a temperature independent exchange interaction. It may well be that when consistent data is available for the temperature dependence of the thermoelectric power and Hall coefficient, the values will need modification.

ACKNOWLEDGMENTS

The authors are indebted to Dr. G. K. Williamson, formerly of the Metallurgy Division, Atomic Energy Research Establishment, Harwell, and Dr. W. E. Gardner, for the provision of the alloys and also for much valuable discussion, and to the Director, Atomic Energy Research Establishment, for permission to publish the results.

Exchange Effects and Anisotropy Broadening of the Hyperfine Spin Resonance Spectrum of the Biphenyl Negative Ion in Solution

By J. G. POWLES and M. H. MOSLEY

Physics Department, Queen Mary College, University of London

MS. received 27th January 1961

Abstract. The electron spin resonance absorption spectrum of the biphenyl negative ion has been measured at 9·5 mm wavelength in solution in tetrahydrofuran and in diethylene glycol dimethyl ether (DGDE) over the temperature range −90°c to +70°c and for concentrations from $1{\cdot}94\times10^{-3}$ to $4{\cdot}35\times10^{-3}$ M. The normal nine line hyperfine spectrum loses its structure with falling temperature for solution in DGDE at about −70°c independent of concentration. It is thought that this is due to a decrease in motional narrowing of an anisotropic hyperfine interaction comparable in magnitude with the isotropic hyperfine interaction. With rising temperature the hyperfine structure again disappears. This occurs at −34°c for a concentration $4{\cdot}35\times10^{-3}$ M and increases with falling concentration to +37°c at $1{\cdot}94\times10^{-3}$ M. After loss of structure the line continues to narrow with increasing temperature. Similar but less extensive measurements have been possible for solution in tetrahydrofuran. This effect is thought to be due to exchange, i.e. perturbation of the electron spins at encounters between the radicals which are diffusing through the solvent. An analysis is carried out using a theory proposed by Pake and Tuttle in 1959 in which a quantity related to the ratio of exchange frequency to collision frequency is derived and which should be constant and of order unity. We find this quantity to be indeed of order unity over a wide range of temperature and for the two solvents but that it varies significantly nevertheless. These variations have not been explained and show that a more elaborate theory even than that proposed by Kivelson in 1960 is required.

§ 1. Introduction, Experimental Arrangement and Results

We have measured the electron spin resonance absorption line for the biphenyl ($C_6H_5C_6H_5$) negative ion in solution in tetrahydrofuran ($(CH_2)_4O$) and in diethylene glycol dimethyl ether ($CH_3O[(CH_2)_2O]_2OCH_3$, which we call DGDE) over the temperature range −90°c to +70°c and over a range of concentration from $1{\cdot}94\times10^{-3}$ M to $4{\cdot}35\times10^{-3}$ M (2×10^{-3} M corresponds to one ion to 7×10^{3} solvent molecules for tetrahydrofuran). The spectrometer operates at 9·5 mm wavelength, and has been briefly described elsewhere (Powles and Mosley 1961). The derivative absorption signal as a function of field is obtained, as shown for instance in Fig. 1.

The biphenyl negative ion was prepared from pure biphenyl using potassium metal and specially purified and degassed solvents (Balk, Hoijtink and Schreurs 1957). The concentration of free radical, which is not readily controlled in the method of preparation, was calculated from the optical absorption using a Unicam SP.500 spectrophotometer and using the results of Balk *et al.* (1957)

for calibration. The solutions remained stable for at least several days at room temperature depending on concentration. They could be heated to 60°c for up to thirty minutes without appreciable degradation.

The viscosity of tetrahydrofuran was only available above 0°c (Timmermans 1950) and that of DGDE was not available. The viscosities, given in Fig. 2, were measured using a thermostatted Ostwald viscometer. The values are thought to be accurate to ±5% and they agree with Timmerman's quoted values to this accuracy where the comparison is possible.

Tetrahydrofuran and DGDE show no apparent freezing point in the temperature range covered and none is reported in the literature. We believe DGDE forms a supercooled liquid and eventually a glass although the glassy state was probably not attained in our measurements. The usual hyperfine spectrum of biphenyl approximates to a nine line spectrum with a spacing of approximately 2·9 gauss (8·1 Mc/s) between lines. This is as reported by De Boer (1956) and is shown in Fig. 1 (*c*). The spectrum is only apparently nine line, some structure is not resolved, and so the spacing 2·9 gauss is not the hyperfine interaction parameter.

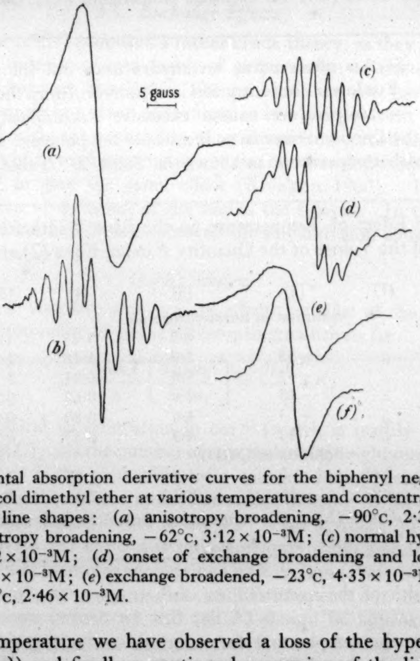

Fig. 1. Experimental absorption derivative curves for the biphenyl negative ion in diethylene glycol dimethyl ether at various temperatures and concentrations illustrating the various line shapes: (*a*) anisotropy broadening, −90°c, $2{\cdot}37 \times 10^{-3}$M; (*b*) partial anisotropy broadening, −62°c, $3{\cdot}12 \times 10^{-3}$M; (*c*) normal hyperfine splitting, −33°c, $3{\cdot}12 \times 10^{-3}$M; (*d*) onset of exchange broadening and loss of structure, −28°c, $3{\cdot}04 \times 10^{-3}$M; (*e*) exchange broadened, −23°c, $4{\cdot}35 \times 10^{-3}$M; (*f*) exchange narrowed, 0°c, $2{\cdot}46 \times 10^{-3}$M.

For rising temperature we have observed a loss of the hyperfine structure (Figs 1 (*d*) and (*e*)) and finally a continued narrowing of the line (Fig. 1 (*f*)). This is similar to the effect noted by Pake and Tuttle (1959) for a solution of diphenyl picryl hydrazil (DPPH) in toluene and by Hausser (1959) for α, γ-bisdiphenylene β-phenyl allyl (BPA) in ethyl alcohol.

The temperature at which the hyperfine structure just disappears, which we call the exchange temperature (say between the two spectra of Figs 1 (*d*) and (*e*)), depends markedly on concentration in DGDE as indicated in Table 1.

The effect of concentration at room temperature only, for DPPH in benzene, was studied by Hutchison, Pastor and Kowalsky (1952).

Table 1. The Effect of Concentration on the Exchange Temperature and Values of the Quantity F (Eqn (2))

(1)	(2)	(3)	(4)
Solution in DGDE			
1·94	+37	0·83	0·67
2·37	− 2	1·65	1·24
2·46	−12	2·16	1·62
3·04	−22	3·1	1·95
4·35	−34	4·7	2·17
Solution in tetrahydrofuran			
3·3	+50	0·47	0·21

(1) Concentration $C \times 10^3$(M); (2) exchange temperature (°c); (3) viscosity (cP); (4) value of F.

The same effect is observed in tetrahydrofuran but for one concentration only (Table 1). For lower concentration in tetrahydrofuran the structure persists until the rise in temperature causes excessive decomposition. For higher concentration the line is narrow over the whole temperature range, but the line width varies with temperature as shown in Table 2. Table 2 also shows the variation in width of the narrowed, i.e. structureless, line for two solutions in DGDE.

Table 2. The Effect of Temperature on the Line Width for Narrowed Lines and the Values of the Quantity F using Eqns (2) and (3)

(1) Concentration $C \times 10^3$(M); (2) temperature (°c); (3) line width δH (gauss); (4) viscosity (cP); (5) value of F.

On lowering the temperature for solutions in DGDE the structure again disappeared (Figs 1 (*a*) and (*b*), note the difference between Figs 1 (*b*) and (*d*)). A similar effect has been reported by Hausser (1959) for BPA in ethyl alcohol and by the authors (Powles and Mosley 1961) for peroxylamine disulphonate in water/glycerol. The temperature at which this occurs is not readily defined but the general effect is shown by the sequence of Figs 1 (*a*), (*b*) and (*c*). This change seems to be independent of concentration over the range measured (see Table 1) and it occurs at $-70 \pm 15\,^{\circ}\mathrm{C}$. It is not clear why some variation in the results from sample to sample, run to run and concentration to concentration occurred.

§ 2. INTERPRETATION OF THE RESULTS

We wished to study further the presumed exchange narrowing effects for free radicals in solution discussed by Pake and Tuttle (1959) and to extend the results of Hausser (1959). The system biphenyl negative ion in tetrahydrofuran, the usual solvent, was not sufficiently flexible. We considered this to be due to the rather small variation of viscosity of tetrahydrofuran over the liquid temperature range and to the fact that the viscosity was too low. De Boer (1956) used tetrahydrofuran or 1, 2-dimethoxyethane which has a similar viscosity range to tetrahydrofuran. It is not easy to find a suitable solvent in which the biphenyl radical can be formed in a suitable range of concentration and in which it is stable over a wide temperature range. DGDE has proved very suitable.

2.1. *Exchange Effects*

Pake and Tuttle (1959) proposed a rather crude theory, as they admit, for the effect of exchange narrowing as a result of perturbation of the electron spins during encounters between the ions. The problem has two parts: one is to calculate how frequently in a given concentration in a given solvent the ions meet, and the other to calculate the probability of an interaction on collision sufficiently strong to cause loss of hyperfine structure or the number and frequency of weak collisions required to give the same effect (Kivelson 1960). The former is essentially a problem of diffusion of the ion in the solvent. In the absence of self-diffusion data Pake and Tuttle removed the self-diffusion constant D by the Stokes–Einstein relation

$$D = kT/6\pi a_r \eta, \qquad \ldots\ldots(1)$$

where η is the shear viscosity and a_r is an effective radius of the diffusing ion. They find for the frequency of phase interrupting collisions f_e,

$$f_e = \frac{N_r kT}{\eta}\left[\frac{4zpa_s^3}{3\lambda^2 a_r}\right] = \frac{N_r kT}{\eta} F, \qquad \ldots\ldots(2)$$

where N_r is the radical concentration in cm^{-3} (which is readily related to the molar concentration C); z is the number of new molecular neighbours encountered per diffusion step; p is the probability of a collision being effective in causing spin dephasing; a_s is the solvent molecular radius introduced via $N_s^{-1} = 4\pi a_s^3/3$ (it would probably be slightly better to use $N_s^{-1} = 8a_s^3$), where N_s is the number of molecules of solvent per cm^3; λ is the elementary jump step in the diffusion process. Rather similar formulae are obtained by Kivelson (1960) if the parameters are interpreted slightly differently. Pake and Tuttle point out that the quantity in the square brackets (which we will call F) should be approximately unity. This is seen by taking the plausible values, $z = 6$, $p = \frac{1}{2}$, $\lambda = 2a_s$ so that $F = a_s/a_r$, and if $a_s \simeq a_r$, $F \simeq 1$.

The experimental results in Table 1 determine a particular value of f_e. At the temperature at which the hyperfine structure is removed by exchange the exchange rate f_e must be comparable with the hyperfine splitting frequency.

In this case there are three sources of hyperfine splitting due to the three types of protons. It would be pointless to try to account for this in detail with the present theory and we shall use the apparent experimental splitting 8·1 Mc/s. With Pake and Tuttle we assume that f_e is about half this, i.e. 4 Mc/s. Hence at the temperature at which the structure disappears f_e is 4 Mc/s, and we calculate $f_e\eta/N_rkT$ and obtain the estimate of F given in Table 1 using Fig. 2.

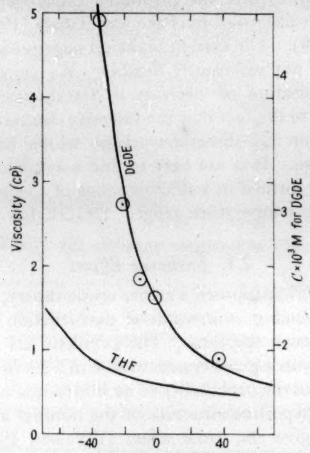

Fig. 2. The curves represent measured viscosity (left-hand ordinate) as a function of temperature for tetrahydrofuran and DGDE. The points show the exchange temperature (abscissa) as a function of ion concentration (right-hand ordinate) in DGDE.

F is indeed close to unity but it varies considerably with concentration although not as much as the viscosity itself. For solution in tetrahydrofuran F is considerably smaller than in DGDE. This difference is not explained by the change in the ratio a_s/a_r which we estimate from molecular volumes of the liquids to change only by the factor 0·75 from DGDE to tetrahydrofuran. It might be regarded as due to appreciable solvation in tetrahydrofuran giving an unexpectedly high a_r in this solvent. Pake and Tuttle find for DPPH in toluene $F=0{\cdot}08$, whereas in this case $a_s/a_r \simeq 0{\cdot}6$. However, high concentrations of radical were used (140×10^{-3} M) and the possibility of multiple collisions cannot be excluded. For BPA in ethyl alcohol, Hausser's results give $F=8$, assuming the exchange temperature is -40°c, and his concentration is exactly 10^{-3} M—we suspect it might have been higher which would lower F.

According to Eqn (2) $\eta \propto CF$ at the exchange temperature where $C\propto N_r$ is the molar concentration. In fact, as shown in Fig. 2, the experimental relation between η and C for DGDE is $\eta=1{\cdot}6C-2{\cdot}1$. Unfortunately for tetrahydrofuran there is only one pair of values of η and C.

As pointed out by Pake and Tuttle, it is also interesting to study the narrowed line with hyperfine structure well removed since then we can again estimate f_e

through the relation (Kubo and Tomita 1954)

$$f_e \simeq \frac{\gamma}{2\pi} \frac{\Delta H_2{}^2}{\delta H}, \qquad \ldots\ldots(3)$$

where γ is the electron spin gyromagnetic ratio, $\Delta H_2{}^2$ is the second moment of the spectrum before exchange narrowing and δH is the line width. Thus a study of δH as a function of temperature also gives f_e, and hence together with η another check on the theory. We take $\Delta H_2{}^2 = 16$ gauss^2 for biphenyl, the experimental second moment of the hyperfine line before narrowing. F is given in Table 2. The value is again of order unity but higher than in Table 2. Part of the discrepancy may reside in the approximate relation (3) which, as shown by Kivelson (1960), depends on the situation by a factor 2 or more. Pake and Tuttle found $F = 0{\cdot}13$ for DPPH in toluene at 28°c. The results of Hutchison, Pastor and Kowalsky (1952) for DPPH in benzene correspond to $F = 0{\cdot}6$, $2{\cdot}9$, and $4{\cdot}2$ for 0·2, 0·02, and 0·0093 M respectively. We note that in our results F varies to a considerable extent with temperature, about as much as the viscosity itself. The change in F with solvent is in the correct direction and nearer to the expected change than found from the 'exchange temperature' (Table 1).

The estimated value of f_e from the exchange narrowing even at -62°c for the $4{\cdot}3 \times 10^{-3}$ M solution in tetrahydrofuran is 8 Mc/s. This is larger than the critical f_e of 4 Mc/s and so makes it clear why the hyperfine structure is still exchange narrowed even at this low temperature. It is also consistent with the observation of hyperfine structure over the whole temperature range below $+50$°c for a concentration of $3{\cdot}3 \times 10^{-3}$ M since f_e is sufficiently lower.

We conclude from the variation in the value of F, using our results as well as those of others, that the theory leaves a lot to be desired, as no doubt Pake and Tuttle would admit. Any attempt to put the theory on a sounder basis, particularly as regards the effectiveness and nature of the encounters in causing exchange narrowing, introduces considerable difficulties, as we see from Kivelson's (1960) rather inconclusive analysis of earlier results.

It ought to be less difficult to reduce the uncertainties associated with the calculation of the frequency of encounter by use of a measured self-diffusion coefficient and a closer study of the diffusion process. Alternatively the rate of radical motion might be more directly obtained from dielectric loss measurements of the polar solvents, as has been found profitable for the peroxylamine disulphonate ion in solution (Powles and Mosley 1961).

2.2. *Anisotropy Broadening*

The loss of hyperfine structure in the region of -70°c for solution in DGDE, as shown in Fig. 1 (*a*), is we believe due to the anisotropic hyperfine interaction which above about -70°c is motionally averaged out to reveal the isotropic interaction only. Pake and Tuttle (1959) have explained similar effects observed by Hausser (1959) in this way. We have already (Powles and Mosley 1961) discussed a similar but rather more elaborate effect.

Following a similar motional narrowing calculation given by Bloembergen, Purcell and Pound (1948), we find for the anisotropic contribution δH_{aniso} to the line width arising from a rigid lattice contribution $\delta H_{\text{r.l.}}$ which is motionally narrowed by radical reorientation at rate ν_c,

$$\delta H_{\text{aniso}} \simeq \delta H_{\text{r.l.}}{}^2 \frac{\sqrt{3}}{\pi^2} \gamma \nu_c{}^{-1}. \qquad \ldots\ldots(4)$$

An independent estimate of ν_c is obtained by use of the formula for the Brownian reorientational motion of a spherical molecule in a viscous medium,

$$\nu_c = \frac{3kT}{8\pi^2 \eta a_r^3}. \qquad \ldots\ldots(5)$$

Hence, using $\eta = 55$ cP (Fig. 2, extrapolated) at −70°c and $a_r \simeq 3{\cdot}2$ Å (from the molecular volume of liquid biphenyl), we obtain $\nu_c \simeq 60$ Mc/s at −70°c. When, as at this temperature, the isotropic hyperfine structure is just appearing we may assume $\delta H_{\text{aniso}} \simeq \frac{1}{3}\delta H_{\text{iso}}$ and we recall that $\delta H_{\text{iso}} \simeq 2{\cdot}9$ gauss. Substituting these values in Eqn (4) gives $\delta H_{\text{r.l.}} \simeq 4{\cdot}3$ gauss. In other words the anisotropic and isotropic hyperfine interactions are comparable in magnitude. This seems a reasonable result.

§ 3. CONCLUSION

It is shown that the observed loss of structure at low temperatures of the hyperfine spin resonance spectrum of the biphenyl ion in DGDE, which is independent of ion concentration, may be due to anisotropic hyperfine interaction which suffers motional averaging and which is comparable in magnitude with the isotropic interaction. The loss of structure and the subsequent continued narrowing at high temperatures which are very concentration dependent are thought to be due to exchange effects. The results are broadly in agreement with the theory of Pake and Tuttle but show significant departures which have not been satisfactorily explained.

ACKNOWLEDGMENTS

The magnet used in these experiments was provided by the Department of Scientific and Industrial Research. Some of the microwave components were loaned by the Services Electronic Research Laboratory. Mr. J. Blackwell of our Chemistry Department suggested using DGDE.

Multiple Proton Magnetic Resonance Relaxation in a Number of Molecular Liquids

By J. G. POWLES and D. J. NEALE
Physics Department, Queen Mary College, University of London

MS. received 1*st February* 1961

Abstract. Experimental results are given for the proton spin-lattice relaxation times T_1 at 47·5 Mc/s for liquid ethyl benzene, bromobenzene, chlorobenzene, fluorobenzene, benzene, aniline, paraxylene, mesitylene and methyl alcohol over the whole liquid range including some supercooling. Where more than one chemical type of proton is present the distinct T_1 values have been measured by a method described earlier this year by Powles and Neale. In ethyl benzene the ring proton T_1 has a minimum but the ethyl proton T_1 does not (as reported by Powles and Neale for toluene), thus emphasizing the difference in their nature. Motional correlation frequencies are deduced from the T_1 values. In ethyl benzene and aniline the substituent correlation frequency agrees with the dielectric correlation frequency. Methyl alcohol is different. The predicted ring proton correlation frequencies are lower to an extent which depends on the particular molecule and on the interpretation adopted. The results are related to shear viscosity data. $\eta T_1/T$ should not depend on temperature but does, in a way depending on the molecule and on the individual value of T_1. Thus the introduction of the viscosity in this way is not very helpful.

It is concluded that in these liquids composed of non-spherical molecules the thermal molecular motions are complex, including motion about different axes at different rates. This complexity should be borne in mind when considering other motionally dependent properties of liquids.

---

§ 1. INTRODUCTION

NUCLEAR magnetic resonance relaxation times can give information about thermal motions. This is because the relaxation is often due to direct dipolar interactions between the magnetic nuclei which are modulated by the random thermal motions. For two or more magnetic nuclei in a molecule the internuclear distance is usually fixed, but the reorientational molecular motion varies the angle which the line joining them makes with the externally applied static magnetic field. In some cases the molecule also has internal flexibility, and then intramolecular magnetic interactions are modulated in this way also. The latter affects the relaxation times in ethyl benzene for instance. Interactions between magnetic nuclei in different molecules also contribute to the relaxation, and so diffusional or translational molecular motion can be investigated. It is desirable in interpreting magnetic resonance data in terms of molecular motion to have independent information, and we use, where appropriate, the dielectric loss correlation frequencies. These indicate directly the motion of the electric dipolar vector. We also consider the relation of our results to shear viscosity data.

We have again (Powles and Neale 1961) taken molecules with more than one chemical type of proton and the several relaxation times must be interpreted. It is necessary to postulate rather complex motions of the molecules in the liquid.

§ 2. Experimental Technique and Results

The proton magnetic resonance spin–lattice relaxation times T_1 have been measured by a method described earlier (Powles and Neale 1961, to be referred to as I). In this method the proton resonance signal in a moderately high resolution apparatus is saturated by a strong radio-frequency field at resonance, and the recovery after removal of this field is monitored by means of a weak radio-frequency field and appropriate field sweep. When only one chemical type of proton is present the method has no particular advantage over pulse methods (Carr and Purcell 1954), but we have nevertheless used it to measure benzene and its monohalogen derivatives (Fig. 4). When more than one type of chemically shifted proton is present the method has considerable advantage over other transient methods since the signal from each type of proton may be observed separately and its relaxation behaviour studied. As for toluene (see I), we find in all cases that the relaxation of chemically different sets of protons is distinct in the sense that the recovery of one set appears to be independent of what is done to any other, and it is in all cases exponential. We therefore report a T_1 value as a function of temperature for each type of proton. In many cases the several T_1's are very different in magnitude and behave differently with temperature.

The measurements were made at 47·5 Mc/s. The accuracy of measurement of T_1 is to about $\pm 7\%$ for the longer T_1's, depreciating to about $\pm 15\%$ for the shorter ones. The materials were Analar grade and were fractionally distilled and purified. Dissolved atmospheric oxygen was removed by a freeze–pump–thaw technique or by a sintered disk method. Contamination by oxygen is readily detected (see I). Measurements were made to within a few degrees of the boiling point at atmospheric pressure and in most cases well below the melting point by careful supercooling. The actual T_1 values varied from 0·2 to 50 seconds.

Shear viscosity values over the required temperature range were not available in the literature. The literature values were checked and the temperature range extended where necessary by means of a thermostatically controlled Ostwald viscometer. Our values agreed with the literature values to $\pm 5\%$ but at low temperatures they are less accurate, possibly to $\pm 10\%$.

§ 3. Discussion of the Results

There is little doubt that the observed spin–lattice relaxation times are mainly due to direct magnetic dipole–dipole interaction modified by the thermal motion. The results are analysed in much the same way as for toluene (see I) but in less detail since the procedure and its limitations were discussed for that liquid.

Valuable auxiliary information about molecular motion is obtainable from dielectric relaxation correlation times. However, for most of our substances this information is lacking or fragmentary and we shall use shear viscosity data to some extent. The latter are more readily available but are less desirable, shear viscosity being a rather indirect method of obtaining information about molecular motion as is magnetic resonance itself.

A satisfactory study of molecular motion by magnetic resonance demands more information than we have, for example, T_1 as a function of resonance frequency and the T_2 values, but it is worth making a preliminary analysis with the present data.

Present theories of magnetic resonance relaxation are not adequate to deal with the complex situations encountered here but we use the following formula (based on Bloembergen, Purcell and Pound 1948, Solomon 1955, Kubo and Tomita 1954, Skrotskii and Kokin 1959, Powles and Neale 1961)

$$\frac{1}{T_1}=\frac{3}{10}\frac{1}{2\pi\nu_r}\gamma^4\hbar^2\left[\frac{2}{n_g}\sum_{i>j}d_{ij}{}^{-6}+\frac{6}{5}\pi\frac{n_m}{2}N_0a^{-3}\right]f\left(\frac{\nu_r}{\nu_c}\right), \quad \ldots\ldots(1)$$

where

$$f\left(\frac{\nu_r}{\nu_c}\right)=\frac{\nu_r/\nu_c}{1+(\nu_r/\nu_c)^2}+\frac{4\nu_r/\nu_c}{1+(2\nu_r/\nu_c)^2},$$

ν_c is the motional correlation frequency, $1/(2\pi\tau_c)$, ν_r the resonant frequency (47·5 Mc/s), γ the proton gyromagnetic ratio, d_{ij} the interproton distances within a molecule, N_0 the number of molecules per cubic centimetre, n_m the number of protons per molecule, n_g the number of protons in the group being considered, and a an effective radius of the diffusing molecule. According to Skrotskii and Kokin (1959) the second term in square brackets in (1) is only valid for $\nu_c > \nu_r$, but this condition will usually be satisfied and in any case it is only applicable to pairs of protons. We have generalized this term from a pair to n_m protons by the factor $n_m/2$ which is no doubt inexact but makes some allowance for the fact that there are more than two protons per molecule. It will be shown that this external term is usually smaller than the first, although by no means negligible, in the present substances. It is more important for the ring than for the substituent protons.

The first term in Eqn (1) for a pair of protons at fixed separation d is known to be d^{-6} (Solomon 1955), and to a good approximation for a trio of protons disposed on an equilateral triangle of side d (Hubbard 1958) it is $2d^{-6}$. For four protons arranged tetrahedrally it is $\frac{3}{2}d^{-6}$. In other cases we use the expression $(2/n_g)\Sigma_{i>j}d_{ij}{}^{-6}$ which gives the above particular results and which appears in the computation of the rigid lattice second moment for a 'powder' sample (Van Vleck 1948). It surely shows the correct trend. An alternative formula proposed by Gutowsky and Woessner (1956) has $\frac{1}{2}\Sigma_j r_{ij}{}^{-6}$ in place of $(1/n_g)\Sigma_{i>j}r_{ij}{}^{-6}$. This has the disadvantage that it depends on the nucleus chosen for groups where all r_{ij} are not equal.

We have in addition to allow for different magnetic nuclei, e.g. ^{19}F in fluorobenzene, by additional terms which however will prove to be small. We have also to allow for the effect of non-resonant protons when two or more chemically shifted sets are present. It is suggested in I that their contribution to relaxation is reduced as compared with that from resonant nuclei. It is necessary, further, to allow for complex molecular motion not described by a single ν_c, and then Eqn (1) will be generalized as in I. Also the correlation frequency for intermolecular interaction is not necessarily the same as for intramolecular since it depends more on translational than reorientational motion.

In the absence of better information we shall usually assume that the two correlation frequencies are the same, to the extent implied by Eqn (1).

We first establish the order of magnitude of the terms in Eqn (1). In benzene and the benzene derivatives studied here N_0 ranges from 7×10^{21} cm^{-3} for benzene to 4×10^{21} cm^{-3} for mesitylene. We shall assume that $(2a)^3$ is the available volume per molecule, i.e. $(2a)^{-3} = N_0$. Hence

$$\frac{6}{5}\frac{\pi n_m}{2} N_0 a^{-3} \simeq 3 \times 10^{-3}\ \text{Å}^{-6}.$$

For a methyl group $(2/n_g)\Sigma_{i>j} d_{ij}^{-6} = 63 \times 10^{-3}$ Å^{-6} and for the six protons in benzene $9{\cdot}2 \times 10^{-3}$ Å^{-6}. Hence the external term is less than the internal although its exact value is rather uncertain. This external term should also probably suffer reduction by a factor for molecules with more than one type of proton (see I). The argument that the intermolecular contribution is the minor one is somewhat reinforced by measurements on proton containing molecules in solution in a proton-free solvent. However, solution may change the molecular correlation frequencies and even the type of motion. The former may be allowed for to some extent by use of shear viscosity (see § 3.1). An analysis by Bovey (1960)† suggests that the intermolecular contribution is probably not more than 50% of the total interaction even in the case of benzene where inter- and intramolecular proton distances are comparable. Our rough calculation based on Eqn (1) gives 30% for benzene. A rather more elaborate analysis of solution results by Mitchell and Eisner (1960) using viscosity still, in our opinion, does not clear up this difficulty. A more reliable test would be to compare the pure liquid T_1's with those for dilute solution in the perdeutero compound. It would then be reasonable to suppose that the molecular motion and the correlation frequencies would be little affected, and so parameters for the pure normal liquid would be obtained.

In the absence of anything better, we shall usually suppose the external interaction to make a minor contribution to $1/T_1$. In that case Eqn (1) can be written

$$\frac{1}{T_1} = \frac{I}{\nu_r}\frac{1}{1{\cdot}42} f\left(\frac{\nu_r}{\nu_c}\right), \qquad \ldots\ldots (2)$$

where

$$I = 1{\cdot}42 \times \frac{3}{10}\frac{1}{2\pi}\gamma^4 \hbar^2 \frac{2}{n_g}\sum_{i>j} d_{ij}^{-6}$$

and hence $I/\nu_r = 1/T_{1\,\text{min}}$. The symbol I is introduced to express the theoretical interaction and distinguish it from the experimental quantity $1/T_{1\,\text{min}}$ which may or may not be available and is not always to be taken as I/ν_r. Also, of course, I/ν_r may depend on temperature.

3.1. *Ethyl Benzene*

We consider ethyl benzene ($C_6H_5C_2H_5$) first since its molecular structure is rather similar to that of toluene ($C_6H_5CH_3$, see I). It will also facilitate the interpretation of the results for the monohalogen substituted benzenes which might appear to be simpler cases to deal with first. The T_1 values for ethyl benzene in Fig. 1 are similar to those of toluene in that the ethyl group signal has no minimum in the available temperature range whereas the ring proton signal does. We were not able to resolve the methyl and methylene proton signals and so $T_{1\,\text{ethyl}}$ is a composite T_1. Probably $T_{1\,\text{methyl}}$ and $T_{1\,\text{methylene}}$ do not differ much. The minimum of $T_{1\,\text{ring}}$ is 0·32 sec whereas it was 1·42 sec in toluene. Neglecting the external interaction we find from $T_{1\,\text{min}}$ and Eqn (2), $I/\nu_r = 3{\cdot}1\ \text{sec}^{-1}$ and $\nu_c = 1{\cdot}62\nu_r = 77$ Mc/s at 148°K. Using this value of I in Eqn (2) and assuming that I is independent of temperature, we find $\nu_{c\,\text{ring}}$ as a function of temperature as shown in Fig. 2.

---

† N.B. The title of this article is a statement of the problem, not the conclusion reached.

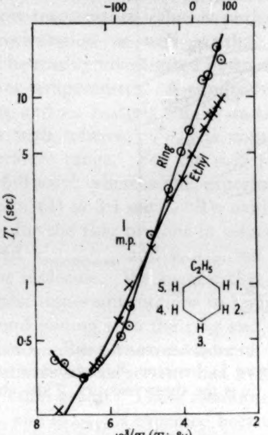

Fig. 1. Proton spin–lattice relaxation times at 47·5 Mc/s for the ethyl and ring protons in liquid ethyl benzene.

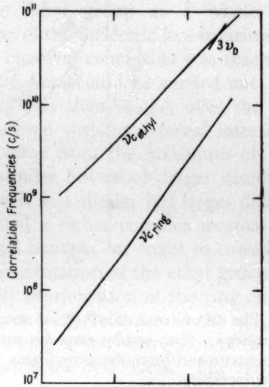

Fig. 2. Correlation frequencies for ethyl benzene deduced from the proton magnetic relaxation times, as described in the text. ν_D is the dielectric correlation frequency (Petro and Smyth 1957).

For $T_{1\,\text{ethyl}}$ we must calculate I. The weighted mean value of $(2/n_g)\Sigma_{i>j}\,d_{ij}^{-6}$ for the two groups is $50{\cdot}3\times10^{-3}\,\text{Å}^{-6}$, so that $I/\nu_r = 41\ \text{sec}^{-1}$ and $\nu_{c\,\text{ethyl}}$ obtained from Eqn (2) is given in Fig. 2. The dielectric correlation frequency ν_D is also given in Fig. 2 (Petro and Smyth 1957) plotted as $3\nu_D$ which is probably to be compared with ν_c (Bloembergen, Purcell and Pound 1948). ν_D is only available over the temperature range 20°C to 60°C.

When $\nu_c \gg \nu_r$ we expect $T_1 \propto \nu_c$ from Eqn (1) and possibly $T/\eta \propto \nu_c$ in view of the Stokes–Einstein relation (see Eqn (3)). Some authors therefore consider whether $\eta T_1/T$ is independent of temperature. This function is given in Fig. 3 for the T_1's of ethyl benzene and shows a considerable variation with temperature,

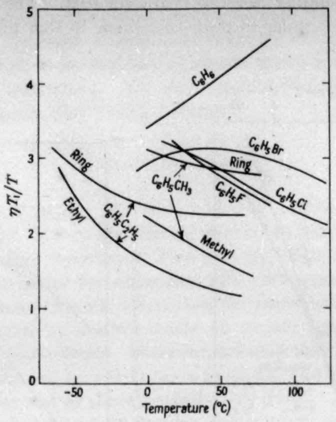

Fig. 3. The dependence of $\eta T_1/T$ on temperature for ethyl benzene for the ring and ethyl protons. Also similar data for toluene (from I), benzene, fluorobenzene, chlorobenzene and bromobenzene (using Fig. 4). η is the shear viscosity, T the absolute temperature.

especially at low temperatures. This may be contrasted with the case of *n*-octyl bromide (Powles and Hartland 1960) and with water (Simpson and Carr 1958) where $\eta T_1/T$ varies much less. It is well known that this use of viscosity tends to be more valid for low viscosity liquids than for high viscosity, and the tendency for $\eta T_1/T$ to vary less with temperature at high temperatures may be related to this fact. The greater constancy of $\eta T_1/T$ for the ring protons could mean that the ring motion is the more closely related to viscosity.

An apparent radius of the moving entity may be deduced from the viscosity and the nuclear correlation time through the appropriate Einstein–Stokes formula,

$$a^3 = \frac{3k}{8\pi^2 \nu_c} \frac{T}{\eta}. \qquad \ldots\ldots(3)$$

This gives at 25°C, $a = 1{\cdot}8$ Å from $\nu_{c\,\text{ethyl}}$ and $a = 3{\cdot}5$ Å from $\nu_{c\,\text{ring}}$. The effective molecular radius deduced from the density is 3·0 Å. The van der Waals dimensions of the ethyl group and of benzene are approximately 1·8 Å and 2·3 Å assuming approximate enclosing ellipsoids (Perrin 1934). There is a temptation therefore to think that the ethyl group and the whole molecule move almost independently as bodies of appropriate size. However, a similar calculation for toluene gives similar results, but it is not reasonable that the motion of the methyl group and the molecule should be independent (except for methyl C_3 reorientation which has special effects). For this reason this explanation of the difference in correlation frequencies was not proposed in I and is not considered a likely explanation here.

Figure 2 shows that there is a close correspondence between $3\nu_D$ and $\nu_{c\,\text{ethyl}}$. This is very satisfactory since the ethyl group carries the electric dipole. We doubt if the difference in rate of variation of $3\nu_D$ and $\nu_{c\,\text{ethyl}}$ with temperature seen in Fig. 2 is significant since the results of Petro and Smyth (1957) showed a similar divergence for toluene and differed in this respect from other dielectric measurements.

It seems unlikely that $\nu_{c\,\text{ethyl}}$ should fall at a lower rate with falling temperature. The low temperature value is perhaps beginning to be affected by the methyl C_3 reorientation as well as that of the ethyl group as a whole. This would be readily investigated by an extension of the dielectric loss measurements to lower temperatures. A similar but not identical conclusion was reached for toluene and an analysis similar to that given here could be carried out.

As with toluene, $\nu_{c\,\text{ring}}$ is considerably less than $\nu_{c\,\text{ethyl}}$ over the whole temperature range. For the ring protons, even without external interactions, $I/\nu_r = 6{\cdot}0\ \text{sec}^{-1}$ whereas the experimental value from the minimum of $T_{1\,\text{ring}}$ and Eqn (2) is $3{\cdot}1\ \text{sec}^{-1}$. To explain a similar but much larger discrepancy in I/ν_r for the ring protons in toluene as well as a similar but larger difference between $\nu_{c\,\text{substituent}}$ and $\nu_{c\,\text{ring}}$, we suggested a rather complex motion of the toluene molecule. We suggest that for ethyl benzene we ought to consider the two most important motions to be firstly reorientation of the ethyl group about the bond joining it to the ring and secondly reorientation of the ring about its 'C_2' axis. Reorientation about a 'C_6' axis (perpendicular to the ring) may be relatively less important than in toluene owing to the obstruction of the much larger ethyl group. These assumptions explain the basic facts. The agreement of $3\nu_D$ and $\nu_{c\,\text{ethyl}}$ is expected because the motion of the dipole is essentially the same as that of the ethyl protons. The slower motion C_2 and possibly C_6 will not affect either to any extent. If the C_2 motion controls $\nu_{c\,\text{ring}}$ the theoretical value of I/ν_r is smaller than that given above because the interactions of ring protons 1 and 2 and 4 and 5 in Fig. 1 are not modulated by the motion and so contribute little to T_1. Interactions 1 and 3 and 1 and 4 are reduced in effective contribution to T_1. A revised estimate of I/ν_r is $4{\cdot}2\ \text{sec}^{-1}$ which is closer to the observed value $3{\cdot}1\ \text{sec}^{-1}$. This argument demands some reconsideration of the external interaction since it could be that the translational motion of the molecules is associated with $\nu_{c\,\text{ring}}$ rather than $\nu_{c\,\text{ethyl}}$. This is only important for $\nu_{c\,\text{ethyl}}$ and increases the contribution from the external interaction by $\nu_{c\,\text{ethyl}}/\nu_{c\,\text{ring}} \simeq 6$ at 25°C (since $\nu_c \gg \nu_r$). The two terms in Eqn (1) would therefore be 50·3 and 18, so that the external interaction is still the less important one for the ethyl protons within the approximation of this analysis. The comparison for the ring protons remains unaffected. Even a serious underestimation of the external interaction for the ring protons could not explain the difference between $\nu_{c\,\text{ethyl}}$ and $\nu_{c\,\text{ring}}$.

The difference between $\nu_{c\,\text{ethyl}}$ and $\nu_{c\,\text{ring}}$ can be explained in a number of ways. We have already mentioned the viscous reorientation of a quasi-independent ethyl group. We have given a detailed discussion of the difference in the ν_c's for toluene (I). Since the present case is no more conclusive we shall not reproduce the arguments here. A worth-while analysis awaits a much more thorough knowledge of liquids and a more detailed knowledge of the nuclear resonance parameters.

We emphasize that the motions we consider are a first approximation to the actual motion of the molecules but that they should be seriously considered in any explanation of transport, and possibly other, properties of this liquid.

3.2. *Fluorobenzene, Chlorobenzene and Bromobenzene*

The T_1 values for the ring proton are given in Fig. 4. Although the liquids were supercooled to a considerable extent no minimum in T_1 was attained.

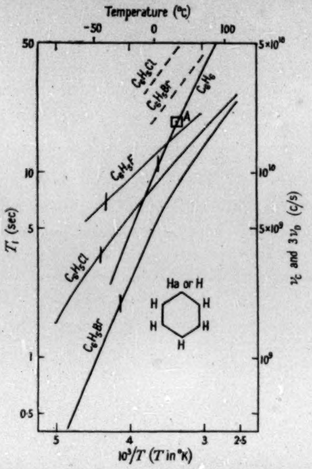

Fig. 4. Proton spin–lattice relaxation times for liquid benzene, fluorobenzene, chlorobenzene and bromobenzene. The right-hand scale indicates estimated values of ν_c (except for benzene). Values of $3\nu_D$ (broken lines) are also given for chlorobenzene and bromobenzene. $T_1 = 19$ sec at 25°c for benzene (A) is widely reported in the literature. Vertical bars on curves indicate the melting temperature.

We therefore assume $\nu_c \gg \nu_r$ and take the calculated value (§ 3.1) $I/\nu_r = 6{\cdot}0\,\mathrm{sec}^{-1}$. Hence from Eqn (2), $\nu_c = 10^9 T_1$ and this scale is given on the right-hand ordinate in Fig. 4. Since all three molecules are polar we can again compare ν_c and $3\nu_D$, although ν_D is only available in a small temperature range near room temperature. Values of $3\nu_D$ for bromo- and chlorobenzene (Branin and Smyth 1952, Hennelly, Heston and Smyth 1948) are given in Fig. 4. The only available value for fluorobenzene is $3\nu_D = 8{\cdot}6 \times 10^{10}$ c/s at 21°c (Poley 1955). $3\nu_D$ is much larger than $\nu_{c\,\mathrm{ring}}$. At 21°c in particular, $3\nu_D/\nu_c = 5{\cdot}5$, $4{\cdot}0$ and $3{\cdot}3$ for fluoro-, chloro- and bromobenzene respectively. In view of the analysis presented for toluene and ethyl benzene and remembering that ν_D refers to the reorientation of the ring to halogen bond while ν_c refers to the reorientation of the ring, we conclude that these differences are significant. (For toluene and ethyl benzene where a minimum *is* attained, the experimental value of I/ν_r is less than $6{\cdot}0\,\mathrm{sec}^{-1}$. For the benzene ring protons and monohalogen benzenes with a lower density of protons it should be even lower. The difference between $3\nu_D$ and ν_c may therefore be even greater than given above.) We conclude that the motion of these molecules is also complex, although the data given here hardly warrant an elaboration of this statement.

Chlorobenzene should perhaps be rather similar to toluene in view of the comparable size of the chlorine atom and the methyl group. We were unable to supercool chlorobenzene sufficiently to attain a minimum of $T_{1\,\mathrm{ring}}$. However, the lowest observed value of $T_{1\,\mathrm{ring}}$ is 1·5 sec and so the minimum must certainly be below the value 1·4 sec observed in toluene, in spite of the lower proton concentration. Toluene and chlorobenzene do not therefore seem obviously similar. For bromobenzene the lowest value of T_1 is 0·45 sec, i.e. well below the minimum value for toluene and only just above the minimum for ethyl benzene. Bromobenzene may therefore be comparable with ethyl benzene and it may be the bulky substituent which gives this result.

Further information about fluorobenzene is obtainable from a study of the relaxation of the ^{19}F nucleus. Owing to the weakness of the signal we were unable to do more than confirm that T_1 for ^{19}F does not differ greatly from the proton T_1.

3.3. *Benzene*

We also give in Fig. 4 our results for benzene itself. One might have expected a uniform gradation from bromobenzene through chlorobenzene and fluorobenzene to benzene, but in fact benzene is very different. This is not due specifically to the effect of the extra proton since this only increases I/ν_{r} by the factor 1·25, but it may well be associated with the increase in symmetry. This peculiarity of benzene as compared with substituted benzenes does not appear in the shear viscosity. $\eta T_1/T$ for benzene in Fig. 3 shows a strong *rise* with temperature. To our knowledge this has not been reported before. Bromobenzene shows a maximum of $\eta T_1/T$. Chlorobenzene and fluorobenzene show a fall with temperature. Such behaviour emphasizes the lack of direct correlation between T_1 and η and is no indication of where the peculiarity lies. It should be recalled that for benzene the external interaction makes a large contribution to T_1 and so the relaxation may be controlled to a much greater extent by the translational motion. If this is so it is even more surprising that $\eta T_1/T$ should be anomalous since the viscosity is surely more dependent on translational than reorientational motion. Our experience with toluene suggests that the C_6 motion of benzene is faster than the C_2 motions but the present results hardly warrant an elaboration of this point of view.

3.4. *Aniline*

In aniline ($C_6H_5NH_2$) the substituent carries only a pair of protons and the dipole moment partially reorients with them. The T_1 values are quite different from those of toluene and ethyl benzene in that the substituent T_1 is lower than the ring T_1 over the whole temperature range. Proceeding as usual we take $I/\nu_{\mathrm{r}} = 40\ \mathrm{sec}^{-1}$ for the NH_2 group, assuming H–H = 1·64 Å and $I/\nu_{\mathrm{r}} = 6{\cdot}0\ \mathrm{sec}^{-1}$ for the ring protons, which gives $\nu_{\mathrm{c\,amide}} = 6{\cdot}7 \times 10^9 T_{1\,\mathrm{amide}}$ and $\nu_{\mathrm{c\,ring}} = 10^9 T_{1\,\mathrm{ring}}$ since evidently $\nu_{\mathrm{c}} \gg \nu_{\mathrm{r}}$. From Fig. 5 $T_{1\,\mathrm{ring}}/T_{1\,\mathrm{amide}} = 2{\cdot}8$ at -15°c and 1·5 at $+107^\circ$c. Hence $\nu_{\mathrm{c\,amide}} \simeq 3\nu_{\mathrm{c\,ring}}$ over the whole temperature range. At 20°c $\nu_{\mathrm{c\,amide}} = 1{\cdot}3 \times 10^{10}$ c/s and this agrees quite well with the dielectric correlation frequency, $3\nu_{\mathrm{D}} = 2{\cdot}4 \times 10^{10}$ c/s at 20°c, the only value available (Fischer 1949). The rather small factor between $\nu_{\mathrm{c\,amide}}$ and $\nu_{\mathrm{c\,ring}}$ and the uncertainty in the I/ν_{r} values we have used makes the simplest interpretation that the ring and amide group motions are essentially similar. Rapid reorientation of $-NH_2$ may be inhibited by weak hydrogen bond formation. The latter may be associated with the unusually high viscosity of this liquid.

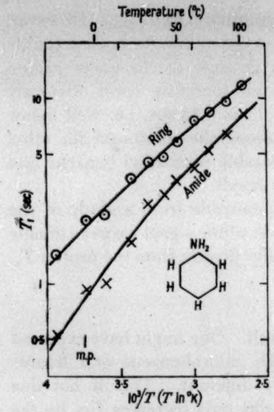

Fig. 5. Ring and substituent proton spin–lattice relaxation times for liquid aniline.

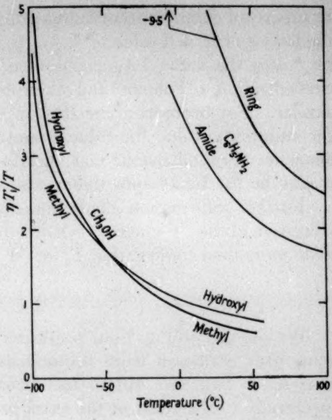

Fig. 6. $\eta T_1/T$ as a function of temperature for aniline and methyl alcohol.

An alternative explanation is that the dielectric correlation frequency corresponds to reorientation of the NH_2 group about the C–N bond. Suppose also that the molecule as a whole reorients and then the appropriate I/ν_r value for the NH_2 group would be reduced by a factor about $\frac{1}{4}$ and $T_{1\,\text{amide}}$ is then controlled by the molecular motion. In that case we find $\nu_{c\,\text{amide}} \simeq \nu_{c\,\text{ring}}$ together with $3\nu_D \simeq 7\nu_{c\,\text{amide}}$ in agreement with the hypothesis. A choice between these alternative explanations is difficult. It is again unfortunate that the lack of a minimum prevents an experimental evaluation of the magnetic interaction. $\eta T_1/T$ is given in Fig. 6 and shows a strong dependence on temperature.

3.5. *Paraxylene and Mesitylene*

The results for paraxylene ($C_6H_4(CH_3)_2$) and mesitylene ($C_6H_3(CH_3)_3$) are shown in Figs 7 and 8. (Note the difference in temperature scale.) Our values agree with those of Nederbragt and Reilly (1956) at 25 °c. Both molecules have zero dipole moment and so dielectric correlation frequencies are not available.

The results for paraxylene are more like those for ethyl benzene than those for toluene, while those for mesitylene are similar to those for aniline. In paraxylene the behaviour of the ring and methyl protons is very different and we feel must correspond to different correlation times and different motions. In view of the symmetry of the molecule it is tempting to suppose that the ring proton T_1 is related to reorientation about what may be called the C_2 axis. This corresponds to a weak interaction since the ring proton's principal interactions are not modulated by this motion.

In contrast with ethyl benzene and toluene (Fig. 3) the value of $\eta T_1/T$ is less dependent on temperature for substituent rather than the ring proton T_1 (Fig. 9). The latter is like that of benzene.

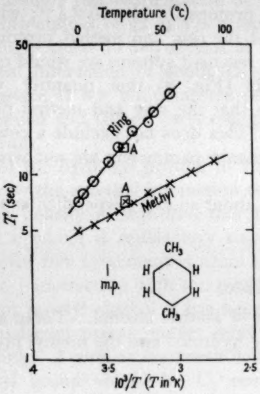

Fig. 7. Proton spin–lattice relaxation times for liquid paraxylene. A, results due to Nederbragt and Reilly (1956).

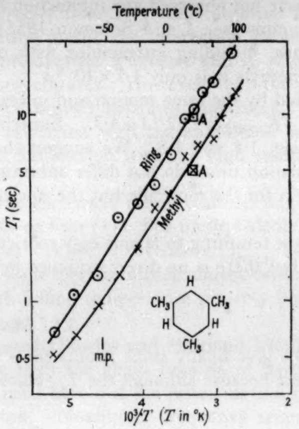

Fig. 8. Proton spin–lattice relaxation times for liquid mesitylene. A, results due to Nederbragt and Reilly (1956).

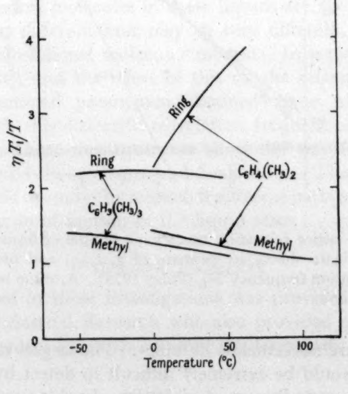

Fig. 9. $\eta T_1/T$ as a function of temperature for paraxylene and mesitylene.

For mesitylene there is even greater difficulty in estimating the interaction of the ring protons. For the methyl protons the I/ν_r value associated with the isolated methyl group is 52 sec^{-1}. In this molecule the interaction between ring and methyl protons in the same molecule must surely be important although we have not observed any interaction between the relaxation of the two systems of protons (see I and Solomon 1955). The sum $(2/n_g)\Sigma_{i>j}\, d_{ij}^{-6}$ for the ring protons, including interactions with methyl protons, is 11×10^{-3} Å^{-6}; without the methyls it is only $1{\cdot}5 \times 10^{-3}$ Å^{-6}. Thus if the ring and methyl protons are affected by the same motion and interact like resonant systems we would expect $T_{1\,\mathrm{ring}}/T_{1\,\mathrm{methyl}} \simeq 52/11 = 4{\cdot}7$. Experimentally (Fig. 8) this quantity varies between 1·4 and 1·8. We suggest therefore that the ring and methyl proton correlation times do not differ substantially. This does not exclude a complex motion for the molecule but the nuclear resonance parameters are not sensitive to it.

It is tempting to favour easy reorientation about an axis perpendicular to the ring but there is no direct evidence for this.

3.6. *Methyl Alcohol*

We give finally some results for a sample of methyl alcohol. These are of interest because although the T_1 values for the hydroxyl and the methyl protons are very close they are nevertheless different. The largest ratio of the two which we find is 1·3 and would be extremely difficult to detect by the usual transient methods (see for example Bonera *et al.* 1960). In this liquid we have hydroxyl proton exchange and a J-type interaction between the two sets of protons, which at low temperatures is not averaged out in this sample (Powles and Hartland 1961). These may be rather dependent on sample purity. The result of Bonera *et al.* (1960) at a single temperature differs from ours.

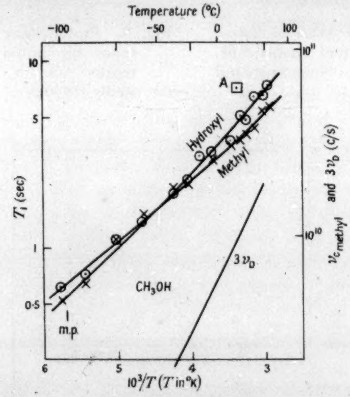

Fig. 10. Proton spin–lattice relaxation times for a sample of liquid methyl alcohol. The right-hand ordinate shows an estimate of $\nu_{c\,\mathrm{methyl}}$ and provides a scale for the dielectric correlation frequency $3\nu_D$ (Poley 1955). A, value reported by Bonera *et al.* (1960).

Because of the strong interaction within the methyl group we consider using the I/ν_r value for an isolated methyl group, i.e. 52 sec^{-1}, and hence

$\nu_{c\ \mathrm{methyl}} = 8{\cdot}6 \times 10^9 T_1$ (since $\nu_c \gg \nu_r$). This scale is indicated on the right-hand ordinate of Fig. 10. Hence $\nu_{c\ \mathrm{methyl}}$ is *greater* than $3\nu_D$. On the other hand if we assume fast reorientation of the methyl group, the interaction parameter for reorientation of its axis is a factor approximately $\frac{1}{4}$ smaller and so $\nu_{c\ \mathrm{methyl}}$ is brought closer to $3\nu_D$ at least at high temperatures. However, then the large external interaction of about 11 sec^{-1} (see below) becomes important. The divergence at low temperatures may be associated with the modulated J-type interaction and should be investigated in conjunction with the high resolution spectrum.

For the hydroxyl proton, in view of the exchange, the interaction might be given by the external interaction term only of Eqn (1). For methyl alcohol the proton density is high and this gives $I/\nu_r = 11$ sec^{-1}. Hence $\nu_{c\ \mathrm{hydroxyl}}/3\nu_D \sim 1$ at 25°C which is satisfactory since the main electric dipole moves with OH. However this agreement is again lost with falling temperature possibly because of the J interaction with the methyl group.

For *n*-octyl alcohol it has been suggested (Powles and Hartland 1960) that the hydroxyl proton moves more slowly than the chain because of hydrogen bonding. A similar argument could be used here but the faster motion of the methyl group would be C_3 reorientation. No higher frequency secondary dielectric relaxation has been observed in methyl alcohol which could be associated with our $\nu_{c\ \mathrm{methyl}}$.

§ 4. CONCLUSIONS

We have shown that the differences between the spin–lattice relaxation times for different chemical types of proton in the same molecule in several liquids are quite marked. Their interpretation forces us to the conclusion that the thermal motions of non-spherical molecules in these liquids are not simple and that the rate of motion about different axes may be very different. Little information is obtained about translational molecular motion. In some cases the molecule has internal flexibility, and the effect of this on the relaxation times has been discussed. The motional parameters obtained agree where expected in a satisfactory way with the dielectric correlation frequencies except in the case of methyl alcohol. These measurements show the way for a more extensive study of molecules of various shapes and flexibilities. They show in particular the value of being able to study the motion of different parts of a complex molecule in elucidating its mode of motion in the liquid state.

ACKNOWLEDGMENTS

The magnet used in these investigations was provided by the Department of Scientific and Industrial Research who also provided a grant for one of us (D. J. N.). The Central Research Fund of the University of London provided a pen-recorder.

The Magnetoelastic Constants of Nickel

By E. W. LEE† and R. R. BIRSS‡

† Department of Physics, The University, Sheffield
‡ Department of Physics, Imperial College, London, S.W.7 §

M.S. received 17*th March* 1961

Abstract. The magnetoelastic constants of nickel are calculated from the magnetostriction constant measured by Birss and Lee in 1960 and elastic constants measured by Alers, Neighbours and Sato in 1960. It is shown that the temperature variation of these magnetoelastic constants is in good agreement with the theory proposed by Kittel and Van Vleck in 1960. According to this theory the magnetoelastic constants depend upon the magnitude of the spontaneous magnetization. This may be increased slightly by a large magnetic field and it is shown that the theory explains, in principle, the origin of the forced magnetostriction.

§ 1. Introduction

In a recent paper (Birss and Lee 1960) we reported measurements of the magnetostriction constants of nickel from the liquid nitrogen temperature up to the Curie point. As we remarked at the time, the magnetostriction constants by themselves do not provide information likely to be of interest to the theorist. What is really required is information on the magnetoelastic constants, which can be derived from the magnetostriction constants only if the elastic constants are also known. At the time our paper was written these were not known for nickel except at room temperature and the discussion of our results was necessarily limited. Since then a paper by Alers, Neighbours and Sato (1960) has appeared which contains, *inter alia*, the measured values of the three elastic constants of nickel from 0°K to 760°K. In this paper we present values of the magnetoelastic constants of nickel, derived from the two sets of results. The temperature variation of these constants is examined in the light of the theory of Kittel and Van Vleck (1960).

§ 2. Theoretical Background

Although the calculation of the magnetoelastic constants is simple it is necessary to write down the basic equations since they will be required later.

The fourth-order equation for the spontaneous magnetostriction λ of a cubic crystal is (see, for example, Birss 1959)

$$\lambda = A_0 + A_1 \mathrm{S}(\alpha_1^2\beta_1^2) + A_2 \mathrm{S}(\alpha_1\alpha_2\beta_1\beta_2) + A_3 \mathrm{S}(\alpha_1^2\alpha_2^2) + A_4 \mathrm{S}(\alpha_1^4\beta_1^2) + A_5 \mathrm{S}(\alpha_1\alpha_2\alpha_3^2\beta_1\beta_2). \qquad \ldots\ldots(1)$$

In this equation, which ignores terms involving powers of α higher than the fourth, α_1, α_2, α_3 and β_1, β_2, β_3 are the directions of the spontaneous magnetization and of measurement respectively with reference to the cubic crystal axes, and the operator S( ) denotes the sum of three quantities obtained by cyclic permutation of the suffixes on the expression within the brackets.

---

§ Now at Department of Electrical Engineering, Imperial College.

To derive Eqn (1) the magnetic energy V is expanded as a Maclaurin series in the strain A_{ij}. Thus

$$V = V^0 + V_p{}^0 E_p + V_{pq}{}^0 E_p E_q. \qquad \ldots\ldots(2)$$

In this expression the suffixes $p, q, \ldots$ run from 1 to 6 and the A_{ij} are related to the E_p in accordance with the scheme $A_{11} = E_1$, $A_{22} = E_2$, $A_{33} = E_3$, $A_{23} = A_{32} = \frac{1}{2}E_4$, $A_{31} = A_{13} = \frac{1}{2}E_5$ and $A_{12} = A_{21} = \frac{1}{2}E_6$. The association of the subscripts $p, q, \ldots$ with V indicates successive partial differentiation with respect to E_p, E_q, ... and the zero superscript indicates that these quantities are to be evaluated at zero lattice strain. If the elastic energy $U = \frac{1}{2}C_{pq}E_pE_q$ is added to Eqn (2) and the quantity $U + V$ is minimized with respect to all E_p, then it may be shown (Birss 1959) that, taking only the first two terms in Eqn (2), the equilibrium strains are

$$E_p{}^V = -S_{pr}V_r{}^0, \qquad \ldots\ldots(3)$$

where the S_{pr} are the elastic compliance moduli. For a cubic crystal in which there are only three independent elastic moduli Eqn (3) reduces to

$$\left.\begin{aligned} E_p{}^V &= -(S_{11} - S_{12})V_p{}^0 - S_{12}(V_1{}^0 + V_2{}^0 + V_3{}^0) \quad \text{for} \quad p = 1, 2, 3 \\ E_p{}^V &= -S_{44}V_p{}^0 \quad \text{for} \quad p = 4, 5, 6. \end{aligned}\right\} \qquad \ldots\ldots(4)$$

The $V_p{}^0$ must depend upon α_i in such a way as to satisfy the lattice symmetry, and it may be shown that for a cubic crystal they must have the form

$$\begin{aligned} V_1{}^0 = L_0 + L_1\alpha_1{}^2 + L_2\alpha_1{}^4 + L_3\alpha_2{}^2\alpha_3{}^2 + L_4\alpha_1{}^6 \\ + L_5\alpha_1{}^2\alpha_2{}^2\alpha_3{}^2 + \ldots, \end{aligned} \qquad \ldots\ldots(5)$$

with corresponding expressions for $V_2{}^0$ and $V_3{}^0$, and

$$V_4{}^0 = \alpha_2\alpha_3(M_0 + M_1\alpha_1{}^2 + M_2\alpha_1{}^4 + M_3\alpha_2{}^2\alpha_3{}^2 + \ldots), \qquad \ldots\ldots(6)$$

with corresponding expressions for $V_5{}^0$ and $V_6{}^0$. The constants L_0, L_1, ... and M_0, M_1, ... are the magnetoelastic constants, which are related to the

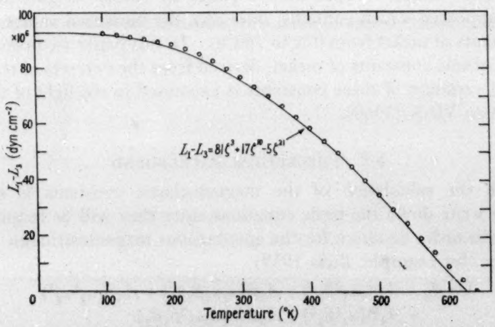

Fig. 1. Magnetoelastic constant $L_1 - L_3$ as a function of temperature. The circles represent experimental values deduced from the magnetostriction constant A_1 and the elastic constant $C_{11} - C_{12}$. The full line is that calculated from Eqn (11).

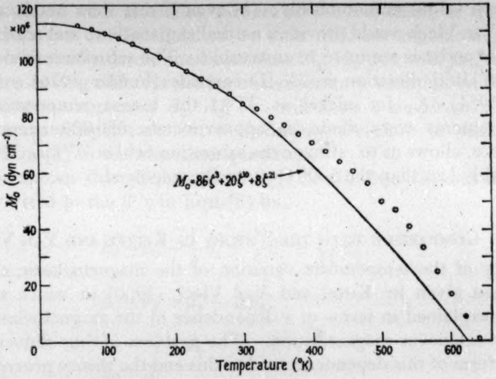

Fig. 2. Magnetoelastic constant M_0 as a function of temperature. The circles represent experimental values deduced from the magnetostriction constant A_2 and the elastic constant C_{44}. The full line is that calculated from Eqn (12).

magnetostriction constants in Eqn (1) by

$$\begin{aligned} A_0 &= -L_0S_{11} - (2L_0 + L_1 + L_2 + L_4)S_{12}, \\ A_1 &= -(L_1 - L_3)(S_{11} - S_{12}), \quad A_2 = -M_0S_{44}, \\ A_3 &= -L_3S_{11} + (2L_2 + 3L_4)S_{12}, \\ A_4 &= -(L_2 + L_3)(S_{11} - S_{12}), \\ A_5 &= -M_1S_{44}, \ldots \end{aligned} \qquad \ldots\ldots (7)$$

Thus from our own measurements of A_1 and A_2 and the elastic constant data of Alers, Neighbours and Sato (1960) the magnetoelastic constants $L_1 - L_3$ and M_0 may be determined. The results are shown in Figs 1 and 2.

§ 3. DISCUSSION

In the first place we notice that the magnetoelastic constants drop sharply to zero at the Curie point. There is no evidence of any 'tail' such as is frequently exhibited by the spontaneous magnetization. At low temperatures both constants appear to be varying continuously towards their value at absolute zero. The observation by Corner and Hutchinson (1958) that the magnetostriction constant A_1 is virtually independent of temperature between 20°K and about 200°K must be ascribed to a fortuitous combination of circumstances in which the rates of change with temperature of the coupling constants and the elastic constants are the same.

In the previous paper we observed that, although the magnetostriction constant A_2 appears to approach its value at absolute zero monotonically, A_1 does not seem to vary with temperature in the same manner but reaches a (numerical) maximum at about 120°K. This behaviour we formerly attributed to the possibility of incomplete saturation in the magnetically difficult [100] direction at low temperatures. We are now inclined to reject this explanation for the following reasons: (a) the magnetoelastic constants $L_1 - L_3$ and M_0 do approach their absolute zero values monotonically; (*b*) even if this were not so the theory of Kittel and Van Vleck would provide a natural explanation; and (*c*) the incomplete saturation hypothesis seems to be untenable. The saturation field for magnetization in a [100] direction is $2K_1/I_s$ oersteds (Fowler 1936). According to Bozorth (1951), K_1 for nickel at 77°K, the lowest temperature at which our measurements were made, is approximately 650 000 erg cm^{-3}. Taking $I_s = 500$ e.m.u. allows us to estimate the saturation field at 77°K as 2700 Oe, which is considerably less than the 5000 Oe actually employed.

§ 4. COMPARISON WITH THE THEORY OF KITTEL AND VAN VLECK

A theory of the temperature variation of the magnetoelastic constants has recently been given by Kittel and Van Vleck (1960) in which the observed variation is explained in terms of a dependence of the magnetoelastic constants upon the spontaneous magnetization. The problem is thus reduced to that of finding the form of this dependence and to this end the theory proceeds along the lines of the conventional theory of the anisotropy constants.

The theory of Kittel and Van Vleck (1960) is, in fact, based on a theory due to Van Vleck (1959) of very general validity. It starts from an expression for the magnetoelastic energy which is, to second-order terms, essentially our Eqn (2) and which they write in the form

$$\begin{aligned} V_A = {} & \beta_0'[E_1+E_2+E_3] \\ & +\beta_1'[(\alpha_1^2-\tfrac{1}{3})E_1+(\alpha_2^2-\tfrac{1}{3})E_2+(\alpha_3^2-\tfrac{1}{3})E_3] \\ & +\beta_2'[\alpha_1\alpha_2E_6+\alpha_2\alpha_3E_4+\alpha_3\alpha_1E_5] \\ & +\beta_3's'[E_1+E_2+E_3] \\ & +\beta_4'[p_4(\alpha_1)E_1+p_4(\alpha_2)E_2+p_4(\alpha_3)E_3] \\ & +\tfrac{1}{2}\beta_5'[(7\alpha_1\alpha_2\alpha_3^2-\alpha_1\alpha_2)E_6+(7\alpha_2\alpha_3\alpha_1^2-\alpha_2\alpha_3)E_4 \\ & +(7\alpha_3\alpha_1\alpha_2^2-\alpha_3\alpha_1)E_5], \end{aligned} \qquad \ldots\ldots(8)$$

with

$$p_4(\mu)=\frac{8}{35}P_4(\mu)=\mu^4-\frac{6}{7}\mu^2+\frac{6}{70}$$

and

$$s'=\mathrm{S}(\alpha_1^2\alpha_2^2)-\tfrac{1}{5}.$$

This grouping of terms is employed instead of the usual arrangement in ascending powers of α_i in order that each magnetoelastic constant β_0', β_1', . . . (not to be confused with the β_1, β_2 and β_3 in Eqn (1)) shall be the coefficient of a homogeneous surface harmonic, of degree 4 for β_3', β_4' and β_5', and of the second degree for β_1' and β_2'. The basis of the theory is then that whilst the spin moments are aligned parallel at saturation, there is nevertheless, at any finite temperature, an angular spread amongst the local units so that, locally, Eqn (8) is true where the β''s are temperature independent. Instead the temperature variation of the magnetoelastic energy is ascribed to local variations in the α's and the problem is to determine the angular averages for a given angular distribution. Kittel and Van Vleck relate these angular averages to the reduced spontaneous magnetization $\zeta = I_s/I_0$, and show that the effective value of each β' at a finite temperature depends on ζ in a way that is determined by the order of surface harmonic with which it is associated. Experimentally it is essential that the magnetostriction constants, and hence the magnetoelastic coupling constants derived therefrom, should be associated with ascending powers of the α's, since, in this way, the various constants can be distinguished by their different angular dependences. Thus the experimentally determined constants A_1, A_2, . . . will, in general, each consist of terms having different modes of temperature variation and it is not to be expected that the constants A_1, A_2, etc. will show a simple or even similar dependence upon temperature. It is necessary therefore to relate the β''s occurring in Eqn (8) to the measured quantities.

It may be shown that the constants $L_1, \ldots,$ in Eqn (5) and $M_1, \ldots,$ in Eqn (6) are related to the β''s in Eqn (8) by,

$$\begin{aligned} L_0 &= \beta_0' - \frac{1}{3}\beta_1' - \frac{1}{5}\beta_3' + \frac{3}{35}\beta_4' \\ L_1 &= \beta_1' + \beta_3' - \frac{6}{7}\beta_4' \\ L_2 &= \beta_4' - \beta_3' \\ L_3 &= \beta_3' \\ M_0 &= \beta_2' - \frac{1}{2}\beta_5' \\ M_1 &= \frac{7}{2}\beta_5'. \end{aligned} \qquad \ldots\ldots(9)$$

According to Kittel and Van Vleck the β''s depend upon temperature through the reduced spontaneous magnetization ζ according to the scheme

$$\frac{\beta'(l)}{\beta'(l)_0} = \zeta^{l(l+1)/2}$$

in which $\beta'(l)$ is a coefficient of a homogeneous surface harmonic of degree l. Thus $\beta_1'/\beta_{1,0}' = \beta_2'/\beta_{2,0}' = \zeta^3$ and $\beta_3'/\beta_{3,0}' = \beta_4'/\beta_{4,0}' = \beta_5'/\beta_{5,0}' = \zeta^{10}$.

Before expressing the measured constants $L_1 - L_3$ and M_0 as functions of ζ it is necessary to enquire into the effect of including terms in α^6 in Eqn (8). If these are also grouped so as to form homogeneous surface harmonics of degree $2n$ then one can predict that higher terms will vary with temperature as $\beta_6'/\beta_{6,0}' = \beta_7'/\beta_{7,0}' = \ldots = \zeta^{21}$ and that these terms will appear in the expressions for $L_1, \ldots,$ and $M_0, \ldots,$ given in Eqn (9). Consequently these constants will in general vary as

$$L_i \text{ (or } M_i) = A_i + B_i\zeta^3 + C_i\zeta^{10} + D_i\zeta^{21} + \ldots \qquad \ldots\ldots(10)$$

To investigate whether our experimentally determined constants $L_1 - L_3$ and M_0 could be fitted to an expression of this form, we first made a logarithmic plot of $L_1 - L_3$ and M_0 against ζ^3 which confirmed the general dependence of the constants upon ζ^3. Further analysis shows that $L_1 - L_3$ can be represented by the equation

$$L_1 - L_3 = 81\zeta^3 + 17\zeta^{10} - 5\zeta^{21}, \qquad \ldots\ldots(11)$$

assuming that this quantity is not vitiated by the effect of non-saturation, and that M_0 may be expressed as

$$M_0 = 86\zeta^3 + 20\zeta^{10} + 8\zeta^{21}. \qquad \ldots\ldots(12)$$

These equations are plotted in Figs 1 and 2 together with the experimental points. Eqn (11) fits the experimental points rather well over the entire temperature range. Eqn (12) on the other hand fits the experimental data extremely well at low temperatures but breaks down just above room temperature. It is evident, though, that the magnetoelastic constants may be represented fairly accurately by Eqn (10) and that the constants A_i, B_i, etc. do, in fact, converge respectably.

§ 5. CALCULATION OF FORCED MAGNETOSTRICTION CONSTANTS

It is observed experimentally in all magnetic materials that above the point of technical saturation the magnetostriction exhibits a weak dependence upon the applied magnetic field H. The variation of λ with H is a linear one and is known as the forced magnetostriction. Although the effect was, for a long time, regarded as a pure volume effect, measurements by Calhoun and Carr (1955) showed the forced magnetostriction of iron to be anisotropic. The effect is small, usually of the order 10^{-10} Oe^{-1}, and has so far been analysed only in terms of the second-order equation for the spontaneous magnetostriction

$$\lambda = C_0 + C_1 \mathrm{S}(\alpha_1{}^2\beta_1{}^2) + C_2 \mathrm{S}(\alpha_1\alpha_2\beta_1\beta_2). \qquad \ldots\ldots(13)$$

The forced magnetostriction is, by definition, $d\lambda/dH$ and the second-order forced magnetostriction constants are C_0', C_1' and C_2', the prime denoting differentiation with respect to field. The work of Calhoun and Carr showed that, in iron, C_1' and C_2' are not negligible in comparison with C_0'. Experimentally it is observed that, for a given material, there is no constant proportionality between the C's and the corresponding C''s. Thus, for example, for iron $C_1 = +31{\cdot}1\times10^{-6}$, $C_1' = 0{\cdot}94\times10^{-10}$ Oe^{-1}; $C_2 = -63{\cdot}6\times10^{-6}$, $C_2' = -0{\cdot}34\times10^{-10}$ Oe^{-1}, and in certain aluminium–iron alloys C and C' do not even have the same sign (Hall 1957).

These observations may be explained as follows. Above technical saturation the spontaneous magnetization I_s is slightly field dependent. The increase of I_s with H is linear and small. Values of the quantity dI_s/dH for a given substance differ widely from one source to another, and almost the only certain thing about it is that it decreases with decreasing temperature. The forced magnetostriction arises because the magnetoelastic constants depend upon ζ and at finite temperatures $d\zeta/dH (\equiv \zeta')$ is finite. Since the magnetoelastic constants are given by Eqn (10) the forced magnetoelastic constants must depend on ζ as

$$L_i' \quad (\text{or } M_i') = \frac{dA_i}{dH} + (3B_i\zeta^2 + 10C_i\zeta^9 + 21D_i\zeta^{20} + \ldots)\zeta', \qquad \ldots\ldots(14)$$

and the forced magnetostriction will have the same kind of dependence. Thus the C's and the corresponding C''s will not bear any simple relation to each other. In particular, since the latter quantities depend much more strongly on terms involving higher powers of ζ than the former, there appears to be no compelling reason for the two quantities even to have the same sign. Although it would be possible in principle to compute the forced magnetoelastic constants for nickel from Eqns (11), (12) and (14), very little purpose would be served thereby because any values of ζ' employed would be little more than a guess and probably uncertain to an order of magnitude; in addition there appear to be no experimental determinations of the forced magnetostriction constants of nickel.

§ 6. DISCUSSION

There seems little doubt that the temperature variation of the magnetoelastic constants of nickel is correctly given by Eqn (10). Thus the observation by Döring (1936) that the polycrystalline magnetostriction constant of nickel is proportional to I_s^2 can only be regarded as fortuitous and well illustrates the dangers of drawing conclusions from the magnetostriction constants alone. However, the very success of Eqn (10) raises a problem, for the theory which predicts it also predicts that the first anisotropy constant of nickel K_1 should vary as $K_1/K_{1,0}=\zeta^{10}$, whereas the experimental data imply a more rapid variation.

Thus the question of a temperature variation of both the anisotropy and magnetoelastic constants whose origin is different from that considered in this paper must be considered. One rather obvious mechanism is through the agency of thermal expansion, and Carr (1960) has shown that if the expression for the variation of the anisotropy constant K_1 with temperature, namely $K_1=K_{1,0}\zeta^{10}$, is regarded as being correct for constant volume then when the thermal expansion of the lattice is taken into account the exponent becomes $10-\kappa\omega A^{-1}T^{-3/2}$, in which ω is a volume strain, $\kappa=(1/K_{1,0})(dK_{1,0}/d\omega)$, A is the constant in the Bloch spin–wave equation, $\zeta=1-AT^{3/2}$, and T is the absolute temperature. Brenner (1957) identified $K_{1,0}\kappa$ with the constant A_3 in Eqn (1), and Carr showed that for iron $10-\kappa\omega A^{-1}T^{-3/2}$ is almost independent of temperature and equal to 8·2 over the small range of temperature where the spin–wave equation $\zeta=1-AT^{3/2}$ is applicable. For iron the recent experimental results of Graham (1958) obey the law $K_1=K_{1,0}\zeta^5$ quite closely. Thus it is clear that when allowance for thermal expansion is made the agreement between theory and experiment is improved although it is still far from perfect. An analysis similar to that of Carr can be carried out for the magnetoelastic constants. Assume for the time that a particular magnetoelastic constant may be expressed as $L(T)=L_0(\omega)\zeta^3$ in which $L_0(\omega)$ is regarded as being volume dependent. Then, from the spin–wave equation and a Taylor expansion of $L_0(\omega)$ it follows that

$$L(T)=L_0(0)\,[1+\kappa'\omega-3AT^{3/2}]$$

where

$$\kappa'\equiv\frac{1}{L_0}\frac{dL_0}{d\omega}.$$

This may be written in the form

$$L(T)=L_0(0)[1-(3-\kappa'\omega A^{-1}T^{-3/2})AT^{3/2}]$$

whence $L(T)=L_0(0)\zeta^n$ where $n=3-\kappa'\omega A^{-1}T^{-3/2}$. Now κ' may be related to a magnetostriction constant in a term which is of the sixth order in α_i. If Eqn (1) is to be of any use at all such a constant must be very small indeed at all temperatures, and since the effect of thermal expansion in higher order terms in Eqn (10) will involve magnetostriction constants of even higher orders than the sixth it would seem that the temperature variation of the magnetoelastic constants is not significantly affected by thermal expansion of the lattice.

An intrinsic effect of temperature on the magnetoelastic constants is, however, not ruled out by the preceding analysis, nor is such an effect wholly unexpected as the following considerations show. The constant β_0' in Eqn (8) and the related magnetostriction constant A_0 in Eqn (1) are due to the effects of exchange. They represent a pure volume effect and give rise to the anomaly in the thermal expansion near the Curie temperature. Now the very existence of such an anomaly indicates that A_0 and β_0' must be strongly temperature dependent, at least in the neighbourhood of the Curie temperature. Nevertheless the theory of Kittel and Van Vleck gives the unequivocal result $\beta_0'/\beta_{0,0}'=1$, independent of ζ. The reason for this is that this theory does not cover the temperature variation of the magnetoelastic constants as such. It relates the value of each magnetoelastic constant at a finite temperature to the average value of the angular spread of the spins about a definite crystallographic axis. This average value, and through this the temperature variation of the magnetoelastic constants, is uniquely related to the order of the harmonic of which each β' is a coefficient. It follows from the theory that the coefficient of the zeroth-order harmonic β_0' must vary with temperature as ζ^0. But this is merely a restatement of the fact that β_0' does not depend on the angle the spin moments make with a crystal axis, i.e. on spin–lattice alignment. β_0' can, and indeed does, vary with the average angle that one spin makes with another, i.e. on spin–spin alignment, but this is outside the scope of the theory of Kittel and Van Vleck. Now it is clear that if β_0' depends on spin–spin alignment the other β''s may do so as well, and although there will in general be some correlation between spin–spin and spin–lattice alignment it is very difficult to predict what form it will take. The rather good agreement we have found between our experimental results for nickel and the theory of Kittel and Van Vleck suggests that the intrinsic temperature dependence of the magnetoelastic constants other than β_0' through spin–spin angular variation is considerably less than that due to the spin–lattice angular variation.

Franck–Condon Factors and *r*-Centroids for the Triplet Band System of CO Molecule

By N. L. SINGH and D. C. JAIN
Department of Spectroscopy, Banaras Hindu University, India

MS. received 28*th February* 1961

Abstract. It has been verified that the Morse potential function is a good approximation for the representation of the potential energy curves of $d^3\pi$ and $a^3\pi$ electronic states of the CO molecule. The Franck–Condon factors for the triplet band system have been computed by the direct method of numerical integration of the Morse wave functions. The *r*-centroids for this band system have been calculated by (i) the direct method of numerical integration and (ii) the quadratic equation method of Nicholls and Jarmain. A close agreement is obtained between the values of *r*-centroids evaluated by both the methods.

Assuming that the electronic transition moment is approximately constant, the relative population of the vibrational levels of the $d^3\pi$ state of the CO molecule has been calculated using Herman and Rakotoarijimy's experimental data on the relative intensity measurement of the triplet bands developed in the presence of xenon.

§ 1. INTRODUCTION

HERMAN AND RAKOTOARIJIMY (1960) have made a quantitative study of the spectrum of CO in the presence of rare gases and have obtained evidence of a marked selective excitation in the triplet band system of CO in the presence of xenon. They have calculated the relative population of the vibrational levels in the $d^3\pi$ electronic state of the CO molecule in the presence of xenon by making use of the Franck–Condon factors, evaluated by Pillow's 'distortion method' (Pillow 1951). We have already reported the Franck–Condon factors for this band system evaluated by the method of numerical integration using Morse wave functions. In the present paper the details of the calculations of the Franck–Condon factors and *r*-centroids for this band system are presented. Using Herman and Rakotoarijimy's experimental data on relative intensity measurement, we have calculated the relative population of the vibrational levels of the $d^3\pi$ state of CO in the presence of xenon, assuming the electronic transition moment approximately constant. These results will have to be further considered in the light of the variation of electronic transition moment to be reported in a subsequent paper.

§ 2. COMPUTATIONAL PROCEDURE AND RESULTS

2.1. *Evaluation of Franck–Condon Factors*

As the form of the wave functions involved in the overlap integrals is very much determined by the potential function used, the ability of the Morse potential function to represent the 'true' potentials of both the electronic states involved in the CO triplet band system had to be checked. This was done by determining the 'true' potential curves by the Klein–Dunham–Jarmain method (Jarmain 1959) using data from Herzberg (1950) and comparing the corresponding points on the Morse potential curves. The values of $r_{\min}$ and $r_{\max}$ for the different vibrational levels of the two electronic states are given in Table 1.

Table 1. 'True' and 'Morse' Potential Curves for d$^3\pi$ and a$^3\pi$ Electronic States of CO

v'	d$^3\pi$ state				v''	a$^3\pi$ state			
	$r_{\min}$(Å)		$r_{\max}$(Å)			$r_{\min}$(Å)		$r_{\max}$(Å)	
	True	Morse	True	Morse		True	Morse	True	Morse
0	1·3348	1·3339	1·4666	1·4657	0	1·1594	1·1594	1·2662	1·2661

4	1·2367	1·2291	1·6424	1·6334	4	1·0770	1·0766	1·4065	1·4061
6	1·2125	1·2020	1·7073	1·6931	6	1·0559	1·0555	1·4578	1·4575
8	1·1936	1·1804	1·7684	1·7477	8	1·0390	1·0387	1·5059	1·5056

The straightforward method of Jarmain and Nicholls (1952) has been used for computing the Franck–Condon factors. The Morse wave functions have been calculated on a desk calculator at intervals of 0·02 Å over the range of r within which they are significant. For higher vibrational quantum numbers, as there is a large cancellation in the Laguerre polynomials, we have carried as many significant figures in the computation as possible. Stirling's approximation to a gamma function of large argument has been employed. The values of wave functions have then been interpolated at intervals of 0·01 Å by means of sufficiently large scale graphs. All the wave functions have been checked for normalization to unity.

The overlap integrals have been evaluated numerically by applying trapezoidal and Simpson rules and the values of Franck–Condon factors obtained by both the methods are in good agreement with a maximum difference of 0·001. This shows that the interval of integration is sufficiently small. The Franck–Condon factors are entered in Table 2.

Table 2. Franck–Condon Factors for the Triplet Band System of CO Molecule

2.2. *Evaluation of r-Centroids*

The r-centroids have been evaluated by two different methods: (i) the direct method of numerical integration, and (ii) the quadratic equation method of Jarmain and Nicholls.

The Direct Method. The integrals

$$\int \psi_{v'} r \psi_{v''} dr$$

have been evaluated numerically using the Morse wave functions by applying Simpson's rule, and $\bar{r}_{v', v''}$ have been calculated by the relation

$$\bar{r}_{v', v''} = \frac{\int \psi_{v'} r \psi_{v''} dr}{\int \psi_{v'} \psi_{v''} dr} \, . \qquad \ldots\ldots (1)$$

The Quadratic Equation Method. The r-centroids of molecular band systems can be evaluated by solving the approximate equation, given by Nicholls and Jarmain (1956),

$$E_{v'}' - E_{v''}' = D_1'[1 - \exp\{-\alpha(\bar{r}_{v', v''} - r_{e1})\}]^2 - D_2'[1 - \exp\{-\alpha(\bar{r}_{v', v''} - r_{e2})\}]^2, \qquad \ldots\ldots (2)$$

where α is the mean of the Morse constants α_1 and α_2 of the potential curves of the two electronic states and the primes over the various quantities indicate that these have been adjusted with respect to the chosen mean value of α (Fraser and Jarmain 1953).

Equation (2) is a quadratic equation in $\kappa(=\exp(-\alpha\bar{r}_{v', v''}))$ having two roots out of which the one that gives real physical meaning to $\bar{r}_{v', v''}$ has been used in the calculation. The Morse constants used are: $\alpha_1 = 1{\cdot}761057 \times 10^8$, $\alpha_2 = 2{\cdot}426142 \times 10^8$, mean $\alpha = 2{\cdot}093600 \times 10^8$. Results of both the methods of calculation of $\bar{r}_{v', v''}$ are given in Table 3.

§ 3. DISCUSSION

It is seen from Table 1 that the Morse potential function is a very close approximation to the 'true' potential of the $a^3\pi$ state of the CO molecule. The 'true' potential of the $d^3\pi$ state is also adequately represented by the Morse potential function in the region of lower vibrational levels. There is, however, some discrepancy in the region of higher vibrational levels due to the comparatively large value of $w_e y_e$ $(-0{\cdot}1125)$ for the $d^3\pi$ state. Nicholls (1960) has reported a similar discrepancy in the $B^3\Sigma_u^-$ state of O_2. On account of this fact the values given in Table 2 may be slightly different from the exact Franck–Condon factors corresponding to the wave functions appropriate to the 'true' potentials of both the electronic states.

It is seen from Table 3 that there is a fairly good agreement between the r-centroids calculated by the two methods, showing that the quadratic equation method is a good approximation up to $v' = 8$, $v'' = 3$. Tawde and Murthy (1960) have drawn similar conclusions in the case of BeO (B → X system) up to $v' = 3$, $v'' = 5$.

Nicholls and Jarmain (1956) have shown that under certain approximations $\Delta\bar{r}(=\bar{r}_{v'+1, v''+1} - \bar{r}_{v', v''})$ in a sequence remains constant. In the case of the CO triplet band system such a regularity is exhibited if we determine $\Delta\bar{r}$ from the values of $\bar{r}_{v', v''}$ calculated by the quadratic equation method. This is because the approximations used in deducing the difference $\Delta\bar{r}$ are the same as applied in the

quadratic equation method. Values of $\Delta\bar{r}$ determined from the values of $\bar{r}_{v',v''}$ calculated by the numerical integration method, however, show some increase for higher bands in each sequence.

The Franck–Condon factors entered in Table 2 have been used for calculating the relative intensities of a few bands of $v''=0$ progression. The intensity of the (0, 0) band has been taken as unity and it has been assumed that (*a*) all the vibrational levels of the excited state have equal population (i.e. $T \rightarrow \infty$), and (*b*) the electronic transition moment is approximately constant. Then by making use of Herman and Rakotoarijimy's experimental data on relative intensities of CO triplet bands in the presence of xenon, the relative population of the vibrational levels of d$^3\pi$ state of the CO molecule has been calculated. The results are shown in Table 4. For comparison, Herman and Rakotoarijimy's results are also entered in the Table.

Herman and Rakotoarijimy have concluded that the population of the fifth vibrational level is much increased due to resonance excitation by collisions of CO molecules with metastable xenon (^{3}P) atoms. Their conclusion is supported by our calculations of the relative population of the vibrational levels based on the more accurate values of the Franck–Condon factors obtained by us by the method of numerical integration using Morse wave functions.

The ^{55}Mn(d, p)^{56}Mn Reaction

By A. W. DALTON, G. PARRY, H. D. SCOTT and
S. SWIERSZCZEWSKI

Department of Physics, University of Liverpool

MS. received 15*th February* 1961

Abstract. The energy spectra of the protons emitted from a manganese target when bombarded with 8·9 MeV deuterons have been measured by magnetic analysis at angles of observation between 5 and 60°. Angular distributions of a number of proton groups have been obtained and compared with theoretical stripping curves to obtain information on parities, spins and reduced widths. The results have also been compared with those of Schiffer, Lee and Zeidman on gross structure in the proton spectra.

---

§ 1. Introduction

The energies of many of the excited states of ^{56}Mn have been determined by Green, Smith, Buechner and Mazari (1957) from a high resolution study of the ^{55}Mn(d, p)^{56}Mn reaction using 6·6 and 7·0 MeV deuterons. The same reaction has been studied in the present investigation using 8·9 MeV deuterons. Angular distributions were obtained for a number of proton groups. These were fitted with Butler type stripping curves to obtain information on parities, spins and reduced widths. The results have also been compared with those of Schiffer, Lee and Zeidman (1959) on gross structure in proton spectra from reactions using 10 MeV deuterons.

§ 2. Experimental and Results

Using the techniques described previously (Dalton, Kirk, Parry and Scott 1960) with a target 0·27 mg cm^{-2} and exposures up to 900 μc, measurements were made at angles from 5 to 60° to the incident beam.

In Fig. 1 is shown the proton energy spectrum obtained at 20° to the beam direction. The groups which have been identified with transitions to states of ^{56}Mn are labelled with their excitation energy in MeV. Detailed measurements were made on groups corresponding to states with excitation energies up to 3·03 MeV and Fig. 2 gives their angular distributions while the information obtained for the transitions is contained in the Table.

Measurements were made on nineteen groups up to this excitation. Eight of these corresponded to single levels as observed by Green *et al.* and were fitted by $l = 1$ curves. The other eleven were composite groups and each one corresponded to two or more levels. Five of these distributions were fitted with $l = 1$ curves, two with $l = 2$ curves and three with curves for $l = 1$ or 2. The remaining distribution at 2·12 MeV excitation was too complex for a single l-value to be assigned. Possibly it contains an $l=0$ component and undoubtedly it contains components up to $l=2$. No obvious $l=3$ distributions were observed although most of the experimental distributions had appreciable yields at the larger angles of observation.

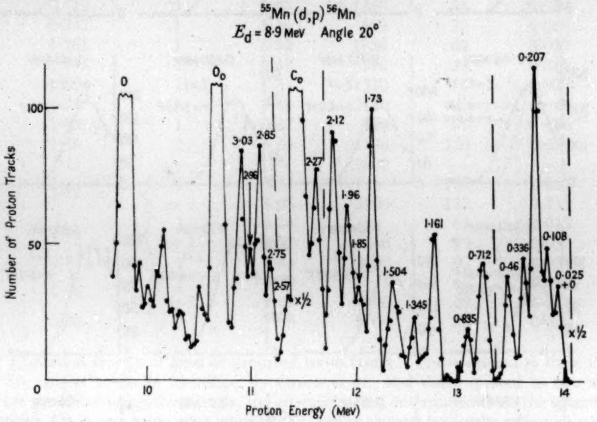

Fig. 1. Proton spectrum observed at an angle of 20° from a target of ^{55}Mn bombarded by 8·9 Mev deuterons.

The spectra became rather complicated at higher excitations but to enable a comparison to be made with the work of Schiffer *et al.* they were examined for possible $l=0$ transitions, particularly in the region corresponding to $Q=1$ Mev where the oxygen impurity gives rise to a group with an $l=0$ distribution. Two strong forward peaking groups were observed corresponding to transitions with Q-values of 0·71 and 1·32 Mev, that for $Q=0{\cdot}71$ Mev being three times the stronger. The cross section at 5° for the transition with $Q=0{\cdot}71$ Mev was about 11 mbn sterad^{-1}. The angular distributions of the two groups can be fitted approximately with either $l=0$ or $l=1$ curves. The group with $Q=0{\cdot}71$ Mev is possibly better fitted by the $l=0$ curve and that at $Q=1{\cdot}32$ Mev by the $l=1$ curve.

As the ground state spin of ^{55}Mn is 5/2 (Mack 1950) unique spin assignments to the states of ^{56}Mn cannot be made. For those states reached by $l=0$ transitions the spin is 2 or 3, for $l=1$ transitions 1 to 4 units and for $l=2$ transitions 0 to 5 units.

§ 3. Discussion

The results of the angular distribution measurements may be compared with those of Schiffer *et al.* In Fig. 3 is shown a gross structure spectrum with impurity contributions removed. Averaging has been performed over an energy interval of about 200 kev. There is considerable similarity between the spectrum and the one shown by Schiffer *et al.* These authors assign the states $s_{1/2}$, $d_{5/2}$, $p_{1/2}$ and $p_{3/2}$ at positions corresponding to Q-values of 0·4, 2·3, 3·1 and 4·6 Mev respectively, corresponding to transitions with $l=0$, 2, 1, and 1 for the ingoing

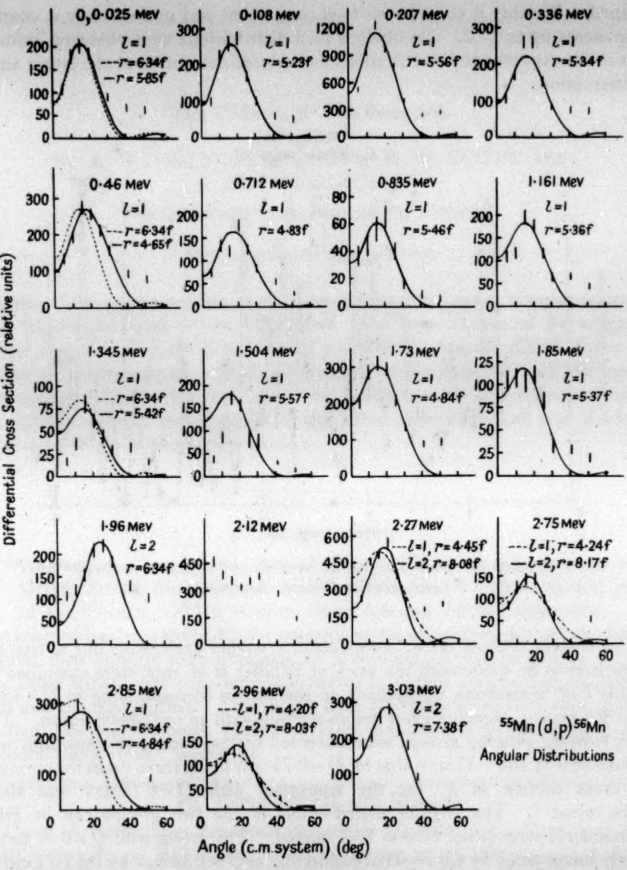

Fig. 2. Angular distributions of proton groups from the ^{55}Mn(d, p)^{56}Mn reaction. The distributions are labelled by the excitation energy of the corresponding final state. 100 units of relative cross section are equivalent to 0·71 mbn sterad^{-1}.

neutron. From our results it is clear that there is a strong $l=1$ group centred round the *Q*-value of 4·84 MeV, and there is probably a strong $l=0$ group centred round the *Q*-value 0·71 MeV. These two broad groups could correspond to the $p_{3/2}$ and $s_{1/2}$ states assigned by Schiffer *et al.* The association of other single particle states with broad groups between these extremes is not at all obvious. Following on the broad $l=1$ group centred round $Q=4·84$ MeV there is a run of $l=1$ transitions with *Q*-values down to 3·20 MeV. These transitions do not produce, when summed, one broad group which can obviously be identified with a single particle $p_{1/2}$ state at about 3·1 MeV. In addition there are in the lower

energy regions of the spectra transitions with appreciable cross sections which may be $l = 1$ transitions. For groups from transitions with Q-values less than 3·0 MEV the experimental angular distributions are such that the clear assignment of one l-value to each group is not possible. This may be due to lack of experimental resolution or to defects in the simple stripping theory. Nevertheless there appear to be two distinct regions where $l=2$ transitions are a strong possibility. The Q-values at the centres of these groups of levels are about 2·90 and 2·05 MeV. It is not obvious that these two groups should be combined in order that the resultant might be identified with the single particle $d_{5/2}$ state assigned by Schiffer *et al.* at about 2·3 MeV.

An Analogue Solution of the Continuity Equation of the Ionospheric F Region

By B. H. BRIGGS and H. RISHBETH†
Cavendish Laboratory, Cambridge

MS. received 6*th March* 1961

Abstract. It is shown that the continuity equation for the electron density in the F region of the ionosphere can be solved by the use of an electrical analogue. The equation which is solved in this way takes account of the rates of production and loss of electrons, and of vertical diffusion, but other types of movement are not included. The rates of production, loss and diffusion are assumed to vary with height in a manner appropriate to a particular model of the atmosphere, based on rocket and satellite data.

The analogue computer is first used to find how the electron density at a series of heights varies with time due to the diurnally varying rate of production. The time of maximum production is at noon, but the time of maximum electron density occurs some time after noon, and the variation of this time lag with height is studied. Near noon, the electron density is found to be a maximum at a height of 250 km. In the evening, the height of the maximum rises to about 300 km, and remains constant during the night. Above the level of the maximum, the ionization is controlled by diffusion and the ionization density falls off exponentially with increasing height; its time variation follows closely the time variation at the maximum.

In other experiments, the production function is modified so as to represent a solar eclipse which occurs near noon. Diurnal curves of electron density are obtained at a series of heights, and the results show how the time of maximum electron density and the percentage decrease of electron density vary with height.

In another type of experiment, the diffusion and recombination of a slab of ionization introduced at a fixed height are studied. It is shown that the slab spreads out to form a 'layer' which eventually assumes a certain fixed shape with a maximum at a fixed height of 300 km, and that this 'shape-preserving' layer then decays with a time constant determined by the rate of recombination at the level of maximum ionization density. The final form of the layer is independent of the height at which the slab of ionization is introduced. These results may be relevant to the behaviour of the F layer at night when production is absent, and diffusion and recombination are the controlling factors.

§ 1. Introduction

The electron density in the F region of the ionosphere is thought to depend largely on the production of ionization by solar radiation, loss by recombination and vertical transport by plasma or ambipolar diffusion. If these three processes only are considered, the continuity equation for the electron density $N(h, t)$ is a partial differential equation, being second-order in height h and first-order in time t.

---

† Now at the Department of Scientific and Industrial Research, Radio Research Station, Ditton Park, Slough.

This paper describes how solutions of this equation may be obtained by the use of an analogue computer. This employs a series of condensers, the charge on any one of which represents the electron density at a certain height. The condensers form part of a network which contains resistors whose values are related to the diffusion and loss coefficients. The diurnal variation of production of ionization is represented by the supply of current from potentiometers, varied periodically by an assembly of cams. The voltage on each condenser is recorded by a pen-recorder, and represents the variation of electron density at the appropriate height. Daytime quasi-equilibrium conditions can be studied by stopping the cams at 'noon' or any other desired position. With the addition of another cam the effects of a solar eclipse can be investigated.

The behaviour of a slab of ionization under the influence of diffusion and loss alone may be investigated by disconnecting the 'production' circuits, giving an initial charge to one of the condensers and recording the voltage as a function of time on each condenser.

In addition to the processes mentioned above, there may exist motions of the ionization caused by electromagnetic forces and diurnal temperature changes. The effects of these are complicated and it is of interest to solve the differential equation which applies if they are neglected. Comparison of the solutions with the actual ionosphere may show the extent to which these movements are important.

It is hoped to present more detailed results in a later paper, and the account given here is mainly concerned with the assumptions made about the ionosphere (§ 2) and the equations governing the circuits (§ 3). A few samples of the results obtained with the first model are presented in § 4.

§ 2. Ionospheric Processes

The equation of continuity satisfied by the electron density N may be written

$$\frac{\partial N}{\partial t} = q - \beta N - \frac{\partial}{\partial h}(N w_D) \qquad \ldots\ldots (1)$$

in which the production rate q is a function of height and of the solar zenith angle $\chi(t)$, and the loss rate β is a function of height. The vertical drift velocity of diffusion w_D depends on the plasma diffusion coefficient D, which is also a function of height, and on gravity.

For the purposes of the model, the neutral constituents of the F region are taken to be atomic oxygen and molecular nitrogen. In the equations which follow the symbols n_j, H_j, A_j denote concentration, scale height and ionization cross section; the suffix $j = 1$ is used for O and $j = 2$ for N_2. The cross sections A_j are assumed to be independent of wavelength.

The processes envisaged are as follows:

(i) Electrons are produced by the photo-ionization of atomic oxygen at a rate $q(h) = A_1 n_1(h) S(h)$, where $S(h)$ is the flux of ionizing photons at height h.

(ii) A proportion of the ionizing radiation is absorbed by N_2 and does not contribute to the observable ionization because the N_2^+ ions recombine rapidly. The ratio of the flux $S(h)$ at height h to the flux S_∞ incident at the top of the atmosphere (which is assumed to be horizontally stratified) thus depends on the distribution of both gases along the path traversed by the radiation.

(iii) The loss process involves an atom-transfer reaction between O^+ ions and N_2 molecules, the resulting NO^+ ions being rapidly lost by dissociative recombination (Bates and Massey 1948). The loss rate is thus $\beta = \lambda n_2$ where λ is the rate coefficient of the transfer reaction, which is assumed independent of height.
(iv) At the top of the F region, the ionization is in diffusive equilibrium.

Low down in the F region, the loss rate is not directly proportional to the electron density as assumed in (iii) because the recombination of NO^+ ions does not proceed rapidly in comparison with the transfer reaction. This circumstance is thought to be responsible for the presence of two peaks of electron density in the F region by day, the F1 and F2 layers (Ratcliffe 1956 a, Hirsh 1959). This bifurcation cannot be reproduced by the analogue, which solves only the linear equation (1) in which the loss rate is proportional to the electron density. In the lower F region the linear equation applies to the concentration of O^+ ions, and the additional electrons associated with molecular positive ions are not represented in the analogue.

With sufficient accuracy for present purposes, the production function given by (i) and (ii) may be written as

$$q = S_\infty A_1 n_1 \exp\{-\operatorname{Ch}\chi(n_1 A_1 H_1 + n_2 A_2 H_2)\}, \qquad \ldots\ldots(2)$$

in which Ch χ is the function defined by Chapman (1931 a, b) and approximates to sec χ for $\chi < 85°$.

The plasma diffusion coefficient D is assumed to be given by the relation

$$\frac{1}{D(h)} = \left[\frac{n_1}{b_1} + \frac{n_2}{b_2}\right]\left[\frac{T+187°}{T^{3/2}}\right]. \qquad \ldots\ldots(3)$$

The dependence of D upon the absolute temperature T is that suggested by Ferraro (1945) and takes account of attractive intermolecular forces. According to Dalgarno (1958), O^+ ions diffuse more slowly in the parent gas than in other gases, and it is later assumed that $b_1 = \frac{1}{4}b_2$. Shimazaki (1957) has shown that if μ is the ratio of the molecular weight of the plasma to that of the neutral atmosphere, and H the atmospheric scale height, then the velocity of diffusion w_D is given by

$$-w_D = D(h)\left[\frac{1}{N}\frac{\partial N}{\partial h} + \frac{1}{T}\frac{\partial T}{\partial h} + \frac{\mu}{H}\right]. \qquad \ldots\ldots(4)$$

The differential equation obtained by combining Eqns (1) and (4) may be transformed into a type suitable for analogue solution by means of two changes of variable, which remove terms due to gravity and temperature gradients. A limiting height h_a is chosen, at the bottom of the F region, and two new variables x and X are introduced, defined by the equations

$$x = \frac{T_a}{T}\exp\left[-\int_{h_a}^{h}\frac{\mu\,dh}{H}\right] \qquad \ldots\ldots(5)$$

$$X = \int_{h_a}^{h} x\,dh. \qquad \ldots\ldots(6)$$

The variable x is dimensionless, and decreases from unity at $h = h_a$ to zero at infinite height; it is approximately proportional to the gas pressure. X has the dimensions of length and increases from zero at $h = h_a$ to a finite value X_∞ as $h \to \infty$. X is termed 'analogue height' and it naturally depends upon the model atmosphere employed.

The dependent variable employed is v, where

$$N(h,t)=x(h)v(h,t). \qquad \ldots\ldots(7)$$

The assumption of diffusive equilibrium of ionization at the top of the atmosphere implies that $NT \sim \exp(-\mu h/H)$ as $h \to \infty$, so that $N \propto x$. At any height $v\delta X$ represents the number of electrons in a unit column of extent δX in 'analogue height' X, and of extent $\delta h = \delta X/x$ in 'real height' h.

Table 1. Some Numerical Data

(i) Atmospheric model

Top	$h=735$ km,	$H=78$ km,	$X=40{\cdot}94$ km,	$x=0{\cdot}0057$
Bottom	$h=140$ km,	$H=20$ km,	$X=0{\cdot}00$ km,	$x=1$
Interval			$\Delta X=0{\cdot}89$ km	
Composition	$n_1/n_2=0{\cdot}76$ whence (above 250 km) $\mu=0{\cdot}35$			
Diffusion	$b_2=4b_1=2{\cdot}5\times10^{18}$ cm^{-1} sec^{-1} deg$^{-1/2}$			
Loss	$\lambda=1{\cdot}75\times10^{-13}$ cm^3 sec^{-1}			
Production†	$S_\infty=7{\cdot}9\times10^9$ cm^{-2} sec^{-1}			
	$\bar{A}=\dfrac{n_1A_1+n_2A_2}{n_1+n_2}=1{\cdot}3\times10^{-17}$ cm^2			

Function	Peak value	Height	Nearest source	Nearest condenser
q	400 cm^{-3} sec^{-1}	200 km	$i=5$	$n=25$
q/x	3050 cm^{-3} sec^{-1}	228 km	$i=6$	$n=29$

(ii) Circuit

Period of revolution of cams = 24 sec
Whence time-scaling factor = $\tau = 3600$
13 cams at heights h_i of 150(10)180(20)280(40)400 and 480 km
47 condensers, 4 μF (within 3%)
Typical values of resistors:
Feeding (r_n) 2 MΩ ($n<40$) 10 MΩ ($n\geqslant40$)
Loss (ρ_n) 4·5 kΩ ($n=0$), increasing to 5 MΩ ($n=42$); omitted for $n>42$
Diffusion (R_n) greatest value 8·9 kΩ at $n=25$, decreasing to 4·8 kΩ at $n=1$ and to 1·3 kΩ at $n=46$

(iii) Calibration

The greatest noon voltage is 6·7 v on source $i=6$. By substitution in Eqn (11), it is found that:

$$F=1{\cdot}3\times10^7 \text{ cm}^{-3}\text{ v}^{-1}=1{\cdot}8\times10^5 \text{ cm}^{-3} \text{ per division on chart}$$

† Calculated for sunspot minimum conditions at equinox, latitude 52°.

The variations of n_1, n_2, H and T with height have been taken from a model atmosphere computed by Dr. K. Weekes and based on rocket and satellite data (see Rishbeth and Barron 1960, Fig. 8). In that model, complete mixing of O and N_2 at all heights is postulated, so that the ratio n_1/n_2 is independent of height.

This is admittedly unrealistic but greatly simplifies the calculation of $q(h, t)$ and of $D(h)$. The limit h_a is taken at 140 km, low enough to include all levels at which the rate of production of ionization is appreciable. From 560 km to the upper limit of the model, at 735 km, the scale height is assumed to be independent of height. A few numerical values are shown in Table 1, and the variation with height of x and X plotted in Fig. 1. The production functions are computed for equinox in latitude 52°.

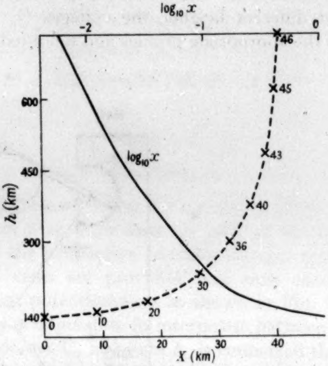

Fig. 1. Variation with height of the coordinates x and X, calculated from Weekes' data by Eqns (5) and (6). The locations of a few condensers are marked.

The value of μ depends on the composition of the neutral atmosphere and the nature of the positive ions. In the F region, above 250 km, nearly all the ions are thought to be O^+, and if the atmosphere consisted entirely of atomic oxygen μ would be $\frac{1}{2}$, a value often used in theoretical work. With the model used here, in which $n_1/n_2 = 0{\cdot}76$, it is found that $\mu = 0{\cdot}35$. Below 250 km, however, the relative abundance of different kinds of ion varies with height, and so μ has been estimated from the results of Johnson, Meadows and Holmes (1958) obtained with a rocket-borne ion spectrograph. The uncertainties introduced by this procedure should not be serious near the level of maximum ionization of the F region, and the present results are mainly concerned with the behaviour at this level and above it.

With the substitutions and transformations outlined above, the continuity equation (1) becomes an equation for v, namely

$$\frac{\partial v}{\partial t} = \frac{q}{x} - \beta v + \frac{\partial}{\partial X}\left[Dx^2 \frac{\partial v}{\partial X}\right]. \qquad \ldots\ldots (8)$$

This transformed equation contains a modified production rate q/x. The diffusion term is now of the standard form appropriate to a straightforward diffusion equation with a diffusion coefficient Dx^2 and the additional terms in the original equation, which represented the effects of gravity and vertical temperature gradients, have disappeared.

§ 3. THE CIRCUIT

A section of the network is shown in Fig. 2. The charge $C_n V_n$ on the nth condenser represents the electron density at one height. This charge is dissipated by leakage through the resistance ρ_n, which represents the 'loss' of ionization by recombination. Charge can also be transferred between condensers by the resistances R_n, and this corresponds to 'vertical diffusion' in the ionosphere. The applied voltage Q_n is varied periodically and simulates the diurnally varying 'rate of production' of ionization. Because the time variation of the production function is different at different heights, the voltages Q_n are controlled by a number of cams cut to the appropriate profiles and mounted on a common shaft.

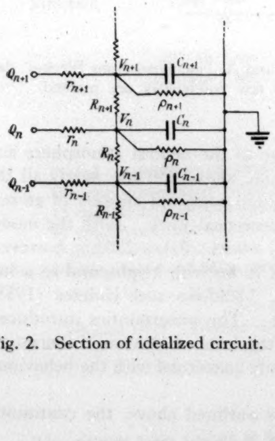

Fig. 2. Section of idealized circuit.

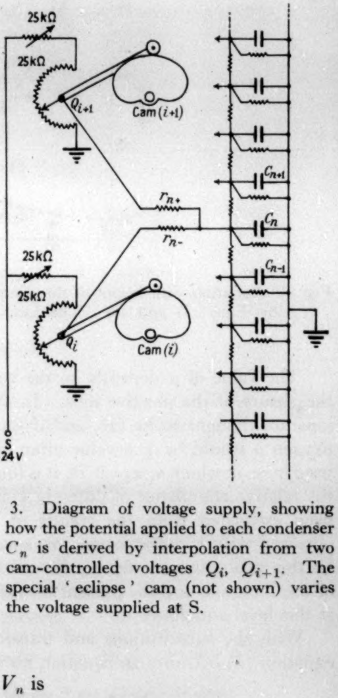

Fig. 3. Diagram of voltage supply, showing how the potential applied to each condenser C_n is derived by interpolation from two cam-controlled voltages Q_i, Q_{i+1}. The special 'eclipse' cam (not shown) varies the voltage supplied at S.

The equation satisfied by the voltage V_n is

$$C_n \frac{\partial V_n}{\partial t} = \frac{Q_n - V_n}{r_n} - \frac{V_n}{\rho_n} + \frac{V_{n+1} - V_n}{R_{n+1}} - \frac{V_n - V_{n-1}}{R_n}. \quad \ldots\ldots(9)$$

This may be rewritten by expressing the finite differences of neighbouring voltages in terms of differentials, and becomes

$$\frac{\partial V_n}{\partial t} = \frac{Q_n}{C_n r_n} - \frac{V_n}{C_n}\left[\frac{1}{\rho_n} + \frac{1}{r_n}\right] + \frac{\partial}{\partial n}\left[\frac{1}{C_n r_n}\frac{\partial V_n}{\partial n}\right], \quad \ldots\ldots(10)$$

This equation is similar to (8), and with a suitable choice of parameters the condensers C_n may be 'labelled' with corresponding heights h_n, which are spaced at equal intervals ΔX in analogue height. A time-scaling factor τ must also be chosen; it is the ratio of the periods of the solar production function (one day) and of the revolution of the cams (twenty-four seconds). Another scaling factor F is required to convert the voltage V into the independent variable v; this is expressed in units of cm^{-3}v^{-1}, and must be determined in each experiment. It then follows that at the height h_n,

$$q(h_n)/x_n = FQ_n(C_n r_n \tau)^{-1} \qquad \ldots\ldots (11)$$

$$\beta(h_n) = (C_n \rho_n' \tau)^{-1} \qquad \ldots\ldots (12)$$

$$D(h_n) = (\Delta X)^2 (C_n R_n' \tau x_n^2)^{-1}, \qquad \ldots\ldots (13)$$

where

$$R_n' = \tfrac{1}{2}(R_n + R_{n+1}) \qquad \ldots\ldots (14)$$

$$(\rho_n')^{-1} = \rho_n^{-1} + r_n^{-1}. \qquad \ldots\ldots (15)$$

Some numerical data concerning the circuit are given in Table 1. It is not necessary to construct a separate cam for each of the forty-seven condensers because the shape of the production function changes quite slowly with height. In practice thirteen cams are provided, and each condenser is fed by two resistors from adjacent potentiometers as shown in Fig. 3. By choosing these two resistors suitably it is possible to interpolate between the two cams.

In general, a condenser C_n at height h_n is connected through a resistance r_{n-} to the source Q_i at height h_i, and through a resistance r_{n+} to the source Q_{i+1} at height h_{i+1}, where $h_i < h_n < h_{i+1}$. The resistances r_{n-} and r_{n+} present a combined parallel resistance r_n, and their ratio depends on the analogue heights X_i, X_n, X_{i+1}. If

$$\theta = (X_n - X_i)/(X_{i+1} - X_n), \qquad \ldots\ldots (16)$$

then

$$r_{n-}/r_n = \theta + 1, \qquad r_{n+}/r_n = (\theta + 1)/\theta \qquad \ldots\ldots (17)$$

and

$$r_n^{-1} = r_{n-}^{-1} + r_{n+}^{-1}. \qquad \ldots\ldots (18)$$

The camshaft is driven by an electric motor, and the cams operate the potentiometers through gears so that a larger angular movement can be obtained. The output of the ith potentiometer varies with time in accordance with the ratio $q(h_i, t)/q(h_i, 12^{\mathrm{h}})$. Each potentiometer is connected to a fixed voltage through a variable resistor which is adjusted to give the correct output at 'noon', and not afterwards changed. The total resistance in each potentiometer circuit ($\sim 50\,\mathrm{k}\Omega$) is small compared with the resistances r_n ($\geqslant 2\,\mathrm{M}\Omega$).

To investigate the effects of a solar eclipse, another potentiometer is used, operated by a cam mounted on the same camshaft. This 'eclipse cam' is cut to give the required obscuration function appropriate to the eclipse which is being studied. The output of the potentiometer is used to feed all the other potentiometers, in place of the fixed voltage normally used. A change-over switch can be arranged so that the main bank of potentiometers can be fed from either the fixed voltage or the 'eclipse potentiometer'; in this way, results for an 'eclipse day' and a 'control day' can be obtained in rapid succession. In this method of simulating an eclipse it is assumed that the time variation of the eclipse function has the same form at all heights; this is not strictly accurate but it is a good approximation for an eclipse which takes place near noon.

The voltages $V_n(t)$ are recorded one at a time by connecting the condensers to a cathode-follower followed by an amplifier, whose output operates a pen-recorder. The scale of the chart is calibrated in terms of the variable v by recording the production voltages $Q_i(t)$ on the chart (Fig. 4); this enables the calibration factor F to be computed from Eqn (11). The electron density at any height h_n is then found by multiplying the deflection by $x(h_n)$. Another pen on the same recorder is used for timing purposes. The time constant of the recorder is about $\frac{1}{2}$ sec.

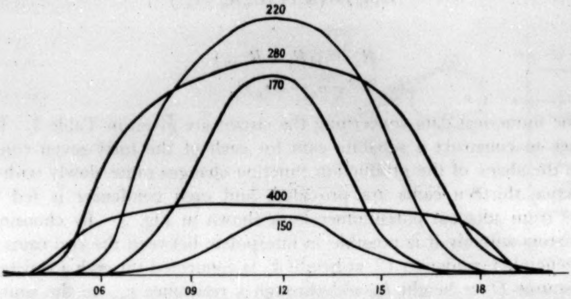

Fig. 4. Outputs of five of the 'production' potentiometers, as functions of apparent time. The height represented, in kilometres, is marked on each curve.

Figure 4 shows the curves obtained by recording the outputs $Q_i(t)$ of a few potentiometers, and so demonstrates the well-known characteristics of the production functions. At great heights, production is small and approximates to an 'on–off' function. The amplitude of $Q_i(t)$ increases with decreasing height and reaches its greatest amplitude for the sixth source at $h = 220$ km. Below this, the amplitudes of the production curves decrease rapidly with decreasing height, and Q is only appreciable for a few hours around noon.

In a different kind of experiment, which will be called a 'pulse' experiment, the behaviour of a slab of electrons injected at a certain height is investigated with the use of a network of condensers and resistors alone. For this purpose, the resistances r_{n+}, r_{n-} are connected to ground instead of to the potentiometers and a 4 μF condenser is charged to a suitable voltage and momentarily connected across one of the condensers C_n; a timing pulse is simultaneously fed to the timing pen. The voltage–time curve on each condenser is recorded and converted to an electron density curve as described above.

§ 4. DISCUSSION OF RESULTS

4.1. *Introduction*

Three kinds of $N(t)$ curves are obtained with the analogue computer, namely 'diurnal', 'eclipse' and 'pulse' curves. In each case a set of curves can be used to find how the electron density varies with height at fixed times. Examples will be given in §§ 4.2–4.4.

In considering the experimental results, it is necessary to bear in mind the limitations of the method. The accuracy is mainly determined by the finite number of condensers, which determines the step length ΔX in the integration by the circuit of the differential equation. The error in the determination of the level of maximum electron density, for example, is of the order of one step (i.e. about 10 km at $h = 250$ km). In addition, there is some uncertainty in the reading and calibration of the chart; an accuracy of about 5% is attempted.

It should be emphasized that the diffusion coefficients (b_1, b_2) used for these initial investigations are larger, by a factor of about five, than those which may be appropriate to the actual F region. Consequently, the results presented here may be thought of as showing the maximum possible effects of diffusion in the F region. Further experiments with smaller values of diffusion coefficient are in hand.

4.2. *Diurnal Variations*

A set of $V(t)$ curves is shown in Fig. 5, and the derived $N(h)$ curves in Fig. 6. In general, the level h_m of maximum ionization is found to lie in the region where the 'diffusion rate' D/H^2 and the loss coefficient β are comparable, as

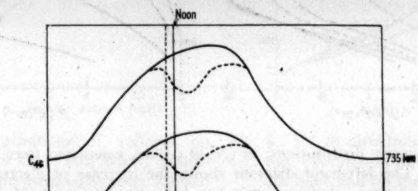

Fig. 5. 'Diurnal' $V(t)$ curves for seven condensers, whose serial numbers and heights in kilometres are shown on the left. The dashed curves refer to an 'eclipse' the timing of which is shown by the arrows below the scale of hours. The centre arrow marks the time of 'totality'; the others show 'first contact' and 'last contact'.

suggested by Rishbeth and Barron (1960). During the night, h_m approaches a constant level and the ionization at all heights decays with approximately the loss coefficient appropriate to that level. By day, the bulk of the production of ionization takes place well below the level h_m, which is lower than it is at night. In the following description of results the level of maximum ionization h_m will for brevity be called the 'F2 peak'.

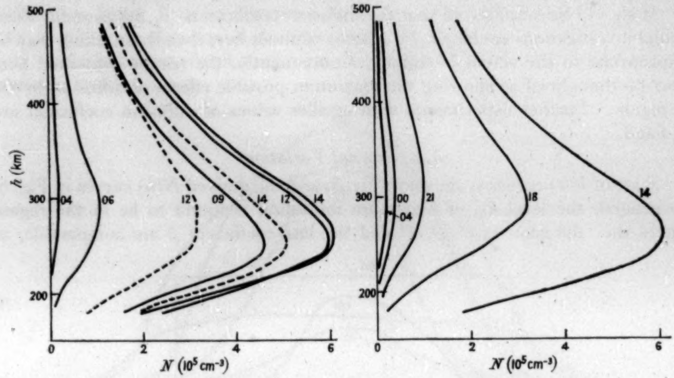

Fig. 6. Electron density distributions, or (N, h) curves, calculated from the (V, t) curves of Fig. 5. The left-hand diagram shows the increase of electron density, from 04^h 'apparent time' (before sunrise) to 14^h; the 'eclipse' (N, h) curves for 12^h and 14^h are shown dashed. The right-hand diagram shows the decrease of electron density during the afternoon and night.

It is interesting to consider the times of maxima of the (V, t) curves at different heights (Fig. 5). These are shown in Table 2 and compared with the values of $1/\beta$ at each height. Below the level of the F2 peak the maximum electron density at a height h occurs at a time of the order of $1/\beta(h)$ after noon, as would be expected if only production and loss processes were important (Appleton 1953). Above the peak production and loss are both small, and the variation of electron density is controlled by diffusion and closely follows the variation at the peak. This is manifested in the circuit by the form of the voltage–time curves, which are almost identical for all condensers above the peak ($n > 35$). In terms of the circuit this is because the top condensers are effectively connected in parallel and have negligible leakage. The time constant for the equalization of charge between neighbouring condensers is very short; for example, $C_n R_n = 0{\cdot}016$ sec for $n = 40$, representing a scale time in the ionosphere of only one minute.

Another way of showing the effect of diffusion is to plot measured voltages as a function of condenser number n, at fixed times (Fig. 7). Near the top, V is independent of height and so the corresponding $N(h)$ curve is exponential (Fig. 8).

The equilibrium $N(h)$ curve for noon (obtained with the cams stationary) is compared in Fig. 8 with the function $q(h)/\beta(h)$ to show how a peak is produced by the action of diffusion. Below the peak, the electron density is not very different from the ratio q/β, and diffusion has little effect. The peak occurs at 250 km, at which height the ratio $\beta H^2/D = 1{\cdot}1$; this agrees well with the results of Rishbeth and Barron (1960) which were based on the assumption of equilibrium (i.e. $\partial N/\partial t = 0$). The $N(h)$ curve for 14^{h} in the time-varying solution is copied from Fig. 6, to show how the F2 layer approaches equilibrium conditions in the afternoon.

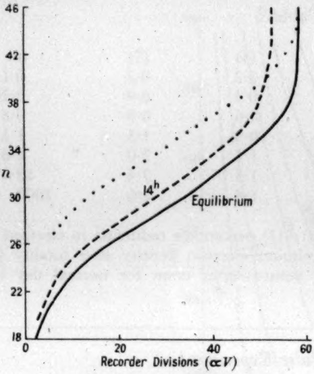

Fig. 7. Distributions of voltages on condensers C_n. Full curve, equilibrium, cams stopped at noon. Broken curve, time 14^{h} of diurnal variation, from Fig. 5. Dotted curve, pulse experiment of § 4.4; the 'shape-preserving' distribution (scaled to coincide at the top with the full curve).

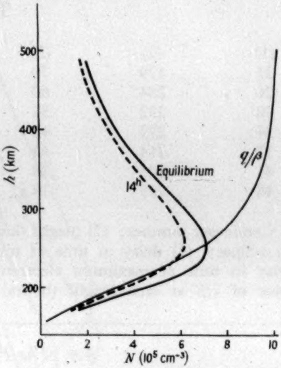

Fig. 8. (N, h) distributions derived from Fig. 7 for noon equilibrium (continuous line), and for the diurnal variation at 14^{h} (broken line) from Fig. 6. The thin continuous line shows the 'equilibrium' electron density distribution $N = q/\beta$ which would be obtained if there were no diffusion and if $\partial N/\partial t$ were negligible.

The $N(t)$ curves are similar to those obtained by Gliddon and Kendall (1960). These authors assumed an isothermal atmosphere and obtained a solution of the continuity equation in terms of analytic functions, which were evaluated with a digital computer.

4.3. *Eclipse Effects*

An initial study of eclipse effects has been made with the special cam set to give an eclipse near noon. The results are not meant to represent any particular eclipse, but to indicate the kind of effects produced. In this example, 'first contact' occurs at 10^{h} apparent time, 'totality' at $11^{\text{h}}30^{\text{m}}$, and 'last contact' at 13^{h}, so that the duration of the whole eclipse is three hours.

The effects observed are illustrated by the dotted curves of Fig. 5 and summarized in Table 2. The greatest reduction of electron density varies from 38% at the top of the F region to 70% at 180 km, and occurs later than totality; the time lag is comparable with $1/\beta$ at heights below the peak, but above the peak the variation of electron density is controlled by diffusion and closely follows that at the peak. This is consistent with the behaviour noted in connection with the diurnal $N(t)$ variation.

Two $N(h)$ curves are shown in Fig. 6. At 12^h the effect of the eclipse is near its maximum; the $N(h)$ curve is flat near the peak, and it is possible that more accurate measurements would show an 'F1½ stratification' of the type suggested by Ratcliffe (1956 b). By the time of the next $N(h)$ curve plotted, at 14^h, the effect of the eclipse has diminished, and it disappears before 18^h.

Table 2

(1)	(2)	(3)	(4)	(5)	(6)
21	179	70	0·2	0·2	0·12
26	204	60	0·3	0·4	0·25
30	232	53	0·6	0·8	0·5
34	272	48	0·9	1·5	1·2
37	314	42	1·1	2·0	2·6
41	405	38	1·3	2·4	12·8
46	735	38	1·4	2·6	1000

(1) Condenser number; (2) height (km); (3) percentage reduction in electron density due to eclipse; (4) delay in time of minimum electron density after totality (hours); (5) delay in time of maximum electron density after noon for normal day (hours); (6) value of $1/\beta$ at each height (hours).

4.4. *The Pulse Experiment*

Figure 9 shows the $V(t)$ curves for a 'pulse' experiment, in which the condenser C_{46}, corresponding to the 'top' of the F region, was suddenly given a charge. For condensers near to the point of entry of the pulse the response is immediate, but the response at more distant points in the circuit is delayed.

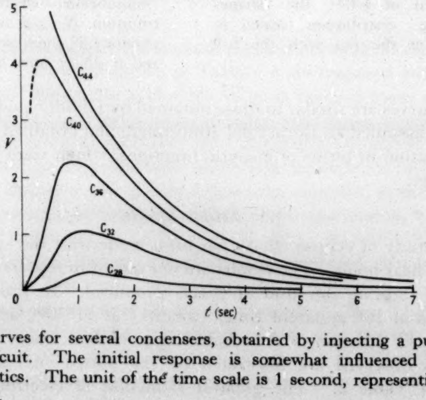

Fig. 9. (V, t) curves for several condensers, obtained by injecting a pulse at the 'top' of the circuit. The initial response is somewhat influenced by the recorder characteristics. The unit of the time scale is 1 second, representing 1 hour in the ionosphere.

After the initial rise, the voltage on all condensers decays with approximately the same time constant. From the voltage distributions at selected times $N(h)$ curves may be constructed (Fig. 10), and these show that the ionization spreads out into a distribution which after about two hours maintains a constant shape and decays with a time constant which is approximately the time constant $C_n\rho_n'$ appropriate to the level of the peak of N. It is found that wherever the pulse is introduced, the same shape-preserving distribution is finally obtained. Since the circuit is linear, this result may be generalized to the conclusion that any initial distribution of voltage on the condensers will evolve into this particular form.

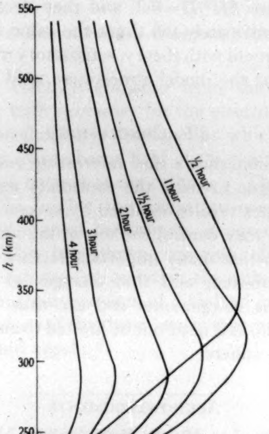

Fig. 10. (N, h) curves for the 'pulse' experiment at times of $\frac{1}{2}$, 1, $1\frac{1}{2}$, 2, 3 and 4 seconds after the injection of the pulse at the 'top' of the circuit (i.e. $\frac{1}{2}$, 1, $1\frac{1}{2}$, 2, 3 and 4 hours in the ionosphere). The curves show the development of the 'shape-preserving' distribution. The scale of N is arbitrary.

The 'shape-preserving' distribution of voltage is shown in Fig. 7, its amplitude having been chosen for comparison with the 'noon equilibrium' distribution discussed in § 4.2. The decrease of voltage with increasing distance from the 'top' of the circuit is slower in the case of the 'noon equilibrium' distribution because of the steady supply of current at lower levels.

The results of the 'pulse' experiment are of interest in connection with the behaviour of ionization in the F region at night, when production is absent. The observed changes of the distributions are not unlike those described by Shimazaki (1957).

It has been shown (Dungey 1956, Duncan 1956, Martyn 1956) that in an isothermal atmosphere an ionized layer would develop into a certain form, under the influence of diffusion and loss, and would then decay without change of shape.

In the special case in which the loss coefficient β decreases exponentially upward with a scale height equal to that of the neutral atmosphere, the shape-preserving solution is a 'Chapman alpha' layer, with its peak at the level where $\beta H^2/D = \frac{1}{4}$, and it decays with the loss coefficient appropriate to this level.

The model atmosphere used for the first version of the analogue computer does assume this variation of β with height, but it is not isothermal. The shape-preserving layers which are formed are very like 'Chapman alpha' layers; their peak is at the level where $\beta H^2/D = 0{\cdot}3$, and they decay with an apparent loss coefficient which is approximately 0·6 times the value of β at this level. There is thus a qualitative agreement with theory, satisfactory in view of the experimental accuracy and the fact that the model atmosphere used is not isothermal.

§ 5. CONCLUSION

The previous discussion shows that interesting results can be obtained by using an electrical analogue to solve the continuity equation for the F region. The analogue demonstrates results obtained by several theoretical investigators, and shows how diffusion may control the top of the ionosphere. In some ways the method is limited, in that many important factors (such as electromagnetic movements) must be omitted, and that changes of parameters involve the replacement of numerous components and are thus laborious to carry out. In other ways it is versatile, as it need not be limited to any special, mathematically simple model of the atmosphere.

ACKNOWLEDGMENTS

The authors are indebted to Mr. P. Noble and to Mr. G. D. Stubbings who carried out most of the constructional work; to Mr. J. P. Dougherty, who suggested the transformations of Eqns (5) and (6); and to Mr. J. A. Ratcliffe for his interest in the investigation and his comments on the manuscript of this paper. The atmospheric model adopted was computed from rocket and satellite data by Dr. K. Weekes.

Part of this work was carried out during the tenure by H. R. of a Senior Research Fellowship, for which he is indebted to the Civil Service Commission.

Electrical Breakdown of Liquid Dielectrics

By D. W. SWAN

Queen Mary College, London, E.1

MS. received 7th October 1960, *in revised form* 17*th March* 1961

Abstract. Assuming that electron emission from the cathode and collision ionization in the liquid are both necessary for the electrical breakdown of liquid dielectrics, a criterion for breakdown is developed in which the cumulative effects of the applied field and the space-charge field of the positive ions produce a continuously increasing electron current at the cathode. The present theory differs from earlier similar theories in that the ionization occurring in the liquid is considered to be very small even at breakdown, in agreement with recent conduction measurements. The breakdown criterion shows clearly how the measured electric strength can depend on either the cathode or the liquid. The influence on the breakdown measurements of dissolved oxygen is also discussed, and the quantitative predictions of the theory are compared with measurements of the electric strength of liquid argon.

§ 1. Introduction

The possible importance of space-charge distortion in electrical breakdown of liquid dielectrics has been realized previously (Macfadyen 1955, O'Dwyer 1954), and a theory has been developed (Goodwin and Macfadyen 1953) in which ions produced in the liquid by collisions between electrons and liquid molecules move to the cathode and enhance the field there to give increased electron emission. At a certain critical field strength this feedback process becomes unstable and breakdown follows. Possibly the most serious objection to the theory is that there is little evidence for collision ionization in liquids, and very large electron multiplication is necessary to satisfy the breakdown criterion. The most recent measurements of conduction in *n*-hexane with pulsed fields up to $1 \cdot 3 \times 10^6$ v cm^{-1} have indicated that there is practically no ionization occurring even at field strengths just below breakdown (Watson and Sharbaugh 1960), and consequently the theory in its present form is not applicable.

It is the purpose of this paper to derive a criterion for the breakdown of a liquid subject to a steady electric field assuming, as in earlier theories, that space-charge distortion at the cathode is important, but that the ionization taking place in the liquid is small. As a result of this small degree of ionization the magnitude of the field distortion is small also, and this enables certain simplifying assumptions to be made. In the derivation of the theory of Goodwin and Macfadyen (1953), it was assumed that the ionization coefficient was constant at all points in the gap, but since a large multiplication rate was necessary to satisfy their breakdown criterion considerable field distortion would have resulted. O'Dwyer (1954) attempted to improve on this by allowing for non-uniformity of the field in the basic equations, but he only shows that a cathode effect may be expected in breakdown measurements, the equations being too complicated to take the theory further.

As a basis of the theory it is necessary to assume some law for the emission of an electron current from the cathode as a function of the cathode field. Conduction measurements at fields below breakdown may be described either by a field emission law (Green 1955, Goodwin and Macfadyen 1953) or by a Schottky-type emission law (House 1957), and the recent pulse conduction measurements of Watson and Sharbaugh (1960) are found to give a good fit to both laws. In the following theory it will be assumed that a simple field emission law adequately describes the current–field relationship, but this does not imply that the mechanism of emission is true field emission. Other laws could equally well be used.

§ 2. THEORY

The emission of electrons from the cathode when subject to a field E_c may be described by an equation of the form

$$j_e = A\mu^2 E_c^2 \exp\left(-\frac{B}{\mu E_c}\right) \qquad \ldots\ldots(1)$$

in which j_e is the electron current density, μ is the local field enhancement factor (Lewis 1955) and A and B are constants depending on the cathode surface. It will be assumed that the cathode field is composed of the applied field E_0 and the field E_+ ($\ll E_0$) due to the positive ions produced in the liquid. If j_0 is the electron current density in the absence of space-charge ($E_c = E_0$ in Eqn (1)), then replacing E_c by $E_0 + E_+$ in (1) gives

$$j_e = j_0\left(1 + \frac{2E_+}{E_0}\right)\exp\left(\frac{BE_+}{\mu E_0^2}\right). \qquad \ldots\ldots(2)$$

It is assumed that μ is independent of field.

If the electronic and ionic mobilities are denoted by k_- and k_+ respectively, and if the ionization coefficient corresponding to a field E is denoted by α, then it may be shown that the field at a distance x from the cathode of a gap of width d is given by (Loeb 1939)

$$\frac{d}{dx}(E^2) = -\frac{8\pi j_e}{\epsilon}\left\{\frac{1}{k_+}\exp\left(\int_0^d \alpha\, dx\right) - \left(\frac{1}{k_+} + \frac{1}{k_-}\right)\exp\left(\int_0^x \alpha\, dx\right)\right\} \qquad \ldots\ldots(3)$$

in which ϵ is the dielectric constant of the liquid. If the distortion due to space-charge is small throughout the whole gap, then E may be replaced by $E_0 + \Delta E$ ($\Delta E \ll E_0$) and little error will be introduced by assuming that the value of α at every point in the gap is that corresponding to the applied field E_0, denoted by α_0.

Integrating (3) and writing $E^2 = E_0^2 + 2E_0\Delta E$ leads to the following expression for the field enhancement,

$$\Delta E = \frac{1}{2\epsilon E_0}\left\{C - \epsilon E_0^2 - 8\pi j_e\left[\frac{x}{k_+}\exp(\alpha_0 d) - \left(\frac{1}{k_+} + \frac{1}{k_-}\right)\frac{1}{\alpha_0}\exp(\alpha_0 x)\right]\right\}.$$

The constant of integration C may be evaluated by noting that

$$\int_0^d \Delta E\, dx = 0,$$

and an equation for the cathode field distortion E_+ is obtained by setting $x=0$. After some rearrangement this gives

$$E_+ = Gj_e \qquad \ldots\ldots(4)$$

where

$$G = \frac{4\pi d}{\epsilon k_+ E_0}\left[\frac{1}{2}\exp(\alpha_0 d) - \left(\frac{1}{k_+} + \frac{1}{k_-}\right)\frac{k_+}{\alpha_0{}^2 d^2}\{\exp(\alpha_0 d) - \alpha_0 d - 1\}\right]. \qquad \ldots\ldots(5)$$

If the rate of ionization occurring in the liquid is small, then $\alpha_0 d$ is small and (5) may be simplified to give

$$G = \frac{2\pi d}{\epsilon k_+ E_0}\left(\alpha_0 d - \frac{k_+}{k_-}\right). \qquad \ldots\ldots(6)$$

The sign of the cathode field distortion is therefore determined by the magnitude of $\alpha_0 d$ and the ratio k_+/k_-. The minimum value of $\alpha_0 d$ required to give a positive field enhancement at the cathode will therefore be different for different liquids, since the ion mobilities may differ widely from one liquid to another.

Much of the experimental work on the breakdown of liquid dielectrics has been concerned with the paraffin hydrocarbons, and of these *n*-hexane has been studied most extensively. This liquid may therefore be considered as representative of the normal liquids used in breakdown experiments. The mobility of the negative ion in *n*-hexane has been investigated in some detail (LeBlanc 1959, Chong and Inuishi 1960, Gzowski and Terlecki 1959), but in recent years there has only been one report of the mobilities of both positive and negative ions (Gzowski and Terlecki 1959). These latter measurements were taken with electric fields less than 1 kv cm^{-1}, and the ratio k_+/k_- was found to be 0·308. While there is evidence that the negative ion mobility is independent of field up to 500 kv cm^{-1} (Chong and Inuishi 1960) it has been suggested that at fields near to the normal breakdown level (about 1 MV cm^{-1}) an increase in mobility may be expected if the electron can be stripped from the hexane molecules by the high fields (Crowe 1956, LeBlanc 1959). The large conduction currents measured by Watson and Sharbaugh (1960) and by Macfadyen and Helliwell (1959) are suggestive of a high mobility ion. Direct measurements of the ion mobilities at breakdown field strengths in these hydrocarbons are necessary before the predictions of the present theory may be compared quantitatively with the existing breakdown measurements, but if it is assumed that k_- may increase from the low field value by a factor of ten at breakdown fields, then k_+/k_- would be only about 0·03. Thus even in the complex liquids $\alpha_0 d$ required for a positive cathode field enhancement can be small, and the theory to be developed here could then be applicable to these dielectrics.

However, it has been established that electrons in liquid argon remain free even at very low fields (Williams 1957), and the ratio k_+/k_- at a field of 100 kv cm^{-1} is about 10^{-4}. Consequently, even for very small $\alpha_0 d$ the factor k_+/k_- in Eqn (6) may be neglected and G may be simplified further to give

$$G = \frac{2\pi\alpha_0 d^2}{\epsilon k_+ E_0}. \qquad \ldots\ldots(7)$$

The electric strength of liquid argon has been reported recently (Swan and Lewis 1960), and it is therefore an ideal liquid for comparison between the present theory and experiment. During breakdown no solid deposits are formed on the electrodes, and this has enabled a thorough investigation of electrode effects to be made. For the hydrocarbon liquids many of these effects may be obscured by deposits on the electrode surfaces. Further calculations will therefore be concerned principally with liquid argon, but the same reasoning may be applied to other liquids, bearing in mind that the important parameters are the positive ion mobility k_+ and the ratio k_+/k_- *at breakdown*.

The factor G in Eqn (7) contains the ionization coefficient α_0, and it is necessary to specify the form of the variation of this coefficient with field. There are no measurements of α in liquids and the choice of the function $\alpha(E)$ is purely arbitrary. In the absence of evidence to the contrary it seems reasonable to assume that the same law for the gas phase may be extended into the liquid phase. Ward (1958) has found that over a very wide range of E/p the variation of α_0 for argon may be expressed as

$$\alpha_0 = C \exp\left(-\frac{D}{E_0^{1/2}}\right) \qquad \ldots\ldots(8)$$

where the constants C and D involve the gas pressure.

Introducing this into (7), and combining with (4) allows the cathode field E_c to be expressed as

$$E_c = E_0 + \frac{2\pi j_e c d^2}{\epsilon k_+ E_0} \exp\left(-\frac{D}{E_0^{1/2}}\right). \qquad \ldots\ldots(9)$$

Figure 1 shows the cathode emission current j_e plotted as a function of cathode field E_c from both Eqns (1) and (9). The ionization and emission constants are given on the diagram together with the values of the other parameters used in the calculation. For low applied fields the characteristics intersect in two places. The smaller of the two intersections represents the stable conduction current finally established, while the second represents an unstable state analogous to many other physical problems, and has no practical significance. For very large applied fields there is no intersection of the characteristics and consequently

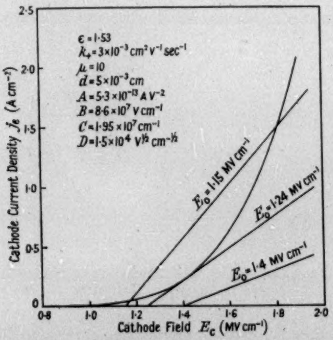

Fig. 1. Graphical representation of Eqns (1) and (9). The curve represents the cathode emission (Eqn 1), while the straight lines show the cathode field–emission current relationship due to the space-charges (Eqn (9)).

there is no stable emission current. Physically this means that the number of ions produced in the liquid causes the cathode field, and therefore the emission current, to increase continuously. The condition for which the two characteristics are tangential therefore represents the state where a stable emission current will be established, but where a slight increase of E_0 will cause this current to increase indefinitely. This is taken to represent the breakdown condition. It is clear that when the breakdown criterion is satisfied the emission current is not infinite, and the cathode current density at breakdown may be conveniently evaluated from Eqns (4) and (2).

Combining these gives

$$j_e = j_0(1 + Pj_e)\exp(Qj_e) \qquad \ldots\ldots(10)$$

where

$$P = 2G/E_0 \quad \text{and} \quad Q = BG/\mu E_0^2.$$

This equation has two roots for small j_0, the smaller one corresponding to the stable conduction current as before. At breakdown these roots are coincident and therefore $\partial/\partial j_e$ of both sides of (10) must be equal. The quantities P and Q depend on the applied field E_0, and before differentiating (10) these must be examined in more detail. Using Eqns (7) and (8), and the constants as given on Fig. 1, the quantities P and Q are found to increase by a factor of about ten when the applied field is increased from 0·8 MV cm^{-1} to 1·5 MV cm^{-1}. For the same field change at the cathode Eqn (1) predicts that j_e is increased by a factor of 10^3, and thus P and Q are only weak functions of j_e and may be considered as constants in Eqn (10). Any realistic form of α_0 as a function of field would lead to a similar result. Differentiating (10) and solving for j_e at breakdown gives

$$j_e^* = E_0^*\Omega/4G \qquad \ldots\ldots(11)$$

where $\Omega = [1 + (8\mu E_0^*/B)]^{1/2} - 1$, and the asterisk denotes the values of the parameters at breakdown. Introducing (11) into (2) gives the breakdown criterion

$$\Omega = 2GA\mu^2E_0^*(2 + \Omega)\exp[-(4 - \Omega)B/4\mu E_0^*].$$

Clearly an explicit expression for E_0^* is not possible, but if G is replaced by (7) and α_0 by (8) an explicit relationship for d^* may be obtained in the form

$$d^* = \left[\frac{\Omega\epsilon k_+}{4\pi\mu^2AC(2+\Omega)}\right]^{1/2}\exp\left[\frac{D}{2E_0^{*1/2}} + \frac{B(4-\Omega)}{8\mu E_0^*}\right]. \qquad \ldots\ldots(12)$$

If the cathode constants are known, and α_0 is a known function of E_0, then d^* may be calculated for a given applied field and the breakdown voltage determined.

§ 3. APPLICATION AND DISCUSSION

Equation (12) shows how the liquid and the cathode can both influence the breakdown voltage at a given gap setting. The first term in the exponential is the ionization term and therefore represents liquid properties, while the second term contains the constants of the cathode. Clearly, depending on the relative magnitudes of these two terms, the cathode may be important or the ionization term may completely mask any cathode changes. For example, if D is very large and the first term predominates, the ionization occurring is small (from (8)), and the field necessary to give breakdown is set by a certain degree of ionization, there being ample electrons available from the cathode by virtue of the smaller term in B. Under these conditions changes in B are not important and the breakdown voltage would not depend on cathode material. On the other hand, if the term in B were predominant the breakdown voltage would depend critically on the cathode, the actual breakdown being governed by the availability of electrons, and not greatly by the ionization rate. Such a balance between two processes, one at the cathode and one in the liquid, has been proposed by Lewis (1953 a), and evidence from breakdown measurements using point-plane electrode configurations in n-hexane suggest that this idea is correct.

Figure 2 shows the breakdown voltage–gap width characteristic as calculated from Eqn (12) for two values of the cathode constant B. The ionization and emission constants are as given on Fig. 1. Because of the lack of experimental information on emission and ionization in liquids choice of the constants A, B, C and D is arbitrary, but an attempt has been made to use realistic values. Also shown on Fig. 2 is a typical characteristic obtained experimentally in liquid argon using gold electrodes. Good agreement could be obtained over the whole curve by adjusting the constants, but exact agreement is meaningless in view of the uncertainties involved. Increase of B in Eqn (1) will reduce the emission at a given field, and consequently a higher field is required to cause the breakdown instability. The criterion for breakdown as expressed by Eqn (12) is very sensitive to changes in B or D.

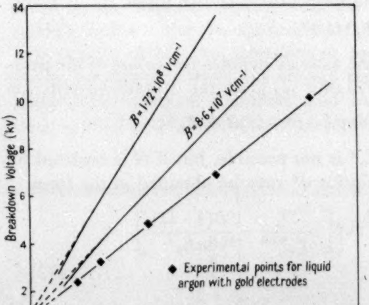

Fig. 2. Breakdown voltage–electrode spacing characteristics calculated from Eqn (12).

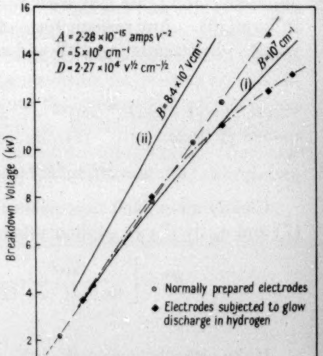

Fig. 3. Breakdown voltage–electrode spacing characteristics calculated from Eqn (12) and compared with measurements in liquid argon.

The shape of the breakdown voltage–gap spacing characteristic depends on which term of the exponential in Eqn (12) is dominant and on the functional relationship of these terms with E_0. With the forms of emission and ionization laws assumed in the derivation of (12) the characteristic can take two distinctly different forms depending on whether the term in $E_0^{-1/2}$ or in E_0^{-1} is of greater importance. It is obvious that the term involving $E_0^{-1/2}$ will result in a more non-linear characteristic than the term in E_0^{-1}. This is illustrated in Fig. 3, where curve (i) has been calculated from (12) with a value of B small enough to make the emission term unimportant. It is seen to exhibit considerable curvature and shows that if the electron supply just prior to breakdown is plentiful the actual breakdown voltage depends strongly on the ionization law. A change in the field dependence of α would change the degree of curvature. With the same ionization constants as before curve (ii) of Fig. 3 has been calculated with B increased until the contribution of the emission term became significant. The introduction of a term in E_0^{-1} reduces the curvature, and the characteristic becomes practically linear.

Results of experiments with liquid argon are again in agreement with this theory. Also shown in Fig. 3 are experimentally determined breakdown characteristics for liquid argon using stainless steel electrodes which were prepared by a normal buffing procedure (Swan and Lewis 1960), but which in one case were used directly and in the other were subjected to a glow discharge in hydrogen prior to the breakdown test. With the normally prepared electrodes the characteristic obtained was linear within the experimental error, while with electrodes that had been subjected to a glow discharge in hydrogen there was considerable curvature. In the light of the theory developed above, this suggests that the normally prepared electrode was not emitting strongly and that the breakdown occurred when a certain level of cathode emission was obtained. A glow discharge in hydrogen would reduce much of the oxide on the cathode surface and an increased electron emission would result. The term involving the ionization could now become significant and the curvature of the characteristic would become appreciable depending on the form of α as a function of field. The constants A, C and D were chosen to make the experimental curve and the theoretical curve with small B in reasonable agreement.

In many experimental determinations of the electric strength of liquids it has been found that the breakdown voltage–gap width characteristic does not pass through the origin when extrapolated to zero gap but that there appears to be an intercept on the voltage axis of about 1000 v. It is significant that for electrode spacings in excess of about 2×10^{-3} cm the characteristics calculated from (12) and shown in Fig. 2 are almost linear, and extrapolation of this linear portion back to the voltage axis shows an intercept of about 1000 v. Large changes of the coefficient B do not appreciably alter this voltage. The characteristic obtained with $B = 10^7$ v cm^{-1} in Fig. 3 is not linear in the range of electrode spacings of interest ($d < 10^{-2}$ cm), but for the smaller gap widths a linear approximation also gives an intercept of about 1000 v. Since it is usual to determine the breakdown voltage at only four or five gap widths in the range up to 10^{-2} cm slight curvature may not be noticed and the characteristic assumed linear, showing the same intercept as is obtained when the term in B is predominant. However, if the breakdown is dependent on the ionization term the introduction of an impurity may change the functional form of α with E, which will alter the curvature and possibly also the apparent intercept. The rapid increase in electric strength as the gap becomes smaller (which gives rise to the apparent voltage intercept) could therefore be attributed to the increase in E_0 required to maintain the necessary degree of ionization.

In *n*-hexane which is free of dissolved oxygen, breakdowns can occur with steady voltage stresses as low as 500 kv cm^{-1}. The recent pulse conduction data of Watson and Sharbaugh (1960) have shown that a measurable α process becomes significant only for fields in excess of 1·2 MV cm^{-1}, so that at first sight it would appear that the theory given here can not be applied to the hydrocarbon liquids. However, there is strong evidence to suggest that these low breakdown strengths are caused by spurious effects. Sletten (1960) has examined the behaviour of particles in *n*-hexane under the influence of electric stress, and has found that it is impossible to remove all particles from the gap and electrode surfaces, even with vigorous flushing and careful filtration of the liquid. These particles oscillate between the electrodes, and under certain conditions the arrival of a positively charged particle from the anode on to the cathode surface has been observed to cause the steady conduction current to increase by a factor in excess of 10^5. Clearly, under these circumstances the mechanism of breakdown might be entirely different.

If short duration impulses are used, the particles do not have time to pass between the electrodes and a higher breakdown strength results. As long as the pulse length is sufficient to allow the positive ion space-charge to accumulate near the cathode without appreciable particle movement the above space-charge theory could hold. For very short impulses the temporal development of the space-charge becomes important.

With air-saturated *n*-hexane the particles do not seem so effective, and in fact are often ejected from the gap after a breakdown (Sletten 1960). Under these circumstances the breakdown strength with direct voltage is found to be about 1·2 MV cm^{-1}, which corresponds to the stress where a measurable α appears. As for measurements in liquid argon, the breakdown voltage–electrode spacing characteristics for the hydrocarbon liquids containing dissolved air exhibit an intercept of about 1 kv (Lewis 1953 b). In liquid argon it is well known that oxygen as an impurity is very efficient in trapping free electrons to form stable negative ions (Davidson and Larsh 1950), and it is possible that this could also occur in *n*-hexane, although the impulse electric strength of this liquid is not affected by the presence of dissolved oxygen, which suggests that attachment may not be important. The breakdown theory developed above could be modified to include electron attachment, but for the present qualitative discussion it is sufficient to note that the loss of electrons to negative ions may be considered as a reduction in α, and that a higher electric field would be necessary to give the required degree of ionization. It is likely that the introduction of oxygen into the liquid will also have an effect at the electrodes where a double layer can be formed due to the chemisorption of the oxygen. This will reduce the emission and change the cathode emission constants.

§ 4. CONCLUSIONS

The theory developed in § 2 differs from previous theories involving a positive ion space charge in that the ionization occurring in the liquid is assumed small, and that the field distortion in the gap is assumed small in comparison with the applied field. From Eqns (4) and (11) the cathode field enhancement is $E_0{}^*\Omega/4$, and for the two characteristics shown in Fig. 2 the ratio $E_+{}^*/E_0{}^*$ is found to be about 0·1. From the definition of Ω in Eqn (11) it is clear that a very low value of B will give rise to a larger cathode field distortion. The values of $\alpha_0 d$ at breakdown corresponding to the two curves in Fig. 2 are found to be between 0·1 and unity, while the theories of Goodwin and Macfadyen and of O'Dwyer would require $\alpha_0 d$ to be about 10^2. With such small values of $\alpha_0 d$ it is unlikely that an α process would be observed in conduction measurements at field strength much below breakdown, in agreement with recent pulse conduction measurements (Watson and Sharbaugh 1960).

The electron emission current density as calculated from Eqn (11) is also of a reasonable magnitude, being less than 1 A cm^{-2} in most cases; and if it is assumed that the discharge develops in a filamentary channel of about 10^{-4} cm diameter, the current at breakdown would be approximately 10^{-9} A. The arbitrary choice of constants involved makes exact calculations unnecessary, but the examples given appear to indicate that the theory derived is consistent with the assumptions made.

The electric strength of liquid argon containing small quantities of oxygen in solution has been found to depend strongly on the anode surface condition and material (Swan and Lewis 1960). This may be explained in terms of a space charge of negative ions near to the anode surface which can lead to a degree of ionization greater than that corresponding to the applied field. The space-charge formed at the anode depends on the insulating properties of that electrode and hence on the surface condition. A full discussion of the anode effects and anode space-charge is to be given in another paper (Swan and Lewis 1961). A few additional ions produced in the enhanced field near the anode would alter the breakdown voltage from the value predicted by Eqn (12) for the case where the anode was not important by effectively changing the ionization coefficients C and D.

While space-charge distortion at the cathode combined with an ionization process in the liquid predicts an instability in the current growth, the final development of the discharge is not explained. A possible explanation is that once the instability criterion is satisfied the current density at the cathode spot increases very rapidly, and the energy liberated there vaporizes the liquid to form a bubble. Any pressure dependence of breakdown must in some way be due to changes in the development of the discharge prior to the attainment of the current instability, and it is reasonable to assume that a change in hydrostatic pressure will alter the gas in equilibrium at the cathode surface, which in turn will change the emission constants.

ACKNOWLEDGMENTS

The author would like to thank Professor M. W. Humphrey Davies for facilities provided, and Dr. T. J. Lewis for helpful discussion and supervision during the experimental investigation. The work was performed during the tenure of a maintenance grant by the Department of Scientific and Industrial Research, which is gratefully acknowledged. Thanks are also due to the British Electrical and Allied Industries Research Association for financial assistance in the purchase of equipment.

The Determination of *m/e* for Free Electrons by Momentum Transfer

By H. A. DAW† and F. S. HARRIS, Jr.
Department of Physics, University of Utah, Salt Lake City

MS. received 25th January 1961

Abstract. A new method for measuring *m/e* for free electrons has been developed by using momentum transfer. A Faraday cage mounted on a torsion device collects electrons from an electron gun. The change in maximum angular displacement of the fibre with electron beam on and off together with the measured current gave a value of *m/e* of $5{\cdot}82\times10^{-12}$ kg c^{-1} compared to the accepted value of $5{\cdot}6854\times10^{-12}$ kg c^{-1}.

§ 1. Introduction

Shortly before the turn of the twentieth century a significant physical constant was measured, the ratio of the mass to charge for cathode rays (Thomson 1897). It has been estimated since, that at least forty-three different methods have been used in making this determination (Hoag and Korff 1948). All of these methods involve however only four basic principles. The four principles may be written as follows in equation form (the symbols have their usual meanings)

$$v=E/B, \quad \ldots\ldots(1) \qquad v=s/t, \quad \ldots\ldots(2)$$

$$Bev=mv^2/r, \quad \ldots\ldots(3) \qquad \tfrac{1}{2}mv^2=eV. \quad \ldots\ldots(4)$$

The first equation represents the velocity filter consisting of crossed electric and magnetic fields as used by Thomson. The second equation determines the same information as the first but is a direct measurement on the time of flight of the electronic stream. This principle was incorporated in the experiments of Wiechert and others (Wiechert 1899, Kirchner 1931, Perry and Chaffee 1931). The latter two equations connect the electrical and inertial properties of the electronic stream. The third equation relates the momentum of the stream to the magnetic field strength, while the fourth equation relates the energy of the stream to the applied voltage. Instances where these principles have been used are numerous (Hoag and Korff 1948, Gerlach 1933).

Of the four principles only the time-of-flight velocity determination is independent of the nature of the electromagnetic field interaction of charged particles. Since for a determination of *m/e* any two of the principles may be used, the combination of (1) with (2) excepted, no determination of this ratio is independent of the nature of the electromagnetic interactions. The nature of the interaction however may be side-stepped if one introduces a new measurement which is independent of the fields, but connects the inertial and electrical properties of the stream. Two solutions suggest themselves: one is to measure electron beam momentum directly as a function of beam intensity, and the second is the measurement of the power directly as a function of beam intensity. The direct measurement of the momentum transferred per unit time by the cathode ray stream is the subject of this paper. Momentum transfer has been used for ions (Lamar 1933).

§ 2. ELECTRON BEAM MOMENTUM METHOD

Consider a current I crossing the boundary x_0 from the left in Fig. 1. The current is carried by a stream of free electrons from the boundary x_0 to the boundary x_2. Here the current I moves away from the boundary to the right.

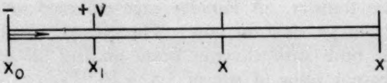

Fig. 1. Electron path in acceleration region and field-free region.

During a portion of the path the stream may suffer an acceleration due to an applied electric field. Let us for convenience suppose this to occur between x_0 and x_1 due to a potential V between these two points, and that the stream then moves in field-free space over the remaining path. The momentum per unit time crossing the boundary x is then given by

$$F = \frac{m}{e} Iv \qquad \ldots\ldots (5)$$

where I is the beam current and m/e is the ratio of the mass to charge for electrons. Making use of Eqn (4) to eliminate the velocity from Eqn (5) one obtains

$$m/e = \frac{F^2}{2VI^2}. \qquad \ldots\ldots (6)$$

If one makes use of Eqn (2) the resulting equation would be simply

$$\frac{m}{e} = \frac{F\Delta t}{I\Delta s}. \qquad \ldots\ldots (7)$$

This latter equation would permit an absolute determination of m/e.

The nature of the field interactions with moving charged particles is dependent on the speed of the particles, and of particular interest is the relativistic region. In this region Eqn (6) becomes

$$\frac{m_0}{e} = \frac{F^2}{I^2 V} - \frac{V}{c^2}. \qquad \ldots\ldots (8)$$

where c is the speed of light. The purpose of this study was to apply the principle stated by Eqn (5) and to determine if the momentum transferred by a moving charged stream could be used to determine m/e with reasonable accuracy.

§ 3. EXPERIMENTAL

Careful consideration was given to the design of suitable measuring equipment. The problems of target weight, detector sensitivity, secondary electron emission, electrostatic forces, etc. were solved by means of the tube design shown in Fig. 2. The body of the tube was made of a one-litre boiling flask. A round glass joint put into the tube wall permitted the insertion of an electron gun. A torsion device was used as the detector and this effectively eliminated gravitational forces. Secondary electron emission was controlled by completely capturing the electron beam in a Faraday cage mounted at the bottom of the torsion fibre, see Fig. 2.

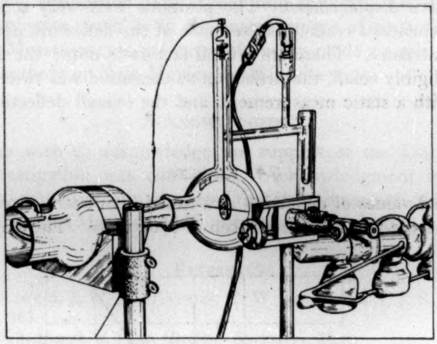

Fig. 2. Vacuum tube showing the Faraday cage and torsion suspension. The focus and deflection coils are at the left, the travelling microscope is in the foreground, and the vacuum system to the right.

The torsion fibre was a 1 mm tungsten wire, spot welded at the lower end to the cage, and attached to a rotatable support at the upper end. The upper support enabled one to adjust the cage position by means of an external magnet. The torsion constant of the suspension fibre was determined by measuring the period of oscillation with a body of known moment of inertia suspended from the fibre. The suspended body was in this case the cage itself. All of its components were carefully massed and measured.

The following values were determined for the detector suspension:

Cage moment of inertia	$31{\cdot}9 \times 10^{-7}$ kg m^2
Period	67·7 sec
Torsion constant	$27{\cdot}3 \times 10^{-9}$ kg m^2 sec^{-2}.

The cage was constructed of brass with a tungsten pointer passed horizontally through a diameter. The semi-length of the tungsten pointer was $5{\cdot}75 \times 10^{-2}$ m. Target holes were drilled in the cage $1{\cdot}45 \times 10^{-2}$ m from the suspension and the cage face coated with willemite. The interior of the tube was completely coated with a semi-transparent coat of silver by means of the Rochelle salt process so that electrostatic charges could not disturb the detector.

The tube was evacuated by means of a fore vacuum pump and a three stage oil diffusion pump, DPI GF 25W. All measurements were made with a vacuum of approximately 10^{-3} micron. The deflections produced by the electron stream were measured in the following manner. A travelling microscope was mounted near the tube wall and focused on the end of the tungsten rod pointer. The microscope was adjusted to the position of maximum (positive) deflection with the electron beam turned off. The oscillations were timed, and after one-half cycle had elapsed from the position of maximum deflection, the electron beam was turned on. The beam had been previously directed to and focused on a hole in the target. The change in the maximum positive displacement was then measured by means of the microscope. The electron beam was turned off after it had been on for one complete cycle and a second reading was made on the maximum positive displacement. The positions were very reproducible. In general five independent readings were made of the deflection produced at each electron beam intensity. There are several factors to note: the damping of the system was negligibly small, the deflection as measured was twice the value one would obtain with a static measurement, and the overall deflection angles were very small.

§ 4. Results

The measured values of deflection as a function of beam current are plotted in Fig. 3. All of the readings were taken at 5000 volts. The slope of the solid line together with the measured values for the instrument were combined to yield F in Eqn (6) which there becomes

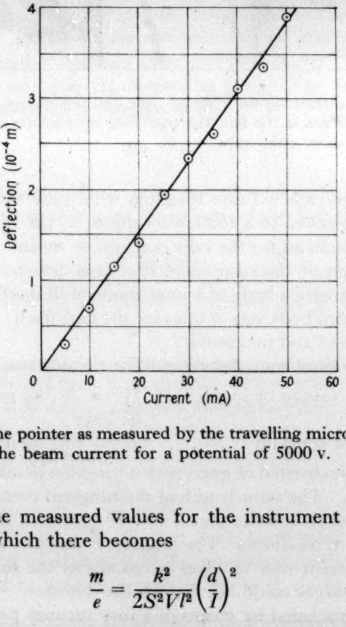

Fig. 3. Deflection of the pointer as measured by the travelling microscope plotted against the beam current for a potential of 5000 v.

$$\frac{m}{e} = \frac{k^2}{2S^2Vl^2}\left(\frac{d}{I}\right)^2 \qquad \ldots\ldots(9)$$

where s is the distance from axis to target hole centre, l the semi-length of pointer, k the torsion constant, V the voltage and d/I the ratio of deflection to current. Upon substitution in Eqn (9) one obtains $5{\cdot}82 \times 10^{-12}$ kg c^{-1} which agrees favourably with the results of other measurements (Cohen, DuMond, Layton and Rollett 1955, $5{\cdot}6854 \times 10^{12}$ kg c^{-1}).

§ 5. CONCLUSIONS

This method of determining m/e has been demonstrated to be practical. The experiment was not designed to yield a precise result and refinements in this direction will require considerable ingenuity. This is a new application of Newton's second law to measurements in the field of electron physics. Aside from its restricted application here, it may find application to measurements in other areas of physics, such as in the measurement of scattering and capture cross section. Measurements are currently being made on relativistic electrons by one of the authors at New Mexico State University.

ACKNOWLEDGMENT

The authors wish to acknowledge the support of the University of Utah where this investigation was conducted. Acknowledgment is also made to Milton Marshall who originally suggested that the momentum of electron streams might be measurable (Marshall 1935, private communication).

Measurement of Ionization and Attachment Coefficients in Carbon Monoxide in Uniform Fields

By M. S. BHALLA and J. D. CRAGGS
Department of Electrical Engineering, The University of Liverpool

MS. received 6th February 1961

Abstract. Measurements of pre-breakdown currents in uniform field conditions, in carbon monoxide at different pressures, in the E/p range of 36 to 200 v cm^{-1} (mm Hg)$^{-1}$ indicate the presence of electron attachment. It is suggested that the mechanism of negative ion formation is due to dissociative attachment, therefore values of α and the dimensionally equivalent attachment coefficient η have been computed from the semi-logarithmic plots of current against electrode separation, by employing the modified Townsend equation for the growth of current. Static breakdown potentials have been measured up to $pd \sim 1050$ mm Hg cm (where p is the pressure and d the gap length) and show that Paschen's law is obeyed. Further, the values of secondary coefficient γ have been computed from upcurving of the semi-logarithmic plots of current against electrode separation. The values of breakdown potential calculated from the breakdown criterion are in good agreement with the measured values, showing that the static breakdown in carbon monoxide is brought about by the Townsend build-up mechanism.

The mean cross sections for ionization and attachment have been calculated for various electron mean energies from the mean values of α/p and η/p obtained from the present study and compared with the values computed from low pressure single collision data, by assuming either a Maxwellian or a Druyvesteyn distribution of electron energies. It is concluded that the Maxwellian distribution is satisfactory to explain the results but the Druyvesteyn distribution does not seem to apply. Calculations show that the electron attachment observed in this study is due to resonant attachment processes occurring at about 10 ev and the contributions due to processes of a continuous nature at about 21 and 23 ev are negligible.

§ 1. INTRODUCTION

THE attachment processes occurring in carbon monoxide when submitted to bombardment by low-energy electrons of well-defined energy, at low pressures, have been studied by Tate and Smith (1932), Lozier (1934) and Hagstrum and Tate (1941). Accurate measurements of attachment and ionization cross sections in carbon monoxide under single collision conditions have been made by Craggs and Tozer (1958) in these laboratories, using a Lozier apparatus.

Earlier workers were unable to observe electron attachment in carbon monoxide in swarm conditions (Bradbury 1934, Loeb 1956). It therefore seemed desirable in view of the single collision data (Craggs and Tozer 1958) to study attachment in carbon monoxide in swarm conditions and to measure the attachment and ionization coefficients for various values of the parameter E/p (E is the field strength and p the gas pressure) in uniform fields.

It has been shown (Harrison and Geballe 1953, Geballe and Reeves 1953) that when electron attachment of the type

$$\mathrm{AB}+\mathrm{e}\rightarrow\mathrm{AB}^- \quad \text{or} \quad \mathrm{A}+\mathrm{B}^- \qquad \ldots\ldots(1)$$

occurs in the growth of the electron avalanche the equation for the current flowing in a uniform field gap is given by

$$\frac{I}{I_0}=\left[\frac{\alpha}{\alpha-\eta}\exp\left[(\alpha-\eta)d\right]-\frac{\eta}{\alpha-\eta}\right]\Big/\left[1-\frac{\gamma\alpha}{\alpha-\eta}\left(\exp\left[(\alpha-\eta)d\right]-1\right)\right] \qquad \ldots\ldots(2)$$

where α is Townsend's primary coefficient, η the attachment coefficient, γ the secondary coefficient, d the electrode separation and I_0 the initial electron current at the cathode.

Provided only those current measurements are considered in which contributions due to secondary processes are negligible then Eqn (2) is reduced to

$$\frac{I}{I_0}=\left[\frac{\alpha}{\alpha-\eta}\exp\left[(\alpha-\eta)d\right]-\frac{\eta}{\alpha-\eta}\right]. \qquad \ldots\ldots(3)$$

Equation (3) indicates that the semi-logarithmic plot of $(I/I_0, d)$ is not linear and that curve fitting techniques are necessary to evaluate α and η accurately.

When α is large compared with η the curvature of the $(\log I, d)$ plots ceases to be apparent and the latter becomes linear. It has been shown by Prasad (1960) that under these conditions the exponential term in Eqn (2) tends to dominate the subtractive term particularly at large values of d ($d>0{\cdot}5$ cm) and the current growth in the gap can be approximated by

$$\frac{I}{I_0'}=\frac{\exp\left[(\alpha-\eta)d\right]}{1-\gamma'\left(\exp\left[(\alpha-\eta)d\right]-1\right)} \qquad \ldots\ldots(4)$$

where $I_0'=I_0\alpha/(\alpha-\eta)$ and $\gamma'=\gamma\alpha/(\alpha-\eta)$. If further $\alpha/(\alpha-\eta)$ is close to unity, then Eqn (4) can be approximated to

$$\frac{I}{I_0}=\frac{\exp\left[(\alpha-\eta)d\right]}{1-\gamma\left(\exp\left[(\alpha-\eta)d\right]-1\right)} \qquad \ldots\ldots(5)$$

as in a non-attaching gas. This shows that the mean slope of the $(\log I, d)$ plot under these conditions would yield an 'apparent' value of $\alpha/p\simeq(\alpha-\eta)/p$ and the value of the secondary coefficient γ would be in error by a factor of $(\alpha-\eta)/\alpha$.

It follows from Eqn (5) that the criterion for breakdown at which current I becomes self-maintained and independent of I_0 is

$$\gamma\left(\exp\left[(\alpha-\eta)d_{\mathrm{S}}\right]-1\right)=1 \qquad \ldots\ldots(6)$$

where d_{S} is the breakdown sparking distance (cm).

Studies by earlier workers, working under single collision conditions, show that a resonant attachment process occurs in carbon monoxide at about 10 ev. The process has been interpreted by Hagstrum (1955) as

$$\mathrm{CO}+\mathrm{e}\rightarrow\mathrm{C}+\mathrm{O}^-. \qquad \ldots\ldots(7)$$

Further processes occur at about 21 and 23 ev and are of a continuous nature involving ion pairs. These are interpreted by Hagstrum as

$$\mathrm{CO}+\mathrm{e}\rightarrow\mathrm{C}^++\mathrm{O}^-+\mathrm{e} \qquad \ldots\ldots(8)$$

$$\mathrm{CO}+\mathrm{e}\rightarrow\mathrm{C}^-+\mathrm{O}^++\mathrm{e}. \qquad \ldots\ldots(9)$$

In the present study it was not possible to observe attachment for the parameter $E/p > 56$ v cm^{-1} (mm Hg)$^{-1}$ corresponding to the mean electron energy of approximately 4 ev because the curvature of the ($\log I, d$) plots ceased to be apparent. Energy considerations indicate that under these conditions, i.e. for mean electron energies less than 4 ev, the possibility of reactions (8) and (9) contributing to the negative ion formation to any appreciable degree can be ruled out (cf. § 5). Thus reaction (7) is the only one that need be considered for mean electron energies less than about 4 ev. However the formation of negative ions at higher pressures where three-body processes must be considered will presumably comprise

$$CO + e \rightarrow CO^{-*} \qquad \ldots\ldots (10)$$

(CO^{-*} denotes an excited state of CO^{-}) together with reaction (7). The degree of branching between (7) and (10) is not known.

Consequently values of α, η, apparent α, γ and the breakdown sparking distance d_s have been calculated in carbon monoxide by employing Eqns (3), (5) and (6). The authors find that the measurements of pre-breakdown currents conform to the above theory over a wide range of pressures.

From the mean values of α/p and η/p so obtained the mean cross sections for ionization and attachment have been calculated for various electron mean energies and an attempt has been made to compare these values of cross sections with the values computed from the low pressure single collision data by assuming either a Maxwellian or a Druyvesteyn distribution of electron energies.

§ 2. EXPERIMENTAL PROCEDURE

A detailed description of the apparatus and the modifications made to improve its performance and accuracy have been published earlier (Hopwood, Peacock and Wilkes 1956, Bhalla and Craggs 1960) and will not be dealt with here. In the present study the ionization chamber was always evacuated to better than 5×10^{-6} mm Hg with an apparent leak of less than $0{\cdot}4\,\mu\,h^{-1}$, before the gas was admitted. The gas used in the experiments up to 100 mm Hg pressure was spectroscopically pure and supplied by British Oxygen Gases Ltd., but preliminary measurements up to 100 mm Hg pressure and the final measurements at 300 mm Hg pressure were made in cylinder gas (97·3% carbon monoxide, 1·7% nitrogen, 0·8% carbon dioxide, 0·2% oxygen) obtained from the Imperial Chemical Industries Ltd. Each gas filling from the cylinder was passed very slowly through a trap maintained at -78°c by using a mixture of solid carbon dioxide and acetone.

The gas pressures were measured (corrected to 20°c) either on an oil manometer using silicone oil of specific gravity 1·09 to within $\pm 0{\cdot}05$ mm Hg or on the micromanometer (cf. Hopwood, Peacock and Wilkes 1956) to within $\pm 0{\cdot}5$ mm Hg. A platinum coated cathode was used throughout this study and its distance from the dural (aluminium alloy) anode was measured to within $\pm 0{\cdot}005$ mm. The voltage applied to the ionization chamber, variable in steps of 0·2 volt (0 to 50 kv) was known to within $\pm 0{\cdot}3$% and the ionization currents produced could be determined to an accuracy better than 1·5%. The overall error in the measurement of α/p should therefore be not greater than 3%. It is very difficult to assess the errors in η/p, since they depend on curve fitting but it is estimated that in the most favourable conditions (medium values of E/p) they are about $\pm 5\%$ increasing to perhaps $\pm 15\%$ for low and high values of E/p.

§ 3. DATA AND RESULTS

The experiments were conducted over a pressure range of 2·5 to 300 mm Hg (corrected to 20°C) and a range of E/p from 36 to 200 v cm^{-1} (mm Hg)$^{-1}$. Some of the typical ($\log I$, d) plots at 25 and 100 mm Hg pressures are shown in Fig. 1. All these plots exhibit curvatures characteristic of Eqn (3), thus justifying the assumption made regarding the mechanism of negative ion formation. It was observed, however, that, beyond a particular value of the parameter E/p, for each pressure the curvature of the plots ceased to be apparent and the latter became linear.

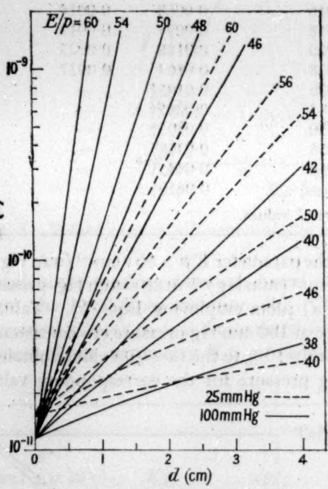

Fig. 1. Ionization currents in carbon monoxide at 25 and 100 mm Hg pressures for various constant values of the parameter E/p (v cm^{-1} (mm Hg)$^{-1}$).

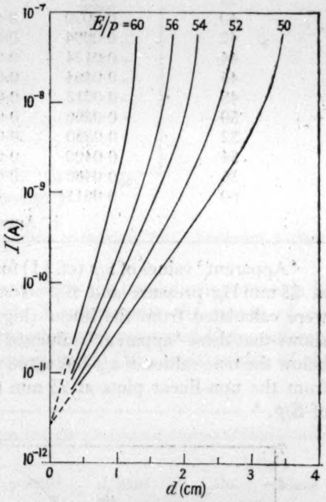

Fig. 2. Ionization currents in carbon monoxide at 100 mm Hg pressure for various constant values of the parameter E/p (v cm^{-1} (mm Hg)$^{-1}$).

Figure 2 shows the upcurving of ($\log I$, d) plots indicating the presence of secondary ionization processes. For the sake of brevity only typical plots for 100 mm Hg pressure are shown, for which the initial photoelectric current I_0 from the cathode was reduced by adding a fine wire gauze filter in the path of the ultra-violet radiation, from the low pressure mercury discharge lamp, incident on the cathode. This enabled pre-breakdown currents to be measured sufficiently close to the sparking distance without causing space-charge distortion of the electric field due to unnecessarily large values of anode current.

3.1. *Evaluation of α and η*

The values of α and η have been computed from the above-mentioned curves by a careful process of curve fitting employing Eqn (3). The values of α/p and η/p obtained in the range of $E/p = 36$ to $60\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$ at 25 and 100 mm Hg pressures are given in Table 1 and the values of η/p are plotted as a function of E/p in Fig. 3, which also includes Prasad's (1960) data in dry air for comparison. Values of α/p and η/p obtained at 300 mm Hg pressure are not included, since they are considered only to be of sufficient accuracy to measure γ and breakdown potentials because of impurities present in the gas (cylinder gas).

† 'Apparent' values.

'Apparent' values of α/p (cf. § 1) for the parameter $E/p > 56\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$ at 25 mm Hg pressure and $E/p > 46\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$ at 100 mm Hg pressure were calculated from the linear ($\log I$, d) plots employing Eqn (5). Table 1 shows that these 'apparent' values of α/p at 100 mm Hg pressure are consistently below the true values of α/p but agree within 10% to the $(\alpha-\eta)/p$ values obtained from the non-linear plots at 25 mm Hg pressure for the corresponding values of E/p.

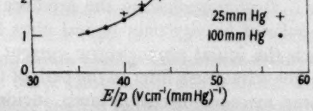

Fig. 3. Values of η/p as a function of E/p in carbon monoxide and in dry air for comparison.

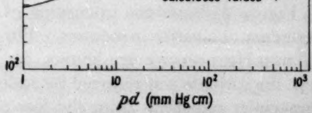

Fig. 4. Observed breakdown potentials as a function of pd in carbon monoxide and in dry air for comparison.

3.2. *Breakdown Measurements and γ*

Breakdown potentials V_s were measured over a pressure range of 2·5 to 300 mm Hg (corrected to 20°c) up to $pd \sim 1050$ mm Hg cm and are plotted (in volts) as a function of pd in Fig. 4, which includes Prasad's (1959, 1960) data in dry air for comparison. Results showed no pressure dependence (within 2% for spectroscopically pure gas and 2·5% for the cylinder gas) for any particular value of pd, thus indicating that Paschen's law is obeyed in this region.

Values of the secondary coefficient γ have been computed from the upcurving of linear ($\log I$, d) plots (cf. Fig. 2) at various pressures employing Eqn (5) and are plotted as a function of E/p in Fig. 5. These values of γ have been used to calculate the sparking distances d_s and consequently the breakdown potentials V_s from the breakdown criterion (6). Table 2 summarizes the values of α/p (apparent values), γ, d_s and calculated V_s, together with measured V_s for different values of the parameter E/p at various pressures. Calculated values of the

breakdown potential agree with the measured values to within 1% (cf. Table 2) and are indicated in Fig. 4. The good agreement between the measured and the calculated values of breakdown potential shows that the static breakdown in carbon monoxide is brought about by the Townsend build-up processes up to a pd of 1050 mm Hg cm.

§ 4. CORRELATION OF RESULTS WITH LOW PRESSURE EXPERIMENTS

Calculated values of mean cross sections for ionization $\overline{\sigma^+}$ and for attachment $\overline{\sigma^-}$ employing the cross section data from low pressure experiments in carbon monoxide (Craggs and Tozer 1958) are compared with the values obtained from the present study, using the electron drift and agitation velocity data from the diffusion experiments (Skinker and White 1923) for the Maxwellian and Druyvesteyn distributions.

The earlier work of Deas and Emeléus (1949), Tozer, Thorburn and Craggs (1958) and Thompson (1959) shows that the mean cross section for any particular collision process for the mean energy $\bar{E}$ of a given energy distribution is given by the equation

$$\bar{\sigma}_{\bar{E}} = \int \sigma_E v_E \, dN_E \Big/ \int v_E \, dN_E \qquad \ldots\ldots(11)$$

where σ_E is the cross section for this process for electrons of energy E ev and v_E is the velocity and dN_E the number of electrons in the range E to $E+\delta E$ of the distribution in the swarm. Further, swarm constants α/p and η/p can be converted into a mean cross section for any particular value of E/p from the knowledge of the drift velocity W, the mean velocity of agitation U and mean energy $\bar{E}$ of the electrons as functions of E/p by using the equation

$$\bar{\sigma}_{\bar{E}} = \frac{1}{N}\frac{W}{U}\frac{\theta}{p} \qquad \ldots\ldots(12)$$

where N is the number of molecules per cm³ at 1 mm Hg at the appropriate temperature and θ represents α or η. However it is to be noted that when employing the data from the diffusion experiments the various quantities should be corrected for the different energy distributions assumed (Healey and Reed 1941, Huxley and Zaazou 1949).

The $\overline{\sigma^+}$ and $\overline{\sigma^-}$ values thus obtained by using the ionization and attachment cross sections from Craggs and Tozer's (1958) low pressure data employing Eqn (11) and the mean values of α/p and η/p from the present measurements employing Eqn (12) are represented in Figs 6 and 7 for both the Maxwellian and the Druyvesteyn distributions.

§ 5. DISCUSSION

The double sets of values at 25 and 100 mm Hg pressures given in Table 1 show that the measured values of α/p and η/p for different gas fillings are consistent and the 'apparent' values of α/p (cf. § 1) agree with the true values of α/p to within 10%. However, for the values of the parameter $E/p > 60\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$ contributions due to the attachment processes decrease rapidly (cf. Fig. 8) and the 'apparent' values of α/p approach the true values of α/p.

Further, the values of α/p obtained at different pressures in the range E/p where the results overlap, also showed good agreement within the experimental limits ($\pm 3\%$). These considerations suggest that α/p and η/p are not pressure dependent and are therefore functions of E/p. The values of α/p and η/p do not depend on the ionization current, which can be seen by a careful consideration of the experimental data such as those, for example, plotted in Fig. 1. However no accurate measurements could conveniently be made at pressures higher than 100 mm Hg because the quantities of spectroscopically pure gas required were prohibitively great.

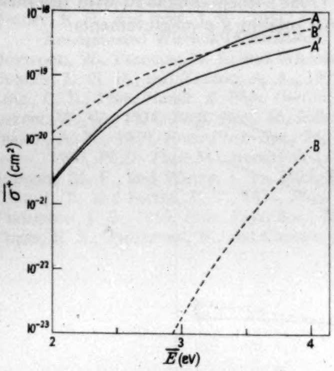

Fig. 6. Mean ionization cross sections in carbon monoxide as a function of mean electron energy. A, calculated from Craggs and Tozer's low pressure data, for a Maxwellian distribution of electron energies; A′, calculated with the data from the present study, for a Maxwellian distribution of electron energies; B and B′, as for A and A′ but with a Druyvesteyn distribution.

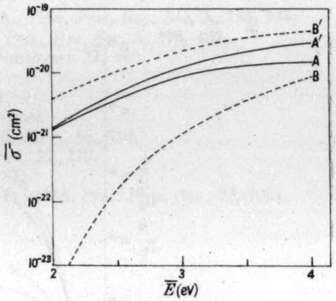

Fig. 7. Mean attachment cross sections in carbon monoxide as a function of mean electron energy. A, A′, B, B′, as in Fig. 6.

Figures 6 and 7 show respectively for ionization and attachment the comparisons between the mean cross sections deduced from α/p and η/p measurements and from the low pressure single collision work of Craggs and Tozer (1958) assuming either a Maxwellian or a Druyvesteyn distribution of electron energies. The results obtained by using the Maxwellian distribution show satisfactory agreement whereas it seems that the Druyvesteyn distribution does not apply. It was therefore decided to use the Maxwellian distribution and extend the calculations for the mean attachment cross sections to 10 ev mean electron energy and estimate theoretically the contributions made by reactions (8) and (9) to the negative ion formation. The mean ionization and attachment cross sections, calculated from the low pressure data as well as from the present measurements, are shown in Fig. 8 as a function of mean electron energy (2 to 10 ev). The mean attachment cross sections are represented by the curve F when contributions due to reactions (8) and (9) are ignored and by the curve G when these are taken into consideration. This indicates that the contributions made by reactions (8) and (9) to the negative ion formation for mean electron energies less than 4 ev are negligible. As mentioned earlier, no attachment could be observed in this study for the parameter $E/p > 56\,\mathrm{v\,cm^{-1}(mm\,Hg)^{-1}}$, i.e. mean electron energy $\simeq 4$ ev, because the curvature of ($\log I$, d) plots ceased to be apparent. These considerations justify the use of Eqn (2) to represent the attachment processes in the present study. Fig. 8 also includes the mean ionization cross sections calculated from the low pressure data of Tate and Smith (1932). These show slightly better agreement than those calculated from the low pressure data of Craggs and Tozer (1958) when compared with the mean ionization cross sections obtained from the present α/p measurements.

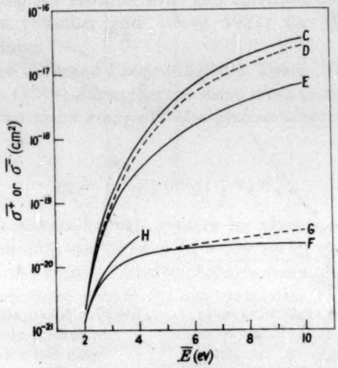

Fig. 8. Mean ionization and attachment cross sections in carbon monoxide as a function of mean electron energy, for a Maxwellian form of electron energy distribution. C, D and E, mean ionization cross sections; F, G and H, mean attachment cross sections. C, F and G, calculated from Craggs and Tozer's low pressure data; D, calculated from Tate and Smith's low pressure data; E and H, calculated with the data from the present study; F and G, see text for details.

It is found that the 'apparent' values of α/p, i.e. $(\alpha-\eta)/p$ in dry air are higher than those in carbon monoxide for the corresponding values of the parameter E/p, e.g. approximately a factor of 3 at $E/p = 50\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$. The secondary ionization coefficient γ in dry air (Prasad 1959) as well as in carbon monoxide is of the same order, e.g. $\gamma \sim 10^{-4}$ at $E/p = 50\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$. Therefore breakdown potentials in dry air should be lower than those in carbon monoxide for the same values of *pd*. Breakdown potentials in carbon monoxide and dry air are indicated in Fig. 4 as a function of *pd* and it shows that the curve for dry air is lower than that of carbon monoxide as expected.

The Influence of Cathode and Anode Surfaces on the Electric Strength of Liquid Argon

By D. W. SWAN and T. J. LEWIS

Electrical Engineering Department, Queen Mary College,
Mile End Road, London, E.1

MS. received 13*th March* 1961

Abstract. The electric strength of liquefied argon is found to depend to a marked degree on the nature of both cathode and anode. This effect has been investigated systematically. The cathode is thought to influence the strength through the process of electron emission into the liquid, whilst the anode becomes important only if the rate of emission from the cathode exceeds that at which the anode can accept charge. In this case a high space charge field is set up near the anode which can lower the applied field necessary for breakdown. By measuring the electric strength of liquid argon containing various concentrations of oxygen, it has been shown that probably the anode space charge is formed only when part of the current before breakdown is carried by negative oxygen ions. The electric strength is found to be very sensitive to small concentrations of oxygen.

---

§ 1. INTRODUCTION

MEASUREMENTS of the electric strengths of liquefied argon, oxygen and nitrogen have been reported in an earlier paper (Swan and Lewis 1960) and it was shown that for argon in particular, the strength was greatly influenced by the nature of the cathode and anode surfaces and by the presence of dissolved oxygen. The experiments reported here are a continuation of that work in which these effects have been studied in more detail. Hancox (1957) has already reported that the degree of cathode surface oxidation can influence the impulse electric strength of transformer oil, and Sletten (1959) has demonstrated that dissolved oxygen increases the strength of *n*-hexane. Both these effects are found to a marked degree with the inert liquid argon, which is ideal for such studies since a minimum of damage occurs to the liquid and electrodes when a discharge takes place. It has been found possible to separate the roles of cathode and anode in determining the strength of liquid argon and to advance reasons for the unusual control exercised by the anode.

The apparatus and experimental techniques were the same as those described in the earlier paper (Swan and Lewis 1960). The electrodes were 5 mm diameter spheres and the electrode spacing could be adjusted externally by means of a micrometer. The procedure for obtaining reproducible surface oxide conditions on the electrodes was simple. Freshly polished electrodes were allowed to oxidize freely in dry air in a desiccator for pre-determined times and the oxide growth was then arrested by immersion in *n*-hexane. This procedure had previously been found to give reliable control of the surface oxide in the measurements reported by Hancox (1957). Except for the experiments using spectroscopically pure argon and mixtures of argon and oxygen, commercial grade argon has been used having a purity of 99·95%; the significant impurities being nitrogen (< 500 parts per million), oxygen (< 20 parts per million), and hydrogen (< 10 parts per million).

§ 2. EXPERIMENTAL RESULTS

2.1. *Influence of Electrodes*

For each sample of liquid and set of electrodes the breakdown voltage was obtained at a number of electrode spacings ranging from 2×10^{-3} cm to 10^{-2} cm. The electric strength was then determined as the slope of this characteristic, which was usually a straight line within experimental error with an intercept of approximately 1 kv if extrapolated to zero electrode spacing. A similar intercept was found in previous measurements with liquefied gases (Kronig and Van der Vooren 1942, Blaisse, van den Boorgaart and Erne 1958) and in measurements on hydrocarbon liquids (Lewis 1953). The reason for this intercept is not fully understood at the moment but in a recent study (Swan 1961) it has been shown that a mechanism of breakdown involving a small degree of ionization in the liquid could account for it (see § 3). At each electrode spacing it was found necessary to record about twenty values of the breakdown voltage in order to obtain a reliable average. Fig. 1 shows the results obtained for a number of electrode materials, and in every case both anode and cathode were treated identically. The results for platinum and gold show that contact with air in the desiccator did not influence the strength. This is consistent with the idea that the surface change for the other metals produced by exposure to air in the desiccator is due to oxidation, since neither platinum nor gold forms oxides at room temperatures. For stainless steel, brass, copper and aluminium electrodes there is a considerable change in electric strength with increasing oxidation time. Maxima occur in the strength for both stainless steel and brass electrodes

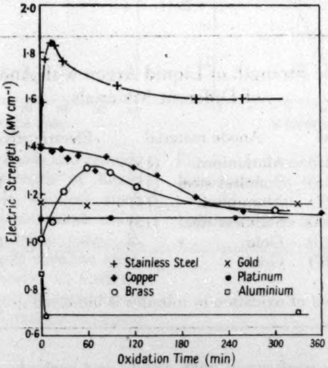

Fig. 1. Electric strength of liquid argon with oxidized electrodes.

but copper and aluminium do not produce an increase in the initial stages of oxidation, the strength falling throughout the entire range of oxidation times. The points on the curve for copper electrodes are seen to be more scattered at the shorter oxidation times than the points obtained with other electrode materials. This is thought to be due to the very temperature-dependent rate of oxide growth on copper, the heating produced during the final stage of polishing being sufficient to cause appreciable variations in the surface conditions from one test to another. Aluminium electrodes produce quite a different characteristic which can be explained in terms of the very rapid initial oxidation of that metal which does not continue at longer times.

Initially (Swan and Lewis 1960), these effects were attributed to the combined but opposing influences of the increasing effective barrier to emission at the cathode due to the growth of the oxide, and the subsequent decrease due to positive ions from the liquid forming a double layer there (Green 1955). If the electric strength were directly related to the emission then a plausible explanation of the results would be possible. The absence of an initial increase of strength when using copper or aluminium electrodes could be attributed to the thickness and nature of the oxide present at 'zero oxidation time' since, in the preparation, a thin layer of oxide will form even when the time in the desiccator is zero. For copper this layer may contain the highly insulating cupric oxide (Ronnquist and Fischmeister 1960) and thus the positive ion layer could form readily, resulting in an increased emission. Aluminium would behave in a similar manner.

Table 1. Electric Strength of Liquid Argon with Anode and Cathode of Different Materials

Cathode material		Anode material		Electric strength (MV cm^{-1})
Aluminium	(15)	Aluminium	(15)	0·69
Aluminium	(15)	Stainless steel	(15)	1·44
Stainless steel	(15)	Aluminium	(15)	0·88
Stainless steel	(15)	Stainless steel	(15)	1·86
Stainless steel	(0)	Gold		1·22
Stainless steel	(17)	Gold		1·26

The period of oxidation in minutes is indicated in brackets.

However, experiments performed with anode and cathode of different materials show that the state of the anode surface also influences the strength, so that these suggestions are not correct. Table 1 gives results for stainless steel and aluminium electrodes and it can be seen that, with an aluminium cathode of 15 minutes' oxidation time, the strength is 0·69 MV cm^{-1} when the anode is aluminium and 1·44 MV cm^{-1} when it is stainless steel. On reversing the aluminium–stainless steel pair, the strength fell to 0·88 MV cm^{-1}, and with both electrodes of stainless steel the strength was 1·86 MV cm^{-1}. As a further check on the influence of the cathode, a gold anode was selected because of its inactivity with oxygen, and the strength determined for changes of oxidation time of a stainless steel cathode (Table 1). There was only a slight increase in strength as the cathode was oxidized to the point corresponding to the peak strength obtained with two stainless steel electrodes (Fig. 1), in fact the strength (1·26 MV cm^{-1}) is little greater than that for two gold electrodes (1·16 MV cm^{-1}). It is concluded that the gold anode is exerting a much greater influence than the cathode in this case.

2.2. *Separation of Cathode and Anode Effects*

In order to obtain results showing cathode effects without anode influence it was necessary to substitute a stainless steel electrode of zero oxidation time for the unsuitable gold anode. As described below, such an electrode will exhibit the least anode influence. With this arrangement curve A of Fig. 2 was obtained.

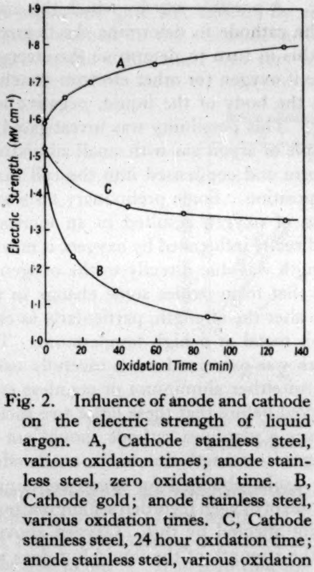

Fig. 2. Influence of anode and cathode on the electric strength of liquid argon. A, Cathode stainless steel, various oxidation times; anode stainless steel, zero oxidation time. B, Cathode gold; anode stainless steel, various oxidation times. C, Cathode stainless steel, 24 hour oxidation time; anode stainless steel, various oxidation times.

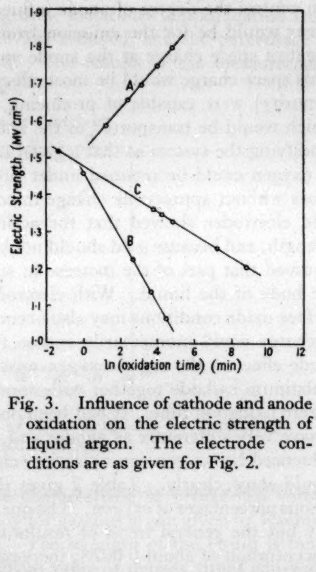

Fig. 3. Influence of cathode and anode oxidation on the electric strength of liquid argon. The electrode conditions are as given for Fig. 2.

The strength is seen to increase continuously for oxidation times up to 140 minutes and there is no tendency for a peak strength at about 15 minutes as occurs when both electrodes are oxidized for the same period. This is considered to be good evidence that the cathode oxidation was responsible for the initial increase of strength when using stainless steel electrodes. A similar cathode oxidation could also produce the increase observed with brass electrodes. To demonstrate that the anode determines the decline in strength for oxidation times beyond the peak in Fig. 1 a gold cathode was employed with stainless steel anodes of different oxidation times. The strength declined continuously with increasing anode oxidation time in the manner shown in curve B of Fig. 2. A similar result shown as curve C was obtained by using a stainless steel cathode which had been oxidized for 24 hours (thus giving a maximum strength due to the cathode) and a stainless steel anode with oxidation times up to 120 hours. The complete characteristic is given in logarithmic form in Fig. 3 together with the results of Fig. 2 curves A and B. The plots are good straight lines showing that the strength varies exponentially with oxidation time, but due to the overall complexity of the relationship between strength and oxide growth, it is not possible to explain why this should be so.

2.3. *Oxygen in Solution*

From the fact that curves B and C of Fig. 3 have different slopes for the anode effect in spite of identical stainless steel anodes, it may be deduced that the cathode can control the degree of anode influence. A possible way by which this could occur would be for the emission from the cathode to determine the degree of negative space charge at the anode and this in turn to determine the strength. This space charge would be most effective if oxygen (or other electron-attaching impurity) were capable of producing, in the body of the liquid, negative ions which would be transported to the anode. This possibility was investigated by modifying the system so that a given sample of argon gas with small admixtures of oxygen could be retained under pressure and condensed into the cell many times without appreciable change in composition. Some preliminary tests with gold electrodes showed that the addition of oxygen resulted in an increased strength, and because gold should not be directly influenced by oxygen, it may be assumed that part of the increase in strength was due directly to the oxygen in the body of the liquid. With electrodes that form oxides some change in the surface oxide conditions may also occur to alter the strength, particularly as each discharge could momentarily expose fresh metal at a high temperature. The anode effect in the argon–oxygen mixtures was examined more carefully using a platinum cathode together with anodes of either aluminium or stainless steel of zero oxidation time. It had been observed before that these latter two metals behave very differently as anodes and, since a platinum cathode should not be influenced by oxygen concentration, changes in strength due to the anode effect should show clearly. Table 2 gives the results obtained for argon containing various percentages of oxygen. The quantities of oxygen recorded are approximate only but the general trend of results is not affected by this. Oxygen above a concentration of about 0·002% increases the strength of the liquid but does not

---

Table 2. Electric Strength of Liquid Argon–Oxygen Mixtures with Aluminium and Stainless Steel Anodes and a Platinum Cathode

	Electric strength (MV cm^{-1})		Difference
	Aluminium	Stainless steel	in strength
Liquid	anode	anode	(MV cm^{-1})
Commercial A 20%	1·35	1·71	0·36
Commercial A 1%	1·33	1·68	0·35
Commercial A 0·002%	0·686	1·07	0·384
Spectroscopic A 0·0002%	0·764	0·888	0·124

The quantity of oxygen in the mixture is given as a percentage in each case.

change the difference in strengths due to the different anodes. With very small oxygen concentrations the influence of the anode is reduced, the difference for spectroscopic grade argon being only 30% of the difference for commercial argon. A significant effect shown by the results of Table 2 is that with an aluminium anode the strength of the mixture first decreases as the oxygen content is increased and then increases in the same way as observed with the stainless steel anode. It might be expected from the earlier results that addition of oxygen should increase and not decrease the strength. The decrease found can be associated with space charge distortion of the field (§3).

It is clear from the foregoing results that the 'intrinsic strength' of liquid argon is not a meaningful quantity, but in order to obtain a reliable value for the electric strength of liquid argon a measurement was made using spectroscopically pure argon and gold electrodes. By using these electrodes contamination from oxygen absorbed on the electrode surfaces was reduced, and the percentage of oxygen in the argon itself was very small. The results of the measurement, shown in Fig. 4, are compared with the characteristic of breakdown voltage against the product of gap width and density for gaseous argon given by Kachikas and Fisher (1953) using brass electrodes. The strength of the liquid is found to be 750 kv cm^{-1}. It is seen that for a given value of density times gap-width the breakdown voltage of the liquid is considerably lower than that of the gas. The implications of this will be discussed in §3. Other measurements for spectroscopically pure argon have been given in Table 2 and in each case the strength is considerably less than 1 MV cm^{-1}.

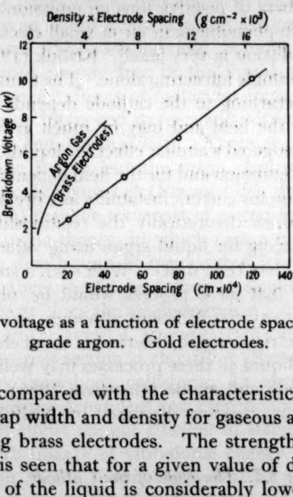

Fig. 4. Breakdown voltage as a function of electrode spacing for spectroscopic grade argon. Gold electrodes.

§ 3. Discussion

3.1. *The Breakdown Instability*

To explain the results obtained, certain breakdown processes are suggested which allow the roles of anode, cathode and the bulk liquid to be distinguished. It is generally accepted that, at the fields existing when breakdown occurs in liquid dielectrics (approximately 1 MV cm^{-1}), there will be significant electron emission from the cathode and that this emission will be field dependent.

It is obvious from the complex nature of the metal–liquid interface that the emission will not occur strictly according to the Fowler–Nordheim law as for a metal–vacuum interface but, nevertheless, available evidence suggests that a relationship with that form of field dependence is adequate for the present purposes (Watson and Sharbaugh 1960, Green 1956), particularly at low temperatures. The electrons emitted drift through the liquid, and if the field is high enough ionizing collisions (α process) could occur, producing positive ions which, moving towards the cathode, enhance the field there, so producing increased emission. This feedback process could cause the emission to increase progressively and so lead to breakdown as a result of high local heat input and vaporization of the liquid at the cathode. The concept of breakdown resulting from vaporization at the cathode has been suggested recently by Watson and Sharbaugh (1960). It should be emphasized that the degree of ionization required in the bulk of the liquid may be very small and not normally detectable at fields below breakdown if the increase of emission with cathode field is very rapid, so that only a small number of positive ions is necessary. Boyle and Kisliuk (1955) have examined the influence of small numbers of positive ions on emission and have used the idea to explain the breakdown phenomena in air at small electrode spacings when the chance of an ionizing collision is very small. Kisliuk (1959) has also considered the emission caused by a single ion acting alone. The number of electrons emitted as a result of one ion returning to the cathode depends on the number of ions already present and on the field and may be much greater than unity. Swan (1961) has recently investigated a similar effect for liquids, and choosing arbitrary but realistic laws for the emission and for the field dependence of ionization in the gap, has set up an equation for current instability as a breakdown criterion. It has been possible to reproduce theoretically the relationship between breakdown voltage and electrode spacing for liquid argon using values of αd (where d is the electrode spacing) much less than unity. With such a small number of ionizing collisions it is unlikely that an α process would be observed in conduction experiments. The necessity for sufficient although very small ionization gives rise to the increase of electric strength observed at small electrode spacings (Swan and Lewis 1960). In a liquid all these processes may well be confined to narrow filaments between cathode and anode (Goodwin 1956) and involve the single ion and the collective ion processes discussed by Kisliuk (1959) and by Boyle and Kisliuk (1955).

3.2. *The Role of the Cathode*

Due to surface dislocations, patches having low work function, and geometrical irregularities, a freshly prepared cathode surface will always be non-uniform in structure and certain sites will be able to emit more freely than others (Lewis 1955). The probability of breakdown being initiated at one of these sites is therefore high. On exposure to air oxidation will commence and this will occur first at those sites where the emission would be greatest (Cabrera 1957). On most metals after the initial preferential oxidation the whole surface will oxidize more slowly and uniformly (Mott 1947). The growth of an oxide layer will decrease the emission by raising the potential barrier at the surface; consequently a correlation between cathode oxidation and the breakdown instability outlined above might be expected. This is supported by the evidence of curve A of Fig. 2, and is in agreement with the work of Hancox (1957) who found similar results with oxidized stainless steel cathodes when measuring the impulse strength of transformer oil. In some experiments the strength did not attain a steady value until several discharges had occurred, and this was probably due to the preferential removal of sites of abnormally high emission. The patchy nature of the surface would give greater scatter in measurements than if it were microscopically uniform and would account for the coefficient of variation of 10% found in nearly every case.

The strong influence of a cathode-dependent field-emission process for breakdown of liquid argon would also account for the difference in breakdown voltage between the gaseous and liquid phases (Fig. 4), because Paschen's law is valid only when the processes of breakdown depend on the ratio of the field strength to density and not on field strength alone.

3.3. *The Effect of Dissolved Oxygen*

After emission from the cathode, electrons will suffer collisions with argon atoms and with impurity molecules as they move to the anode. The measured drift velocity of electrons in liquid argon is about 10^6 cm sec^{-1} for fields above about 5 kv cm^{-1} (Williams 1957, Malkin and Schultz 1951) and this value indicates that the electrons remain free in the liquid at these stresses. The presence of very small concentrations of molecular impurities can influence the motion of electrons (Swan 1960) and oxygen and nitrogen will produce stable negative ions (Davidson and Larsh 1950). There is no direct evidence for collision ionization in the liquid, but the mean electron energy in a field of 10^5 v cm^{-1} is likely to be only about 1 ev (Stacey 1959, Swan 1960). It has been suggested by Swan (1960) that the transport of electrons in liquid argon can be described by classical kinetic theory, in which case a field of 1 MV cm^{-1} would give an electron energy distribution of mean value 5·5 ev. This value is large enough to suggest that there would be sufficient electrons in the high energy tail of the distribution to produce the small degree of ionization required.

If oxygen is present in the argon a strong electron attachment process could exist having a maximum cross section at about 1 ev (Biondi 1960) in which stable O_2^- ions are formed by three-body collisions. In oxygen gas the three-body attachment process is pressure dependent and a second oxygen molecule stabilizes the excited ion. Argon atoms are not efficient in stabilizing the molecular ion since they cannot absorb quanta of vibrational energy and for this reason the concentration of oxygen in the liqiud argon will be very important. If the stabilizing collision occurs with a third body capable of resonant absorption, as would be the case when both the ion and the third body were identical molecules, the cross section for the transfer of the excess energy can be quite large. If n is the percentage concentration of oxygen in the liquid argon, N the number density of argon atoms and Q the cross section for the attachment process, the mean free path for attachment λ is given by $\lambda = (nNQ \times 10^{-2})^{-1}$. For liquid argon N is 2×10^{22} cm^{-3}, and if Q is taken to be 10^{-14} cm^2 (Massey 1938) the mean free path for attachment at an oxygen concentration of 0·001% is 5×10^{-4} cm. Clearly, since the electrode spacing is normally much larger than this many of the electrons will be attached to form negative ions at some point in the gap even at this low concentration. Another attachment process occurring at about 7 ev (Hurst and Bortner 1959) has a much smaller cross section but its influence on the number of electrons reaching higher energies may be very important. Thus both attachment processes could reduce the number of electrons making ionizing collisions. A greater electric field is then necessary to produce the required 'α' coefficient for breakdown.

3.4. *The Anode Process*

For breakdown measurements with steady voltage, the voltage is increased slowly over a period of time and many ions could be formed even at the lowest oxygen concentrations. These ions drift to the anode and, unless instantaneous neutralization of charge is possible there, a space charge will be formed. On a clean surface it is likely that neutralization can occur without difficulty, but if there is a semiconducting or insulating layer on the anode it is possible for this layer to acquire negative charge and prevent further neutralization of ions.

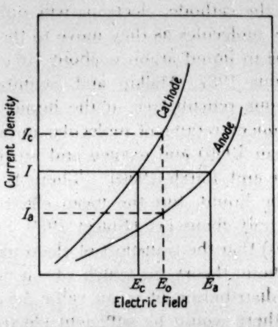

Fig. 5. Hypothetical representation of field–current characteristics for cathode and anode.

A space charge formed at the anode will enhance the field there as can be seen by considering a simple model in which the rates of charge emission from the cathode I_c and neutralization at the anode I_a are field dependent (Fig. 5). If, for a given mean applied field E_0, I_a would be less than I_c at that field, then a space charge will be produced to reduce the applied field at the cathode to E_c and raise it at the anode to E_a until $I_c = I_a = I$ (Fig. 5). A problem of this type but with different boundary conditions has been examined by Fan (1948). An analysis of the present situation including the effects of diffusion of the ions shows that the cathode field is practically undistorted whilst the anode field is increased until the current taken at that electrode is equal to that emitted from the cathode. This is a consequence of the large value of E_0 applied near to breakdown which causes the diffusion layer of ions to be very compact and against the anode surface. The growth of an insulating oxide layer on the anode surface will increase the blocking properties of the anode and alter the law relating I_a to the anode field. This will lead to a greater anode space charge field.

Thus, when the anode is blocking, the emitted charges will cross the gap in a field that is practically undistorted by space charge until they are very near to the anode surface. Here the field can increase rapidly, and an enhanced ionization rate α will occur. Since the space charge layer is small, the increased number of ionizing collisions will not be large, but only a few additional ions are necessary to cause an instability in the current from the cathode (Swan 1961). If the number of additional positive ions is small and they are removed rapidly from the space charge region by the high field, they will have a negligible effect on the field distribution.

The experimental curves in Fig. 1 can now be explained as follows. For zero oxidation time with stainless steel and brass electrodes the anode is not important in the breakdown process since the surface layer is not sufficiently insulating to prevent ion neutralization. This results in practically no anode space charge and the actual breakdown strength is determined by the emission properties of the cathode and by the positive ion space charge set up there by ions produced uniformly in the bulk of the liquid. As the oxide layer on the electrodes increases in thickness the cathode emission is reduced, and if the anode space charge is still insignificant a rise in the electric strength will result. When the electrode layers are sufficiently thick the emission from the cathode could exceed that accepted by the anode, resulting in an anode space charge field enhancement and an increased α value. The strength now depends more upon the anode surface condition than upon the cathode. Further increase of oxide layer increases simultaneously the space charge field at the anode and the production of positive ions in that region. The mean electric field required for breakdown is therefore reduced. Curves A and B of Fig. 2 can be explained in similar terms. The absence of the initial cathode-dependent range when using copper and aluminium electrodes (Fig. 1) can be explained if it is assumed that even at zero oxidation time the anode surface is sufficiently insulating to set up an appreciable space charge. With platinum and gold electrodes it is not possible to deduce whether the anode or the cathode is predominant since no variation with oxidation time was observed. However, the last two results in Table 1 suggest that a gold anode can give rise to a space charge since if the cathode had been the controlling electrode in these experiments the measured electric strength should have been much greater in magnitude. The existence of an insulating surface layer on gold has been proposed by Green (1955), who found that his results for the conduction current in *n*-hexane with gold electrodes could be explained in terms of an adsorbed hydrocarbon layer. It is quite possible that during electrode preparation a chemisorbed hydrocarbon layer could have been formed, thus giving rise to the observed effects.

If it is assumed that the law relating I_a to anode field is some rapidly increasing function of field, then, once a space charge has been established for a given pair of electrodes and a fixed applied field, the magnitudes of the space charge field will not be very dependent on oxygen concentration. An increase in the rate of arrival of negative ions will be compensated for by a small change in anode field. Consequently, in this case, the influence of the anode on the measured breakdown strength will be almost independent of oxygen concentration. The results in Table 2 confirm this. For commercial argon and argon with greater concentrations of oxygen, the strength increases with increasing oxygen content but the difference in strength due to different anode materials remains the same. The increase in strength with increasing oxygen content can, in this range, be attributed to a reduction in the number of electrons as a result of attachment in the liquid as discussed earlier. When the oxygen concentration is very small and ion formation in the liquid is less probable, no appreciable space charge is formed and the influence of the anode is reduced. From Table 2 it can be seen that for the spectroscopically pure argon the change in strength due to the different anodes was reduced to 30% of that observed at large oxygen concentrations. That a difference was still found suggests that, even in the purer argon, electron attachment was occurring, although at a very much reduced rate. For a stainless steel anode the strength increases continuously with increasing oxygen content, but with an aluminium anode there is a reduction in strength for very small oxygen concentrations which is followed by a continuous increase with the addition of more oxygen. This behaviour suggests that a stainless steel surface of zero oxidation time does not give rise to an anode space charge, so that the continuously increasing strength observed with increasing oxygen content and a stainless steel anode can be attributed to progressively increased electron attachment in the liquid. Aluminium, however, forms a highly insulating surface layer immediately on exposure to air. It is to be expected, therefore, that a space charge would form even at very low oxygen concentrations when only a small percentage of the electrons emitted form ions, and as a result of this an appreciable anode field enhancement could be set up during the period of voltage increase prior to breakdown. In this situation the α process would increase and the strength decrease with increasing oxygen concentration until attachment in the body of the liquid became predominant. At this point the effective reduction in α outweighs the increase due to the anode space charge, and the strength increases in a similar way to that observed with a stainless steel anode.

§ 4. CONCLUSIONS

As far as the authors are aware, this is the first time that the influence of the anode material on the electric strength of liquids has been examined in detail, although Sharbaugh, Crowe, Cox and Auer (1956) did observe a 9% reduction in the impulse strength of *n*-hexane when the anode surface was roughened. It is possible that for hydrocarbon liquids and oils which contain dissolved oxygen an anode influence may still be important, but that the solid deposits and adsorbed surface layers completely mask any variations in the properties of the underlying surface. With liquid argon, however, the absence of solid deposits allows slight changes of the electrode surfaces to be effective, and the influence of the cathode and anode may be investigated separately.

The formation of an anode space charge depends on the ease with which negative charge can be accepted at that electrode, and it is to be expected that negative ions in which the excess electron is more strongly bound would give rise to a greater space charge distortion than free electrons or ions on which the electron is only weakly attached. The much reduced anode influence observed with spectroscopic grade argon suggests that oxygen as an impurity is particularly important in this respect.

The mechanism postulated for the anode behaviour requires the establishment of a space charge at the anode surface, and is time dependent therefore. By using pulse fields of short duration it should be possible to prevent the development of the space charge, and the electric strength measured in this way should be independent of the anode. Work is now in progress to check this.

The Electronic Structure and Spectrum of Nitrobenzene

By T. E. PEACOCK
Chemistry Department, Kings College, Strand, London, W.C.2

MS. received 27*th March* 1961

Abstract. The self-consistent field molecular orbital theory has been used to calculate the π electronic structure and spectrum of nitrobenzene.

---

§ 1. Introduction

The self-consistent field molecular orbital theory (Roothaan 1951), as applied to π electron systems (McWeeny 1956, McWeeny and Peacock 1957), has been used to calculate the π electron charge distribution and spectrum of nitrobenzene. The matrix elements of the self-consistent field Hamiltonian are given by (McWeeny 1956)

$$h_{ii}^{\mathrm{F}} = \omega_i + \tfrac{1}{2}P_{ii}\gamma_{ii} - \tfrac{1}{2}\gamma_{ii}^{\mathrm{C}} + \sum_j (P_{jj} - Z_j)\gamma_{ij}$$

and

$$h_{ij}^{\mathrm{F}} = \beta_{ij} - \tfrac{1}{2}P_{ij}\gamma_{ij}$$

where the $\omega_i - \sum_j Z_j \gamma_{ij}$ (Z_j is the number of π electrons supplied by atom j) and the β_{ij} are the elements of the 'bare' framework Hamiltonian. The P_{ij} are the elements of the 'charge and bond order' matrix and the

$$\gamma_{ij} = \langle i(1)j(2)|\tau_{12}^{-1}|i(1)j(2)\rangle$$

are the two-electron interaction integrals. γ_{ii}^{C} is the one-centre two-electron integral for an atomic orbital centred on carbon atom i.

For a heterocyclic molecule the equation for h_{ii}^{F}, corresponding to a heteroatom, is (McWeeny and Peacock 1957)

$$h_{ii}^{\mathrm{F}} = \omega_i + \delta\omega_i + \tfrac{1}{2}P_{ii}\gamma_{ii} - \tfrac{1}{2}\gamma_{ii}^{\mathrm{C}} + \sum_j (P_{jj} - Z_j)\gamma_{ij}.$$

We choose $\omega_i + \frac{1}{2}\gamma_{ii}^{\mathrm{C}}$ as the energy zero, and then the h_{ii}^{F} vanish for alternant hydrocarbons. The energy unit β, is chosen to have the value of the resonance integral for nearest neighbours in benzene, i.e. $-4{\cdot}79$ ev (McWeeny and Peacock 1957). For a nitrogen atom contributing two π electrons $\delta\omega_i = 2{\cdot}80\beta$ (Peacock 1959 c) and for an oxygen atom contributing one electron $\delta\omega_i = 0{\cdot}8\beta$ (Sidman 1957). β_{ij} for N–O bonds was given the value $0{\cdot}570\beta$ and for C–N bonds $0{\cdot}538\beta$. The electron interaction integrals have the values assigned in previous calculations (McWeeny and Peacock 1957, Peacock 1959 a, b, c). In particular $\gamma_{ii}^{\mathrm{C}} = -2{\cdot}380\beta$ and $\gamma_{ii}^{\mathrm{N}} = -2{\cdot}672\beta$. γ_{ii}^{O} is given the value $-3{\cdot}060\beta$ (Sidman 1957). The Hamiltonian and the charge and bond order matrix are made self-consistent using McWeeny's iterative procedure (McWeeny 1956). The electronic spectrum was then calculated as in previous work (McWeeny and Peacock 1957, Peacock 1959 a, b, c).

§ 2. Results

Nitrobenzene was considered as a π electron system containing ten electrons; one from each carbon and oxygen atom and two from the nitrogen atom.

The self-consistent field molecular orbitals together with their energies are given in Table 1. The numbering of the atoms in the molecule is given in Fig. 1. The molecule has the symmetry C_{2v} and the molecular orbitals are given the symbols A and B, depending upon whether they belong to the symmetric or antisymmetric representation of the point group. The self-consistent charges and bond orders (for nearest neighbours) are shown in Fig. 2. From this charge distribution the π dipole moment is estimated to be 3·06 D.

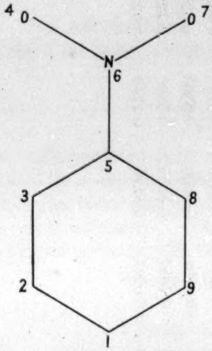

Fig. 1. The nitrobenzene molecule.

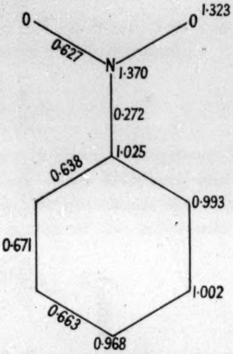

Fig. 2. π electron charges and bond orders.

For the calculation of the excited states, all of the configurations involving the molecular orbitals C, B, A, B′ and C′, in which one electron has been excited, were used. For completeness the ground state configuration was included; although as expected its interaction with the excited states was negligible. The symmetries of the configurations which arise are given in Table 2. The wave functions for the excited states in terms of the interacting configurations are given in Table 3.

Table 2

$\Psi_{A3} = 0{\cdot}0052\Phi(0) - 0{\cdot}2871\Phi(B \rightarrow B') + 0{\cdot}9579\Phi(C \rightarrow C')$	51200

§ 3. DISCUSSION

The observed spectrum of nitrobenzene has three main bands (Wolf and Strasser 1953) at 40 000$\bar{\nu}$, 36 000$\bar{\nu}$ and 30 200$\bar{\nu}$. These bands can be interpreted in terms of the excited states listed in Table 3. The 30 000$\bar{\nu}$ transition can be identified with the state in which $\Phi(A \to B')$ is prominent. The 36 000$\bar{\nu}$ transition is associated with the $\Phi(C \to B')$ and $\Phi(B \to B')$ states. Finally, the band at 40 000$\bar{\nu}$ can be associated with $\Phi(A \to C')$. From an examination of the orbital coefficients, the 30 000$\bar{\nu}$ is confined to the nitro-group. Both the A and B′ orbitals are fairly well localized on the nitro-group and this transition will therefore be characteristic of the nitro-group. Furthermore it is a $\pi \to \pi^*$ transition and not $n \to \pi$ as previously assigned. A recent interpretation of the experimental data confirms this (Godfrey and Murrell 1961).

Similarly the 36 000$\bar{\nu}$ transition will be expected to be benzene-like in character. $\Phi(C \to B')$ and $\Phi(B \to B')$ are the analogues of the benzene α and p bands, but they are heavily perturbed by the nitro-group. This leads to considerable charge transfer from ring to nitro-group (about $\frac{1}{2}$ electron in each case). Observations of the crystal spectrum should indicate that this band is both long and short axis polarized. The 40 000$\bar{\nu}$ band involves the transfer of almost a whole electron from the nitro-group to the ring. The A orbital is localized on the nitro-group, whereas the C′ orbital is concentrated in the ring. This band will be characteristic of benzenoid nitro-groups.

The observed behaviour of the three bands is in agreement with this interpretation. The model used gives a satisfactory interpretation of the spectrum of nitrobenzene.

ACKNOWLEDGMENTS

The author wishes to thank Professor D. P. Craig of University College London for many helpful discussions on the interpretation of the spectrum. He also wishes to thank Messrs. Shell Research Ltd. for financial support whilst he was at University College London, during which time this work was commenced.

LETTERS TO THE EDITOR

A Corrigendum to the Article 'Double Beta Decay' by H. Primakoff and S. P. Rosen in *Reports on Progress in Physics*

The following corrections should be made to Eqn (44) of the article mentioned in the title (Primakoff and Rosen 1959): in the coefficient of

$$|\langle\Psi_f^*|\sum_{n,m}\tau_n^{(\pm)}\tau_m^{(\pm)}\boldsymbol{\sigma}_n\,.\,\boldsymbol{\sigma}_m/r_{nm}|\Psi_i\rangle|^2 \equiv |M_2|^2 \qquad \ldots\ldots(1)$$

replace f_i by $\frac{1}{9}f_i$ for $i=1, 2, 3$, and in the coefficient of

$$\begin{aligned}2\mathscr{R}\ \langle\Psi_f^*|\sum_{n,m}\tau_n^{(\pm)}\tau_m^{(\pm)}/r_{nm}|\Psi_i\rangle\langle\Psi_f^*|\sum_{n,m}\tau_n^{(\pm)}\tau_m^{(\pm)}\boldsymbol{\sigma}_n\,.\,\boldsymbol{\sigma}_m/r_{nm}|\Psi_i\rangle^*\\ \equiv 2\mathscr{R}(M_1M_2^*) \qquad \ldots\ldots(2)\end{aligned}$$

replace f_i by $\frac{1}{3}f_i$ for $i=1, 2, 3, 6$; all other terms remain unchanged. Eqn (44) is now positive definite and in agreement with earlier, independent calculations of both authors (Primakoff 1952, Rosen 1957). Moreover the numerical estimates of no-neutrino $\beta\beta$ decay lifetimes (Eqn (54)) do not involve M_2 and are unaffected by these corrections.

At first sight, the corrected form of Eqn (44) does not appear to include, as a special case, the results of Greuling and Whitten for $m_\nu = V = 0$ (Greuling and Whitten 1960, Eqns (35)–(38)); in particular it does not contain the matrix element

$$M_3 \equiv \langle\Psi_f^*|\sum_{n,m}\tau_n^{(\pm)}\tau_m^{(\pm)}(\boldsymbol{\sigma}_n\,.\,\mathbf{r}_{nm})(\boldsymbol{\sigma}_m\,.\,\mathbf{r}_{nm})/r_{nm}^3|\Psi_i\rangle\,. \qquad \ldots\ldots(3)$$

The discrepancy can be resolved, however, by observing that the passage in our paper from Eqn (36) to Eqn (41) involves an average over the direction of $\mathbf{r}_{nm}$. This procedure automatically eliminates the matrix element

$$\left.\begin{aligned}M_4 &\equiv \langle\Psi_f^*|\sum_{n,m}\tau_n^{(\pm)}\tau_m^{(\pm)}T_{nm}/r_{nm}^3|\Psi_i\rangle\\ &\equiv 3M_3 - M_2\\ T_{nm} &\equiv \tfrac{3}{4}\sum_{\lambda,\mu=1}^{3}(\sigma_{n\lambda}\sigma_{m\mu}+\sigma_{n\mu}\sigma_{m\lambda}-\tfrac{2}{3}\delta_{\lambda\mu}\boldsymbol{\sigma}_n\,.\,\boldsymbol{\sigma}_m)\\ &\qquad\qquad \times(2(\mathbf{r}_{nm})_\lambda(\mathbf{r}_{nm})_\mu-\tfrac{2}{3}\delta_{\lambda\mu}r_{nm}^2)\end{aligned}\right\} \quad \ldots\ldots(4)$$

from our expression and replaces M_3 by $\frac{1}{3}M_2$ in the results of Greuling and Whitten. It then follows that Eqn (44) does contain their results as a special case, except for a difference in the sign of M_1.

The average over the direction of $\mathbf{r}_{nm}$ is a good approximation only if the initial and final 0^+ nuclear states are, to a large extent, spherically symmetric in ordinary space (i.e. ${}^1S_0$). Therefore, within the limits of this approximation, our results agree with those of Greuling and Whitten, except for the sign of M_1. Since our independent calculations (Primakoff 1952, Rosen 1957) agree on this sign, we believe ours to be correct.

LETTERS TO THE EDITOR

We should like to draw readers' attention to the publication of Letters to the Editor in this journal. We have arranged with our printers to publish letters six to seven weeks after receipt, provided they are reported upon favourably by our referees. For example, items for publication in the November issue of the journal should be received in the office not later than 20th September. This also applies to the other two journals of The Institute of Physics and The Physical Society, i.e. the *British Journal of Applied Physics* and the *Journal of Scientific Instruments*.

REVIEWS OF BOOKS

Angewandte Gitterphysik, 3rd Edn, by W. KLEBER. Pp. xii + 291. (Berlin: Walter de Gruyter, 1960.) DM 38.

This book makes an introductory survey of the whole field of crystal properties and their relation to lattice structure. Dr. Kleber is Professor of Mineralogy and Crystallography in the Humboldt University of Berlin, and has the primary aim of giving students who are only moderately equipped in mathematics an understanding of the fundamentals of crystal lattice theory and its applications. This aim determines the scope of the book, which is mainly concerned with the general properties of crystals at medium and high temperatures and says comparatively little either about low temperatures or about refined theories.

After an introductory section on the principles of crystal structure and its experimental determination, the greater part of the book deals with physical and physical chemical properties (both bulk and surface) of ideal crystals, and how they can be at least partly understood in terms of crystal structure and intermolecular binding. A final section discusses the real structure of crystals and properties dependent on lattice imperfections.

The book is clearly written, and avoids most of the complicated mathematical detail that so often obscures physical significance to the common reader. In places, however, it could have been improved by referring some of the sections to specialists for comment. The discussion of thermal properties, which is particularly interesting to the present reviewer, is probably one of the worst examples: it has no references after 1939, contains several inaccuracies and betrays an odd emphasis in its selection of topics. Zero-point energy is not mentioned, and the lattice is stated to be at rest at $T=0$; the cyclic boundary condition is stated to be physically equivalent to holding the end atoms of a chain fixed; and the coefficient of linear expansion (denoted by γ!) is continually confused with the coefficient of volume expansion, so that two different values for NaCl are even quoted on the same page (p. 160). A rather unrealistic model proposed by Klemm in 1928 for the vibrations and melting of NaCl is treated in considerable detail, but Lindemann's simple treatment is not mentioned. No indication is given of what the frequency distributions of crystals are really like (and hence why Debye's approximation is so good), and it is implied that the anharmonic contribution to the specific heat is necessarily positive. Nevertheless, even this section will give many students a clearer idea of thermal properties of crystals than they would get from trying to study the usual treatises.

In short, this is a good book, but a thorough critical revision could make it much better. Naturally it is rich in German references, which English readers should find refreshing. It is very well printed and bound. T. H. K. BARRON.

Atomic Theory for Students of Metallurgy, by WILLIAM HUME-ROTHERY. Pp. viii + 418. (London: Institute of Metals, 1960.) 50*s*.

Since it was first published in 1946 this book has been revised and reprinted several times and has become firmly established as an introduction to modern physical ideas on the structure and properties of metals and alloys, not only for the 'Students of Metallurgy' to whom it is addressed but also for physicists and chemists with an interest in the metallic state. The title has always been misleading and does the book less than justice for it deals with far more than atomic theory as such, three-quarters of it being an account of the properties, mainly electronic, of bulk metals and alloys.

The present edition is considerably enlarged (by 85 pages) and many chapters have been rewritten to take into account recent advances in knowledge. In particular there is a useful new chapter summarizing the experimental methods that are available for investigating electronic structure. The arguments are presented in a delightfully clear and usefully critical manner and the book contains probably as complete an elementary account of the electronic properties of metals as is to be found anywhere. Those familiar with earlier editions will welcome this more up-to-date treatment and to those coming new to the subject it may be warmly recommended as an excellent introduction to it. The book is well produced and the price is not unreasonable. A. D. L.

Physics of the Upper Atmosphere, ed. J. A. Ratcliffe. Pp. xi + 586. (New York, London: Academic Press, 1960.) $14.50.

The investigation of the upper atmosphere of the earth has long been the concern of physicists, radio scientists, astronomers and magneticians, and workers in the field have to be familiar with a correspondingly wide range of studies. In recent years the intensive measurements made during the International Geophysical Year, and the remarkable developments in space research, have both enhanced the importance of the subject and accelerated the study of it. The publication of this comprehensive and authoritative survey is thus very timely and greatly to be welcomed.

This volume is a co-operative effort on the part of a team of workers under the general editorship of Mr. J. A. Ratcliffe, formerly of the Cavendish Laboratory, Cambridge, and now Director of the Radio Research Station, Slough. Each of the contributing authors is an acknowledged authority in the branch of the subject concerned, and each chapter is, in effect, a monograph critically surveying the present state of knowledge and including a list of the more important references. The individual topics and authors are: The thermosphere—the earth's outermost atmosphere (S. Chapman), The properties and constitution of the upper atmosphere (M. Nicolet); The upper atmosphere studied by rockets and satellites (Homer E. Newell, Jr.); The sun's ionizing radiations (H. Friedman); The airglow (D. R. Bates); General character of aurorae (D. R. Bates); The auroral spectrum and its interpretation (D. R. Bates); Radar studies of the aurora (H. G. Booker); The ionosphere (J. A. Ratcliffe and K. Weekes); The upper atmosphere and geomagnetism (E. H. Vestine); The upper atmosphere and meteors (J. S. Greenhow and A. C. B. Lovell). The book was in preparation at the time of the International Geophysical Year and since the upper atmosphere was the subject of very intensive study during that period, it is fitting that in the final chapter of the book the authors have taken the opportunity of summarizing the significant advances in this field which occurred during the I.G.Y. and details of which had been published up to December 1959.

The planning and production of the book are of the highest quality and there can be no doubt that it will prove to be of the utmost value to all workers in this field. W. J. G. BEYNON.

High Energy Electron Scattering Tables, by R. HERMAN and R. HOFSTADTER. Pp. ix + 278. (Stanford, California: University Press, 1960.) 68*s*.

The study of high-energy electron scattering has made rapid progress in the past few years and an increasing number of laboratories are taking part or planning to take part in this work. In this book much of the information needed for the planning and interpretation of experiments is assembled, and it will surely take its place not only on the library shelves but also in the research rooms of these laboratories.

It deals essentially with the elastic scattering of electrons from nucleons and nuclei and is divided into two parts. The first 70 pages, which form an introduction to the tables, are also an excellent survey of the theoretical and experimental results in this field.

The second part, occupying about 200 pages, contains the following main groups of tables: (1) Nuclear charge density distributions for eleven different models. (2) The nuclear form factor for these tabulated against qa, where q is the momentum–energy transfer parameter and a is the root mean square radius. (3) The Rosenbluth scattering cross sections for point protons and neutrons from 50 MEV to 10 000 MEV, and the coefficients of the form factors F_1 and F_2 used in extending the Rosenbluth formula to nucleons of finite size. Values of q are also tabulated and these can be readily applied to the previous sets of tables. (4) Tables relating to scattering from the deuteron, in particular the cross section for inelastic scattering according to the point proton and neutron theory of Jankus and some sets of values from an extension of the theory to finite nucleons.

These are the chief contents. There are also graphs based on the tables, lists of kinematic relations, information on electron–electron and muon–nucleus scattering and much more.

Some of the material in this book may well become obsolete in a few years and in fact the authors say that they intend it as a preliminary handbook to be brought up to date as occasion demands. Nevertheless, it contains sufficient basic information to make it extremely useful for some time to come.

J. R. HOLT.

Graphite and its Crystal Compounds, by A. R. UBBELOHDE and F. A. LEWIS. Pp. xii + 217. (Oxford: Clarendon Press, 1960.) 35*s*.

Graphite is a material of great interest to the pure scientist, and of considerable and growing importance to technologists in many fields of activity. The authors have done a useful service to workers in both categories by bringing together much of the information available about graphite and related substances in a way that certainly fulfils their aim, that of giving descriptive access to current lines of research.

Inevitably, no single viewpoint can be used as a starting point for the discussion of properties as various as the thermoelectric power, the mechanical properties, and the oxidation of even pure, defect-free graphite; and an extension to compounds ranging from dilute solid solutions to materials behaving like organic macromolecules must introduce further complexities. The authors have shown great flexibility in adjusting their terminology to the topic under discussion, and are rightly aware of the part that can be played by defects of various types in rendering interpretations of a given property uncertain.

Some of the discontinuous impressions one receives, however, might surely have been avoided by a more logical arrangement of the material of the book, and by the inclusion in the earlier sections of some brief account of the theoretical models for metals and semiconductors, with which comparisons are often made. If a description of the structures of graphite and its compounds (including for this purpose boron nitride, the structure of which is described in the chapter on the thermal properties of graphite) had been followed at once by an account of models for their electronic structures, the discussion of individual properties in later sections could be handled more conveniently. As it is, the electron band structure of graphite is dealt with towards the end of the chapter on electronic properties, and after reference has been made in earlier sections to electronic contributions to the specific heat and transport properties, while a discussion of changes in energy band populations in the compounds comes three chapters later.

There can be no doubt however that this book will prove very useful to the growing number of people who are concerned with graphite and related materials; and its extensive bibliography provides convenient access to specialized accounts of the many theoretical, experimental, and technological points referred to. B. R. COLES.

From Dualism to Unity in Quantum Physics, by ALFRED LANDÉ. Pp. xvi + 114. (London: Cambridge University Press, 1960.) 18*s*. 6*d*.

The main theses of this book are roughly as follows. Statistical behaviour is a *fundamental* characteristic, both of classical and of quantum phenomena. Hence no distinction should be made between accidental and essential indeterminacy. This is supported by the following arguments: (*a*) absolute determinism can never be established as a physical doctrine; (*b*) it is a known fact (not logically impossible) that in many physical situations specific causes lead to randomly distributed effects; (*c*) this randomness is intrinsic, a fact supported by the conformity, or harmony, between *a priori* mathematical probability theory and statistical observed behaviour.

Though randomness is intrinsic, it is no mere *ad hoc* brute fact but can be shown to follow from the application of the principle of continuity. Randomness then is due to transitions between causally determined states.

The transition may be considered in connection with an important conceptual unit, the filter, leading to the definition of statistical passing fractions (of the passage of particles in a given state passing through a filter itself being in some state or other), using the principle of symmetry. Given the additional postulate of reproducibility, the passing fractions become transition probabilities. These may be expressed through matrices for which certain mathematical correlation laws hold, in particular a triangular matrix multiplication law, the law of unitary transformation, which turns out to be identical with the law of interference of probabilities. With the addition of the postulates of the homogeneity of space (q) and momentum space (p variable) together with the assumption of the dependence of transition values of observables on p- and q-intervals only, the author deduces the wave function $\psi(q, p) = \text{const.} \exp(2iqp/h)$.

This is a unitary theory because it insists that "particles are real things, ψ-waves are not" (p. 73), i.e. there is no need to invoke a principle of complementarity. Instead of wave-theory, we need no more than the concept of statistical frequency applied to the transition probabilities of particles subjected to some physical process of interference. The dualistic wave-particle ideas of the Copenhagen School as well as recent attempts at a determinist substructure for quantum mechanics (Bohm etc.) are both rejected.

Professor Landé is particularly concerned to show that the rules of quantum mechanics are not merely *ad hoc* but " can be understood as *necessities* rather than as oddities under certain simple ground postulates " (pp. 49–50). Actually, however, his argument for basic universal indeterminacy seems itself to involve a brute fact, viz. the harmony between statistical experienced behaviour and *a priori* probability theory. More specificially, even if the principle of continuity bestows rationality upon statistics, the statement that if the ratio of the number of particles blocked by a filter to that passed " is not to be quite erratic, *it can only be a definite* statistical ratio " (p. 19, italics mine) is certainly far from being transparently " self-evident " (p. 41). Further, Landé admits that he possesses no proof of the *uniqueness* of the " unitary transformation law" (p. 46), limiting himself to the statement that " it seems *inconceivable* " that another could be constructed, though quoting Eddington's remark, " The building at this point shows some cracks ".

Still, his attempt to " dispel the aura of incomprehensibility " of quantum mechanics by " simple, almost self-evident physical ground axioms, so that we can recognize it as a necessity rather than an oddity " (pp. 41, 42) is courageous, refreshing, and curiously harks back to seventeenth and eighteenth century modes of physical thought—indeed, Descartes is quoted approvingly on p. xv!

Although the author displays verbally hostility to " positivism " (pp. xi, 97), its essential approaches are fortunately frequently retained; thus we find on page 31 that the definition of the state of a system " has no concrete meaning unless it is (observationally) substantiated ". But one wonders how strictly the author has applied the principle himself ? Well-defined states must be reproducible. But though " position x of a particle is not a well-defined state, . . . position x at a certain time instant t is " (p. 29). Now how can the latter be reproduced ?

This is a most important and stimulating volume. It breaks fresh ground in fundamentals and one can only hope that it will be followed by more work on the explication of the simple meanings of quantum mechanics, in lieu of the " semantic tricks " (p. 72) with which only too much recent exploratory literature has been burdened. GERD BUCHDAHL.

The Hydrogen Bond, by G. C. PIMENTEL and A. L. MCCLELLAN. Pp. xii + 475. (San Francisco, London: W. H. Freeman, 1960.) 82*s*.

This work represents the first survey in book-form of the hydrogen bond in all its manifestations. About 2250 references to publications covering research done in the main in the last thirty years, testify to the growing interest in this field. The investigation of the hydrogen bond has for a long time been considered as a byway of physics and chemistry; with the increasing success in the elucidation of the structure of proteins and nucleic acids it has, however, become apparent that hydrogen bonds play a decisive role in the configuration of these spiral structures. A real understanding of this curious effect to which we may owe our very existence, becomes of increasing importance to the biochemist and biologist, quite apart from its intrinsic interest to the student of the nature of chemical bonding. This book will therefore fulfil a very useful function. It provides a detailed and complete discussion of the various phenomena produced by the presence of hydrogen bond such as anomalies in the pressure–volume–temperature curves, in the values of dielectric constants, the shifts and widths of infra-red and Raman spectra, in the spacings observed in the x-ray spectra of crystals, in the fine structure of nuclear magnetic resonance spectra and in neutron diffraction. So far, the last two methods have not come up to expectation; infra-red spectroscopy provides still the most accurate criterion for the presence of hydrogen bonds. The work done in this field is mainly, in spite of the great number of publications, in the qualitative stage; it lacks systematic attack and careful quantitative determinations are confined to Professor Mecke's admirable studies. Two chapters are devoted to the role of hydrogen bonds in the configuration of proteins, nucleic acids, industrial substances and the human body. The various attempts at a theory of the hydrogen bond are discussed. They have so far been unsuccessful. The experimental results are summarized in a great number of tables and diagrams illustrate the text.

The authors have been extremely thorough in the treatment of their subject but not very critical. The over emphatic presentation of the material is not quite in keeping with its general importance. L. KELLNER.

Field Theory of Guided Waves, by R. E. COLLIN. Pp. xiii + 606. (London: McGraw-Hill, 1960.) 128*s*.

The propagation of waves in transmission lines, waveguides and free space is studied in most honours degree courses in physics and electrical engineering. The engineer approaches the subject most readily through the distributed circuit concepts of transmission lines in terms of voltages, currents and impedances. He then discovers the limitations and finds that further progress requires the field approach using Maxwell's equations. For the physicist, on the other hand, Maxwell's equations frequently provide the starting point for the transmission and propagation of electromagnetic waves. Although this approach is more fundamental and more rigorous the ideas of equivalent circuits and impedances are most powerful in solving many problems, and it is most desirable that the serious microwave experimenter should be well versed in both methods.

The book under review is concerned with postgraduate study, and it is based almost entirely on field concepts though occasionally it uses equivalent circuits. It is assumed that the reader has a previous knowledge of microwave theory such as would be covered in a first course in physics or electrical engineering. The chapter headings are: Basic electromagnetic theory, Green's functions, Transverse electromagnetic waves, Transmission lines, Propagation in cylindrical waveguides, Inhomogeneously filled waveguides, Excitation of waveguides, Variational methods for waveguide discontinuities, Periodic structures, Integral transform and function theoretic techniques, Surface waveguides, Artificial dielectrics. There is a mathematical appendix and there are sets of problems at the end of each chapter. It will be seen that this is a fairly advanced text and it requires some mathematical ability in the reader. The coverage is wide and much of the material has not previously been collected together in one volume. The general presentation is first class. The book can be thoroughly recommended for reference purposes in all microwave laboratories. M. R. GAVIN.

Théorie des Groupes en Physique Classique et Quantique, Vol. 1, *Structures Mathématiques et Fondements Quantiques*, par TH. KAHAN. Pp. xxiv + 664. (Paris: Dunod, 1960.) 75 n fr.

The theory of the physical applications of groups and their representations is certainly a sufficiently large and well established subject to warrant up-to-date and unified treatment in a printed book. At present the student has at his disposal one or two excellent but old textbooks, a few key published papers, and a medley of mimeographed notes. The present attempt to give a complete account of the entire field of group theory in physics is therefore welcome. There is to be a second volume dealing with particular applications of groups. The first volume is largely of a mathematical nature. It is in seven parts, by different authors, each of which is nearly self-contained.

Part 1, by Cavaillès and Kahan, is the longest and also the most unusual. Its aim is to provide a thorough and rigorous understanding of all the mathematical notions directly or indirectly involved in group theory. This is done by a formal series of definitions and theorems, starting from the elements of mathematics, together with a few illustrative examples about rotation groups and spinors.

It seems to the reviewer that this was a misguided effort. The theoretical physicist will normally prefer a less formal treatment; or else he will do better to turn to an actual mathematics textbook. The physicist confronted with a mathematical term he does not understand may, however, find this part useful to refer to.

Part 2, by T. D. Newton, is about the inhomogeneous (and extended) Lorentz group and its unitary representations. Whilst chiefly concerned to recover the classic results of Wigner, the author combines this with some other material and presents it in a unified way which is nowhere else available in book form.

Part 3, by Gouarné, is on the theory of abstract groups; and Part 4, by Rideau, on group representations. Part 5 is also by Rideau and is about permutation groups and their representations. Part 7, by Nataf, deals with the three-dimensional notation group. This part contains the results most familiar to ordinary physicists, on angular momentum, Clebsch–Gordan coefficients, tensor operators, and so on. These four parts give straightforward and useful accounts of important topics, but they are portions of the theory already quite well covered by existing books.

Part 6, by Kahan, is on the axiomatic foundations of quantum theory, and does not seem to occupy a very natural place in the book.

The book as a whole suffers greatly from being by several different authors. There is considerable overlapping between different parts, and unity of presentation is not achieved. For example, rotation groups are mentioned in several places in unconnected ways. The work cannot help but be a useful source of reference, but a judgment on the value of the project must await the publication of the second volume. J. C. TAYLOR.

The Energy Levels of the Magnesium Isotopes of Mass 25 to 28

By S. HINDS, H. MARCHANT and R. MIDDLETON
Atomic Weapons Research Establishment, Aldermaston, Berks.

Communicated by K. W. Allen; *MS. received 7th March* 1961

Abstract. The energy levels of the magnesium isotopes of mass 25 to 28 inclusive have been measured with a broad-range magnetic spectrograph using a variety of deuteron and triton induced nuclear reactions. The following is a list of the reactions used to study each magnesium isotope together with the number of levels observed below a particular excitation energy:

^{25}Mg	^{24}Mg(d, p)^{25}Mg	54 levels below 7·64 Mev
	^{27}Al(d, α)^{25}Mg	54 levels below 7·64 Mev
^{26}Mg	^{25}Mg(d, p)^{26}Mg	49 levels below 8·617 Mev
	^{24}Mg(t, p)^{26}Mg	63 levels below 9·370 Mev
	^{27}Al(t, α)^{26}Mg	87 levels below 10·515 Mev
^{27}Mg	^{26}Mg(d, p)^{27}Mg	18 levels below 5·017 Mev
	^{25}Mg(t, p)^{27}Mg	42 levels below 7·031 Mev
^{28}Mg	^{26}Mg(t, p)^{28}Mg	19 levels below 6·759 Mev

The ground state *Q*-values of the above reactions were also measured.

---

§ 1. Introduction

The work described in this communication originated as a study of the energy levels of ^{25}Mg using the ^{24}Mg(d, p)^{25}Mg and the ^{27}Al(d, α)^{25}Mg reactions. However, due to the presence of small amounts of ^{25}Mg and ^{26}Mg in the enriched ^{24}Mg target it was also thought desirable to study the ^{25}Mg(d, p)^{26}Mg and the ^{26}Mg(d, p)^{27}Mg reactions. This greatly assisted in the analysis of the ^{25}Mg data and also provided much new information about the nuclei ^{26}Mg and ^{27}Mg. Recently, when tritium was accelerated in the Aldermaston 6 Mev electrostatic generator, it was possible to confirm the latter results with measurements made using a number of triton induced reactions. Thus, ^{26}Mg was further studied using the ^{24}Mg(t, p)^{26}Mg and the ^{27}Al(t, α)^{26}Mg reactions and ^{27}Mg using the ^{25}Mg(t, p)^{27}Mg reaction. Some energy levels of ^{28}Mg have also been measured from the ^{26}Mg(t, p)^{28}Mg reaction but it was not possible to confirm these because of the lack of convenient reactions proceeding to this nucleus.

The energy levels of ^{25}Mg have previously been measured, below 4·2 Mev excitation energy, by Endt, Enge, Haffner and Buechner (1952), Enge (1954) and Sheline, Nielson and Sperduto (1959). In all of these investigations high resolution magnetic analysis was used to study the ^{27}Al(d, α)^{25}Mg reaction and in the case of Endt, Enge *et al.*, also the ^{24}Mg(d, p)^{25}Mg reaction. Recently, the well-known state at 3·40 Mev has been shown to consist of two groups by Hinds, Middleton and Litherland (1961) having components at 3·398 and 3·407 Mev. A few states have also been reported above 4·2 Mev by Hinds, Middleton and Parry (1958) from a low resolution study of the ^{24}Mg(d, p)^{25}Mg reaction. Two neutron resonance levels have also been reported at 7·411 and 7·581 Mev and have recently been confirmed by Newson, Block, Nichols, Taylor, Furr and Merzbacker (1959).

The energy levels of ^{26}Mg have previously been measured by Endt, Haffner and Van Patter (1952) from a magnetic analysis study of the ^{25}Mg(d, p)^{26}Mg reaction. Blair and Hamburger (1960) have studied this reaction and also the ^{26}Mg(d, d′)^{26}Mg reaction and report an additional level at $3·614 \pm 0·020$ Mev which was not observed by Endt, Haffner and Van Patter.

The energy levels of ^{27}Mg are not accurately known and only the first excited state has been precisely measured. This was done by Endt, Haffner and Van Patter (1952) who employed magnetic analysis to study the ^{26}Mg(d, p)^{27}Mg reaction. Several higher excited states have also been reported by Hinds, Middleton and Parry (1958) from a low resolution study of the same reaction. A neutron resonance level, at 6·726 Mev and having a natural width of greater than 75 kev, has also been reported by Newson *et al.*

The authors are unaware of any previous measurements of the energy levels of ^{28}Mg.

§ 2. EXPERIMENTAL PROCEDURE

Thin aluminium and enriched magnesium isotope targets were bombarded with 5·5 to 6·0 Mev deuterons and tritons from the Aldermaston electrostatic generator and the charged reaction products analysed with a broad-range magnetic spectrograph. The latter instrument has previously been described, see Hinds and Middleton (1959 a). Prior to striking the target, the ion beam from the accelerator was defined to an area of 0·25 mm by 1·5 mm and this bombarded portion of target served as an object for the spectrograph. In general several exposures were made at different angles of emission for each target and frequently two exposures were made at one angle with different field strengths. The latter was done to increase the effective energy range of the instrument which is normally restricted by the length of the nuclear plate. Exposure strengths were about 500 to 3000 μc depending upon the target thickness, the angular acceptance of the spectrograph and the reaction cross section.

Normally 100 μ thick Ilford C2 nuclear plates (recently replaced by K2) are used in the spectrograph to record all types of particles. However, trouble has been experienced when exposing at small angles of emission. This arises from the spurious scattering of the primary particles and in a (d, p) reaction, for example, results in a dense continuous background of deuteron tracks which makes the counting of proton tracks difficult. In this example, the background can be effectively prevented by placing an absorber in contact with the emulsion of sufficient thickness to stop the deuterons while still permitting the protons to pass through into the emulsion. This is clearly not possible in the case of a (d, α) or a (t, α) reaction because the range of the α-particle is generally less than that of the deuteron or triton. A very satisfactory solution has been found to this problem by using Ilford K minus 1 nuclear plates. These record α-particle tracks clearly but little more than a few grains are produced by protons, deuterons and tritons of more than 2 or 3 MeV. They also have the advantage of being less sensitive to γ-rays and are almost completely insensitive to neutrons.

The magnesium isotope targets were prepared from enriched magnesium oxide supplied by the Atomic Energy Research Establishment, Harwell. This was evaporated from a tantalum boat directly on to a thin carbon film (about $10\,\mu\text{g}\,\text{cm}^{-2}$) which had previously been mounted on a target frame. Tantalum was used as a boat material because it reduces the magnesium oxide to basic metal and since this is more volatile than either tantalum or its oxide, only the magnesium metal evaporates. Relatively pure targets of ^{24}Mg, ^{25}Mg and ^{26}Mg were prepared in this way ranging in thickness from about 20 to $40\,\mu\text{g}\,\text{cm}^{-2}$. The aluminium targets consisted of self-supporting films of about 10 to $30\,\mu\text{g}\,\text{cm}^{-2}$ and were also prepared by the evaporation process. Some difficulty was experienced with the thinner aluminium targets since they were extremely fragile and rarely permitted more than a single exposure to be made before breaking.

§ 3. RESULTS AND DISCUSSION

3.1. *The Energy Levels of ^{25}Mg*

The energy levels of ^{25}Mg were measured using the ^{24}Mg(d, p)^{25}Mg and the ^{27}Al(d, α)^{25}Mg reactions, the latter being preferred and generally considered to yield the more consistent results. This preference was based on the general observation that individual α-particle groups from a (d, α) reaction are usually of comparable intensity (neglecting isotopic spin considerations) while the proton groups from a (d, p) reaction frequently differ very strongly in intensity. Thus, in a (d, p) study there is a greater probability of missing a group, particularly if weak and neighbouring a strong group. The energy resolution, however, is generally less in the (d, α) reaction because of the greater loss of energy of the α-particle in traversing the target. In principle this can be compensated for by using a thinner target but in practice generally only partial compensation can be achieved because thin targets are extremely fragile and will not withstand prolonged ion bombardment.

Two typical spectra from the ^{24}Mg(d, p)^{25}Mg reaction are shown in Fig. 1. The upper was measured at an incident energy of 5·721 MeV and with the spectrograph at a laboratory angle of 30° and a magnetic field strength of 8690 gauss. The lower spectrum was obtained at an incident energy of 5·60 MeV, an angle of 31° and with a field of 6576 gauss. Other energy spectra were measured at 60° and 90° with the higher field setting and at 20° and 60° with the lower field. The proton groups corresponding to states in ^{25}Mg were identified by their characteristic variation of energy with angle and are labelled numerically, with '0' referring to the ground state. Groups arising from target impurities of ^{12}C, ^{14}N, ^{16}O and ^{28}Si are labelled by the symbols of their residual nuclei with a subscript referring to the appropriate excited state. It will be noticed that the groups arising from ^{14}N and ^{28}Si are very weak and only the more prominent groups have been labelled. Identification of groups from the latter impurity was greatly facilitated by a previous study of the ^{28}Si(d, p)^{29}Si reaction (unpublished).

The incident deuteron energy for each exposure was computed from the measured energy of the ground state proton group from the $^{16}O(d, p)^{17}O$ reaction and the known *Q*-value of this reaction. A value of 1·917 Mev was assumed for the latter which was derived from the recent compilation of nuclear masses by Everling, König, Mattauch and Wapstra (1960). This method of determining the beam energy was preferred to the more direct method dependent on measuring the energy of the elastically scattered deuterons since it is almost completely independent of target thickness. Beam energies measured in this way are thought to be accurate to within ± 10 kev. The *Q*-value of the $^{24}Mg(d, p)^{25}Mg$ reaction has been computed, from several such measurements, to be $5·096 \pm 0·012$ Mev which is in good agreement with the value of $5·097 \pm 0·007$ Mev reported by Endt, Enge, Haffner and Buechner (1952). Agreement is not quite so good, but within the experimental error, with the value of 5·106 Mev obtained from the masses reported by Everling *et al.* (1960) (N.B. The mass data reported by Everling *et al.* were used to obtain all other mass *Q*-values referred to in this communication).

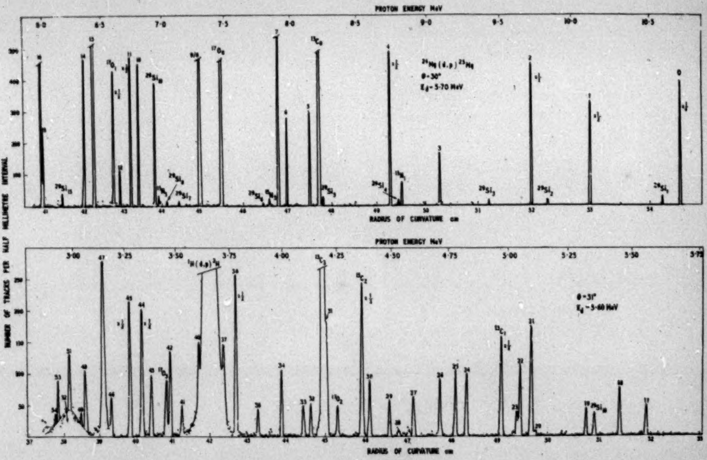

Fig. 1. Proton energy spectra measured from the $^{24}Mg(d, p)^{25}Mg$ reaction. The upper spectrum was obtained at an angle of observation of 30° using deuterons of 5·721 Mev and the lower spectrum at 31° with deuterons of 5·60 Mev.

The mean values of the energy levels of ^{25}Mg, determined from the $^{24}Mg(d, p)^{25}Mg$ reaction, are listed in column (1) of Table 1. The levels above 7·331 Mev are virtual, but of these only the 7·399 and the 7·57 Mev states were observed to have appreciable natural widths. These were measured to have widths respectively of 13 ± 3 kev and 80 ± 20 kev and are to be compared with the values of $7·8 \pm 0·5$ kev and 75 ± 15 kev reported by Newson *et al.* from neutron scattering measurements.

(1) Measured from the ^{24}Mg(d, p)^{25}Mg reaction; (2) measured from the ^{27}Al(d, α)^{25}Mg reaction; (3) mean values of (1) and (2); experimental error is ±10 kev, except for $7{\cdot}538 \pm 0{\cdot}015$ and $7{\cdot}57 \pm 0{\cdot}02$ Mev; (4) measurements of Endt, Enge *et al.* (1952) and Enge (1954); (5) measurements of Sheline, Nielsen and Sperduto (1959); (6) measurements of Hinds, Middleton and Parry (1958); (7) neutron resonance scattering measurements of Newson *et al.* (1959).

Alpha-particle energy spectra, from the $^{27}Al(d, \alpha)^{25}Mg$ reaction, were measured at laboratory angles of 15°, 30° and 60° at incident energies of 5·60, 5·70, 5·72 and 6·01 Mev. Most of these exposures were made with relatively low magnetic field strengths and were primarily intended to study the higher excited states and only two exposures were made which included the ground state. One of these, obtained at an incident energy of 5·704 Mev, a laboratory angle of 30° and with a field strength of 9169 gauss is shown in the upper half of Fig. 2. The lower spectrum was also obtained at 30° but with an incident energy of 6·01 Mev and a field of 8455 gauss.

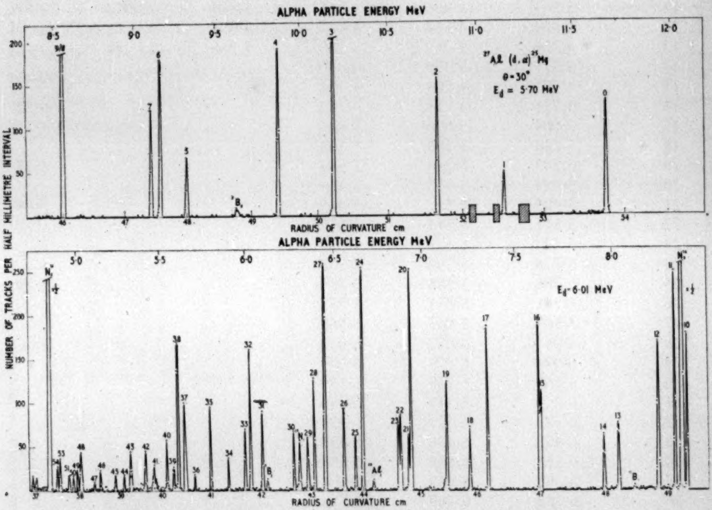

Fig. 2. Alpha-particle energy spectra from the $^{27}Al(d, \alpha)^{25}Mg$ reaction measured at an angle of 30°. The upper and lower spectra were obtained with spectrograph magnetic field strengths of 9169 and 8455 gauss using 5·704 and 6·01 Mev deuterons respectively.

The α-particle groups corresponding to states in ^{25}Mg were identified by their characteristic variation of energy with angle and are labelled numerically. Several groups were also identified as arising from target impurities of ^{13}C, ^{16}O and ^{28}Si and these are labelled by their symbols for the residual nuclei. It is notable that two strong groups were observed from the $^{16}O(d, \alpha)^{14}N$ reaction corresponding to the ground and second excited states of ^{14}N and also a weak group proceeding to the $T = 1$ first excited state. The latter transition can only proceed by violating the isotopic spin selection rule (see Browne 1956). Alpha-particle groups were observed corresponding to all the states of ^{25}Mg excited in the (d, p) reaction except for the broad state at 7·57 Mev. A weak group of α-particles was also observed corresponding to a state at 7·538 Mev. This may have escaped detection in the (d, p) reaction because of the masking effect of the broad 7·57 Mev group.

The energy of the incident deuteron beam was calculated from the measured energy of the ground state α-particle group from the $^{16}O(d, \alpha)^{14}N$ reaction and the mass Q-value of 3·110 Mev. From this the mean Q-value of the $^{27}Al(d, \alpha)^{25}Mg$ reaction was calculated to be 6·691 ± 0·012 Mev which is in good agreement with the value of 6·694 Mev reported by Endt, Enge *et al.* Both these values agree, within the experimental errors, with the mass Q-value of 6·700 Mev.

The mean values of the energy levels of ^{25}Mg, measured from the $^{27}Al(d, \alpha)^{25}Mg$ reaction, are listed in column (2) of Table 1. In column (3) are the weighted mean values from both reactions which are subject to an experimental error of ± 10 kev except for the levels at 7·538 and 7·57 Mev for which errors of ± 15 and ± 20 kev respectively are possible. Columns (4) and (5) of the Table contain respectively the aforementioned results of Endt, Enge *et al.* and Sheline *et al.* Agreement between the three sets of measurements is good and particularly so in the cases of the present results and those of Endt, Enge *et al.* where the maximum deviation is only 4 kev. In column (6) are the levels reported by Hinds, Middleton and Parry from a low resolution study of the $^{24}Mg(d, p)^{25}Mg$ reaction. It is of interest to note that although many states were missed in this investigation, most of these were weakly excited and a recent study of the proton angular distribution (Middleton and Hinds, to be published) revealed that most of these were formed by processes other than stripping.

3.2. *The Energy Levels of* ^{26}Mg

The energy levels of ^{26}Mg have been measured using three independent nuclear reactions and a typical energy spectrum from the $^{25}Mg(d, p)^{26}Mg$ reaction is shown in Fig. 3. This was obtained at a laboratory angle of 50°, an incident deuteron energy of 6·020 Mev and with a spectrograph magnetic field of 10100 gauss. Similar energy spectra were measured at angles of 31°, 40° and 60° at a slightly lower bombarding energy. Groups corresponding to states in ^{26}Mg were identified as previously described and are labelled numerically, with '0' referring to the ground state. Strong impurity groups were observed arising from ^{12}C and ^{16}O and these are labelled in Fig. 3, using the same notation as previously. It should be noted that several weak groups were also observed arising from ^{24}Mg but only the ground state is labelled in the figure. Also at the particular angle illustrated groups 22 and 37 are masked respectively by the intense proton groups corresponding to the ground and first excited states of ^{17}O.

The incident deuteron energy was calculated for each angle of observation from the measured energy of the ground state proton group from the $^{16}O(d, p)^{17}O$ reaction and the mass Q-value. From these the mean Q-value of the $^{25}Mg(d, p)^{26}Mg$ reaction was calculated to be 8·861 ± 0·012 Mev. This is to be compared with the value of 8·880 ± 0·012 Mev reported by Endt, Haffner and Van Patter and with 8·873 Mev expected from nuclear mass data. Agreement between these values is not very good.

A more convenient and reliable reaction for studying the energy levels of ^{26}Mg is the $^{27}Al(t, \alpha)^{26}Mg$ reaction. This has the advantage of proceeding from a target of a 100% isotopic abundance and thus the probability of incorrectly assigning a group is considerably reduced. Alpha-particle energy spectra have been measured at laboratory angles of 30°, 40° and 50° at an incident energy of 5·95 Mev and in Fig. 4 is shown a typical spectrum obtained at 40° with a

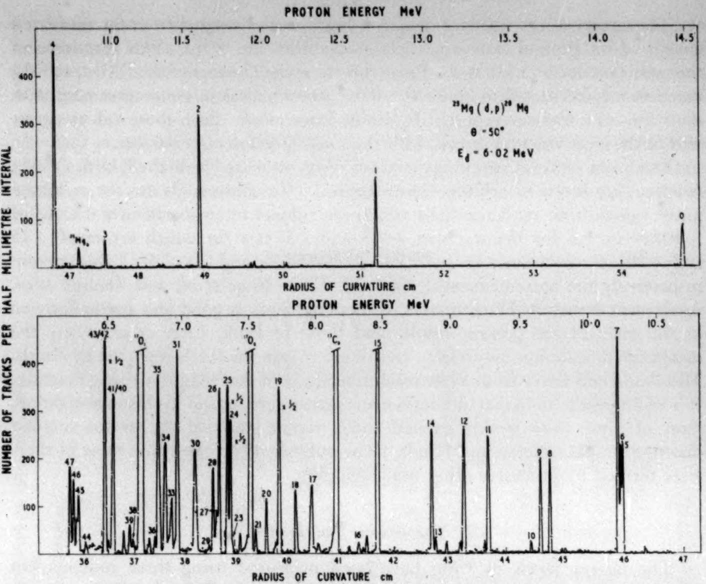

Fig. 3. An energy spectrum of the protons from the ^{25}Mg(d, p)^{26}Mg reaction obtained at an angle of observation of 50° with incident deuterons of 6·020 MeV.

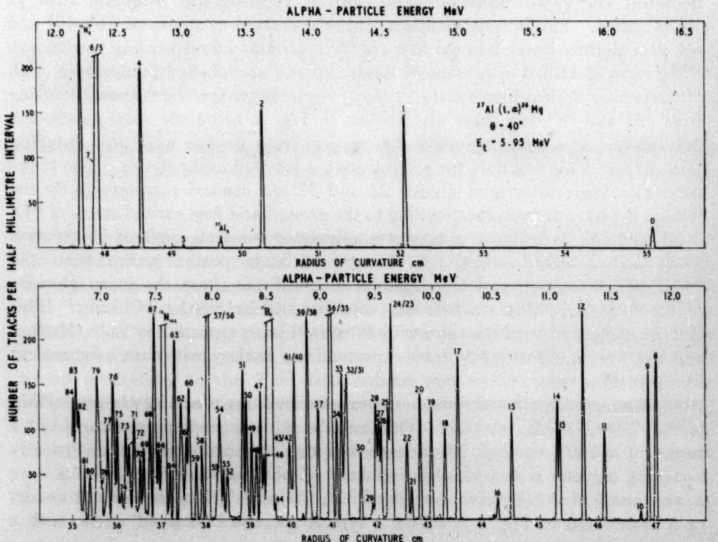

Fig. 4. A typical alpha-particle energy spectrum from the ^{27}Al(t, α)^{26}Mg reaction. This was measured at an angle of observation of 40° at an incident triton energy of 5·95 MeV.

spectrograph field of 10 569 gauss. Groups were identified and are labelled as previously described. Strong impurity groups were observed arising from ^{12}C and ^{16}O and also a weak group from the ^{28}Si(t, α)^{27}Al reaction corresponding to the ground state of ^{27}Al.

The incident triton energy was determined by measuring the energy of the ground state α-particle group from the ^{16}O(t, α)^{15}N reaction and by assuming a *Q*-value of 7·687 MeV for this reaction. The latter value was obtained from nuclear mass measurements. This led to a triton energy of 5·951 ± 0·010 MeV and from this the *Q*-value of the ^{27}Al(t, α)^{26}Mg reaction was determined to be 11·541 ± 0·012 MeV. This is in excellent agreement with the value of 11·540 MeV expected from nuclear mass data. We are not aware of any previous direct measurements of this *Q*-value.

The third reaction used to study ^{26}Mg was the ^{24}Mg(t, p)^{26}Mg reaction and a typical energy spectrum is shown in Fig. 5. This was obtained at a laboratory angle of 60°, an incident energy of 6·015 MeV and with a spectrograph magnetic field of 10 334 gauss. Similar spectra were measured at the same incident energy at angles of 30° and 45°. Groups corresponding to states in ^{26}Mg and those arising from impurities were identified and labelled as previously described. It will be noticed that a weak group of protons was observed arising from the

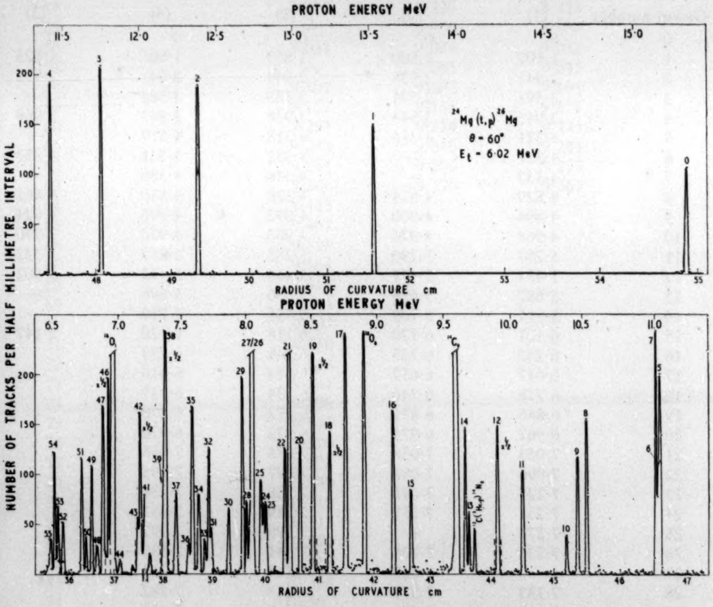

Fig. 5. A proton energy spectrum from the ^{24}Mg(t, p)^{26}Mg reaction measured at an angle of observation of 60° and at a bombarding energy of 6·015 MeV.

^{12}C(^{3}He, p)^{14}N reaction, indicating the presence of a small percentage of ^{3}He in the triton beam. However, since we had previously studied the ^{24}Mg(^{3}He, p)^{26}Al reaction (Hinds and Middleton 1959 b) we were able to verify that none of the proton groups appearing to correspond to states in ^{26}Mg did in fact correspond to states in ^{26}Al.

The incident triton energy was determined from measurements made on the ^{16}O(t, p)^{18}O reaction and by assuming the mass Q-value of this reaction to be 3·706 Mev. From this the Q-value of the ^{24}Mg(t, p)^{26}Mg reaction was determined to be 9·930 ± 0·012 Mev which is to be compared with the mass Q-value of 9·946 Mev.

The energy levels of ^{26}Mg measured from the ^{25}Mg(d, p)^{26}Mg, the ^{27}Al(t, α)^{26}Mg and the ^{24}Mg(t, p)^{26}Mg reactions respectively are listed in columns (1), (2) and (3) of Table 2. In column (4) are the weighted mean

(1) Measured from the ^{25}Mg(d, p)^{26}Mg reaction; (2) measured from the ^{27}Al(t, α)^{26}Mg reaction; (3) measured from the ^{24}Mg(t, p)^{26}Mg reaction; (4) weighted mean values of (1), (2) and (3); (5) reported by Endt, Haffner and Van Patter (1952).

Experimental error: ±10 kev for levels 1 to 49, in column (4); ±12 kev for levels 50 to 63, in column (4); ±15 kev for levels 64 to 87, in column (2).

values which are subject to an experimental error of ± 10 kev for groups 1 to 49, ± 12 kev for groups 50 to 63 and ± 15 kev for groups 64 to 87. The energy levels in parentheses are doubtful and were in general observed only with one nuclear reaction. It may be noted that although according to the Table groups 32 and 39 were observed only with one reaction their existence was supported by one or both of the other reactions studied.

In column (5) of Table 2 are listed the energy levels of ^{26}Mg reported by Endt, Haffner and Van Patter (1952) from a magnetic analysis study of the ^{25}Mg(d, p)^{26}Mg reaction. These are not in good agreement with the present values but if allowance is made for the omission of certain levels the remainder are found to be consistently greater than the present values by about 25 kev. This suggests that an error may have been made in the determination of the ground state *Q*-value. Blair and Hamburger (1960) also report a level at 3·614 ± 0·020 Mev which was not observed by Endt, Haffner and Van Patter but which may be identified with our level at 3·584 ± 0·010 Mev.

3.3. *The Energy Levels of* ^{27}*Mg*

The energy levels of ^{27}Mg have been measured using the ^{26}Mg(d, p)^{27}Mg and the ^{25}Mg(t, p)^{27}Mg reactions and a typical proton energy spectrum from the former reaction is shown in Fig. 6. This was measured at an angle of 31° using

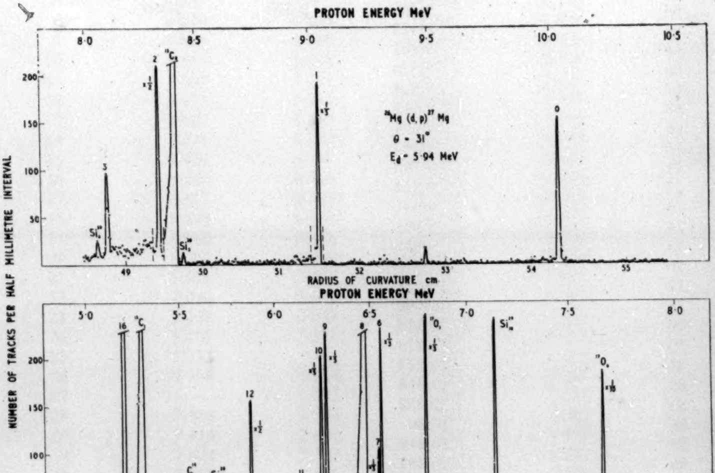

Fig. 6. Energy spectrum of the protons from the ^{26}Mg(d, p)^{27}Mg reaction measured at a laboratory angle of 31° and at an incident deuteron energy of 5·937 Mev.

deuterons of 5·937 Mev and with a spectrograph magnetic field of 8455 gauss. Energy spectra were also measured at angles of 25, 40 and 60° using deuterons of slightly lower energy. The various proton groups were identified in the manner previously described and those corresponding to states in ^{27}Mg are labelled numerically. Strong impurity groups were observed arising from carbon and oxygen and several weak groups from ^{13}C and ^{28}Si. The groups arising from the latter impurity were difficult to identify by their characteristic variation of energy with angle from those arising from ^{26}Mg. Identification, however, was simplified by comparison with previously measured proton energy spectra obtained at a similar deuteron energy with a target of ^{28}Si.

The incident deuteron energies were determined individually at each angle in terms of the accurately known *Q*-value of the ^{16}O(d, p)^{17}O reaction. From these the mean *Q*-value of the ^{26}Mg(d, p)^{27}Mg reaction was calculated to be $4{\cdot}213 \pm 0{\cdot}012$ Mev which is in excellent agreement with the mass *Q*-value of 4·212 Mev. Agreement is also good with the previous measurement of Endt, Haffner and Van Patter who reported a value of 4·207 Mev.

Proton energy spectra from the ^{25}Mg(t, p)^{27}Mg reaction were measured at angles of 30, 45 and 60° at incident triton energies of 6·024, 6·017 and 6·014 Mev respectively. The 30° spectrum is shown in Fig. 7 which was obtained with a spectrograph magnetic field of 10 100 gauss. Groups were identified following our usual procedure and those corresponding to states in ^{27}Mg are labelled numerically using the same notation as was used in the ^{26}Mg(d, p)^{27}Mg reaction. As is evident from the spectrum a fairly strong proton group was observed arising

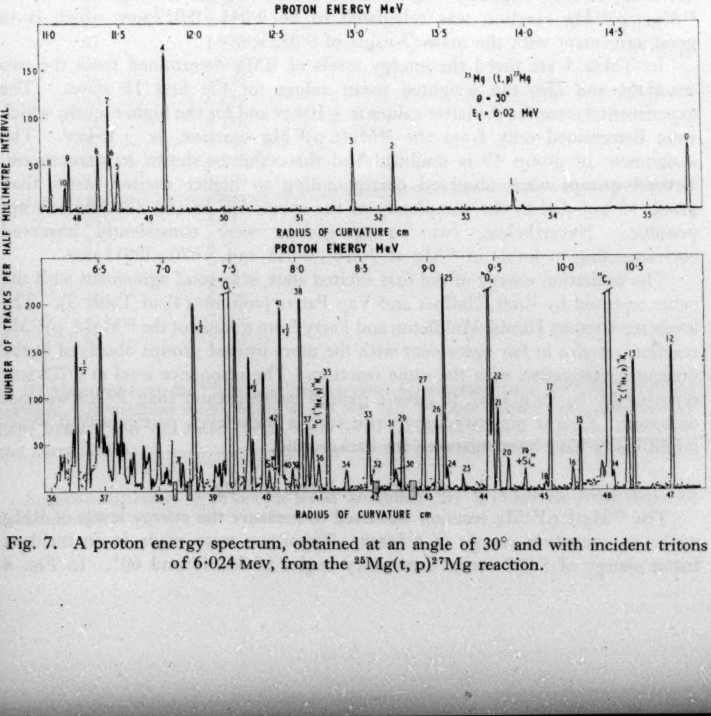

Fig. 7. A proton energy spectrum, obtained at an angle of 30° and with incident tritons of 6·024 Mev, from the ^{25}Mg(t, p)^{27}Mg reaction.

from the $^{12}C(^3He, p)^{14}N$ reaction indicating that our triton beam contained a significant contamination of ^3He ions. This was particularly disturbing since it is kinematically impossible to distinguish between a $(^3He, p)$ and a (t, p) reaction proceeding from the same target nucleus and some of the groups attributed to states in ^{27}Mg might be due to the $^{25}Mg(^3He, p)^{27}Al$ reaction. To eliminate this possibility repeat exposures were made at 30° and 45° using carefully purified tritium gas in the ion source. Neither of these spectra exhibited a group corresponding to the $^{12}C(^3He, p)^{14}N$ reaction and from them we were able to confirm that our previous assignments to states in ^{27}Mg were correct. It may also be noted that the ^3He contamination of the beam obtained with the purified gas was measured to be less than 0·1% by observing the elastically scattered groups from an aluminium target.

Strong impurity groups were observed in all exposures arising from ^{12}C and ^{16}O and also a significantly strong group from the $^{28}Si(t, p)^{30}Si$ reaction corresponding to the 39th excited state of ^{30}Si. The latter assignment was possible because the authors had previously studied the $^{28}Si(t, p)^{30}Si$ reaction (to be published). Other impurity groups from this reaction are of negligible intensity except for that leading to the 15th excited state of ^{30}Si. Unfortunately this group coincides at most angles of observation with group 19 from the $^{25}Mg(t, p)^{27}Mg$ reaction. Group 19 is tentatively assigned to ^{27}Mg because it was consistently observed to be too strongly excited to be entirely accounted for by the $^{28}Si(t, p)^{30}Si$ reaction.

The energy of the incident triton beam was determined for this exposure in terms of the *Q*-value of the $^{16}O(t, p)^{18}O$ reaction in the manner described in the study of the $^{24}Mg(t, p)^{26}Mg$ reaction. From this the mean *Q*-value of the $^{25}Mg(t, p)^{27}Mg$ reaction was calculated to be $9{\cdot}045 \pm 0{\cdot}012$ MeV which is in good agreement with the mass *Q*-value of 9·052 MeV.

In Table 3 are listed the energy levels of ^{27}Mg determined from the two reactions and also the weighted mean values for the first 18 states. The experimental error for the latter values is ± 10 kev and for the higher levels, which were determined only from the $^{25}Mg(t, p)^{27}Mg$ reaction, is ± 15 kev. The assignment of group 19 is doubtful and this value is shown in parentheses. Several groups were observed corresponding to higher excited states than group 43 but due to the complexity of the spectrum, precise analysis was not possible. Nevertheless, two strong groups were consistently observed corresponding to levels in ^{27}Mg at $7{\cdot}240 \pm 0{\cdot}015$ and $7{\cdot}676 \pm 0{\cdot}015$ MeV.

The excitation energy of the first excited state is in good agreement with the value reported by Endt, Haffner and Van Patter (column (4) of Table 3). The levels reported by Hinds, Middleton and Parry from a study of the $^{26}Mg(d, p)^{27}Mg$ reaction are also in fair agreement with the more intense groups observed in the present investigation with the same reaction. The resonance level at 6·726 MeV reported by Newson *et al.* to have a natural width greater than 75 kev was not observed. This is not surprising since such a wide level, particularly if weak, might easily have been mistaken for background.

3.4. *The Energy Levels of* ^{28}*Mg*

The $^{26}Mg(t, p)^{28}Mg$ reaction was used to measure the energy levels of ^{28}Mg up to an excitation energy of 6·8 MeV. Exposures were made at an incident triton energy of 5·957 MeV at laboratory angles of 30, 45 and 60°. In Fig. 8

is shown a typical proton energy spectrum obtained at 45° with a spectrograph magnetic field of 9160 gauss. Groups were identified as previously described and those corresponding to states in ^{28}Mg are labelled numerically. Strong impurity groups were observed due to ^{12}C and ^{16}O and also several weaker groups due to the presence of a small amount of ^{28}Si.

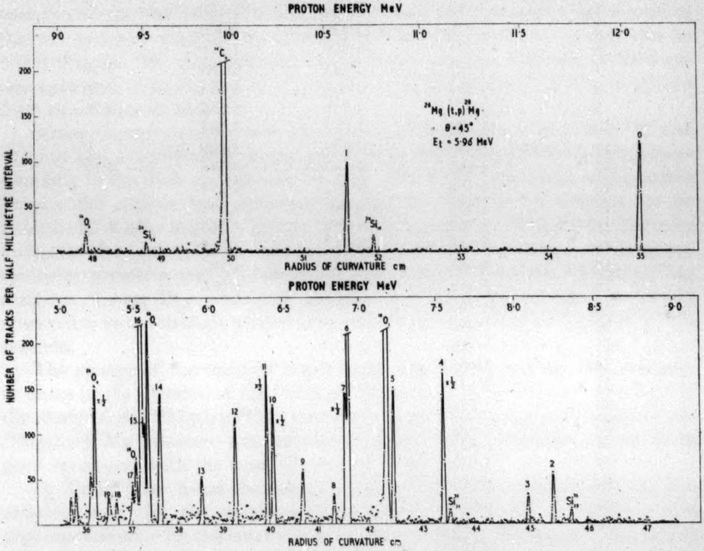

Fig. 8. A typical proton energy spectrum from the ^{26}Mg(t, p)^{28}Mg reaction. This was measured at a laboratory angle of 45° and at an incident triton energy of 5·957 MeV.

As for the other (t, p) reactions the beam energy was measured in terms of the ^{16}O(t, p)^{18}O ground state Q-value. From this the mean Q-value of the ^{26}Mg(t, p)^{28}Mg reaction was calculated to be 6·466 ± 0·012 MeV, which is in good agreement with the mass Q-value of 6·460 MeV. No previous direct determinations have been made of this Q-value. The energy levels of ^{28}Mg are shown in Table 4 where the experimental error is ± 12 kev for levels 1 to 4 and ± 15 kev for the remainder. These errors are slightly larger than usual since they are the means of only three determinations and it was not possible to verify them using another reaction.

3.5. *Discussion of Ground State Q-values*

The ground state Q-values reported in this communication are such that their internal consistency may readily be verified. This is illustrated in Table 5 by comparing the ^{25}Mg–^{26}Mg mass excess difference, which may be calculated in four independent ways from the present results. The first two columns of the

Table 4. The Energy Levels of ^{28}Mg

Group number	Level energy (Mev)	Group number	Level energy (Mev)
0	0	10	5·652
1	1·468	11	5·695

8	5·264	18	6·708
9	5·463	19	6·759

Experimental error: ±12 kev for levels 1 to 4; ±15 kev for levels 5 to 19.

Table contain respectively the reaction and its measured *Q*-value. From the latter the mass excess differences between the initial and final nuclei have been determined and these are listed in column (3). By subtracting successive pairs of values from column (3), three independent values of the ^{25}Mg–^{26}Mg mass excess difference were obtained and these are listed in the fourth column together with the directly determined value from the ^{25}Mg(d, p)^{26}Mg reaction.

The four independent determinations of the ^{25}Mg–^{26}Mg mass excess difference agree with each other within the stated experimental errors. The mean value of the ^{25}Mg–^{26}Mg mass excess difference is 3·023 ± 0·008 Mev which is in good agreement with the mass value of 3·026 ± 0·003 Mev. All mass excess values are referred to the scale where ^{12}C has zero mass excess.

Twinning in a Cation-deficient Spinel Structure

By J. GOODYEAR and G. A. STEIGMANN
Physics Department, University of Hull

MS. received 28*th March* 1961

Abstract. Crystals of β-In_2S_3 have been studied under the polarizing microscope and by X-ray diffraction. Optical examination has shown that the crystals are twinned, and the relative orientations of the twin components have been determined by rotation and oscillation X-ray photographs. The diffraction data have also confirmed the body-centred tetragonal cell proposed by Rooymans. Assuming that the material has a spinel structure, deficient in cations, it follows that twinning takes place when a redistribution in the tetrahedrally occupied sites occurs.

---

§ 1. Introduction

The structure of β-In_2S_3 has been studied by Rooymans (1959) using an X-ray powder technique. The powder pattern contained a large number of weak reflections which were attributed to a superlattice based on a cation-deficient spinel structure. Rooymans found that the supercell was body-centred tetragonal with $a=a'/\sqrt{2}=7{\cdot}62$ Å and $c=3a'=32{\cdot}32$ Å, a' being the parameter of the spinel-type cell from which the structure was derived. The absence of $00l$ reflections with $l\neq 4n$ (n being an integer), and the assumption that the structure is essentially that of a spinel with 4 tetrahedrally coordinated cation vacancies per supercell, suggested that the space group was $I4_122$, the four vacancies being located at the equivalent positions of the 4_1 screw axes of the space group. However, Rooymans also mentioned that the structure might possibly have a lower symmetry because of the observation of a weak reflection at about 3·6 Å which was not reconcilable with a tetragonal lattice.

Single crystals of β-In_2S_3 have recently been prepared in this department for infra-red luminescence study. Equivalent amounts of indium and sulphur were placed separately in silica boats in a sealed evacuated tube. The portion of the tube containing the sulphur was heated at 600°C and that containing the indium at 1060°C, indium sulphide forming in the boat containing the indium. Plate crystals were found on the edges of the boat containing the indium, and although only about $10\,\mu$ in thickness, were quite extensive (as much as several millimetres) in their dimensions parallel to their flat faces. When examined under the microscope the crystals showed three directions of growth edge at 60° to each other, and were found to be birefringent and twinned on a macroscopic scale.

The purpose of the present study is to check Rooymans' cell using single crystal diffraction data, and to examine the nature of the twinning phenomenon in relation to the crystal structure.

§ 2. OPTICAL AND X-RAY DATA

Crystals of β-In_2S_3 were examined between crossed polaroids with their flat faces lying parallel to the microscope stage. With most of the crystals it was observed that different parts of the specimen were extinguished in turn as the stage was rotated, in one direction, through multiples of 30°. This suggested that there were three twin components oriented at 120° to each other. Some of the crystals were lath-like in shape showing well-defined growth edges parallel to the elongated axis, and one such crystal was selected for X-ray examination. Figs 1 (*a*), (*b*) and (*c*) (Plate I) show the extinction positions for the twin components in such a specimen. For convenience the components will be labelled types (*a*), (*b*) and (*c*) depending on whether extinction occurs when the specimen axis is parallel, at 30° or at 60° respectively, to the vertical crosswire when the microscope stage is rotated in a clockwise direction.

An X-ray rotation photograph of type (*a*) material, taken with the elongated axis parallel to the rotation axis, showed layer lines corresponding to an identity period of about 7·6 Å parallel to the specimen axis. Corresponding rotation photographs of type (*b*) and (*c*) specimens were identical, with layer line spacings corresponding to an identity period of about 22·9 Å. In terms of Rooymans' cell these correspond to the following axes: type (*a*) to the [100] axis, types (*b*) and (*c*) to the [331] axis. Oscillation photographs taken about each specimen axis, with the flat face of the crystal approximately perpendicular to the X-ray beam, revealed that the crystal face of each component was the (013) or ($0\bar{1}3$) face. When these observations are considered in relation to the optical data, the extended face of each individual of the twin can be taken as the (013) face with specimen axes as [100] for a type (*a*) crystal, [$\bar{3}\bar{3}1$] for type (*b*) and [$\bar{3}3\bar{1}$] for type (*c*).

At this stage it seemed worth while to check Rooymans' cell using both single crystal and powder diffraction data. Oscillation photographs, about both the *a* and *c* axes, yielded reflections which could be accounted for by Rooymans' cell, the only systematic absences being of the type $h+k+l=2n+1$ and, for $00l$ reflections, $l \neq 4n$ (where n is an integer in each case). The space group is thus $I4_122$, $I4_1/a$ or $I4_1$. Fig. 2 (Plate II) shows a c axis rotation photograph and, as one would expect, the principal (non-superlattice) reflections occur on layer lines with $l=0$ or a multiple of 3.

Powder photographs of the material were taken with a crystal-focusing camera, of effective diameter 22·9 cm, employing CuKα radiation. The cell parameters, calculated from the powder data, are $a=7{\cdot}62_3$ Å and $c=32{\cdot}3_6$ Å, and a comparison between the observed and calculated lattice spacings is given in the Table. The agreement with Rooymans' parameters is within the experimental error, and it can be concluded that Rooymans' cell is correct. It thus seems most probable that the extra reflection observed by Rooymans was due to some impurity in his powder specimen.

§ 3. A STRUCTURAL INTERPRETATION OF THE TWINNING PHENOMENON

In discussing the twinning in terms of the crystal structure, it is convenient to consider an alternative unit cell whose base is parallel to the (013) face of the tetragonal cell. This secondary cell is side face-centred monoclinic and its relation to the more fundamental tetragonal cell is shown in Fig. 3 (*a*). Fig. 3 (*b*) shows the orientation of the secondary cell in the three components of a lath-like crystal. These orientations are possible because the identity periods along the specimen axis of type (*b*) and (*c*) crystals are each exactly three times that along the axis of a type (*a*) specimen.

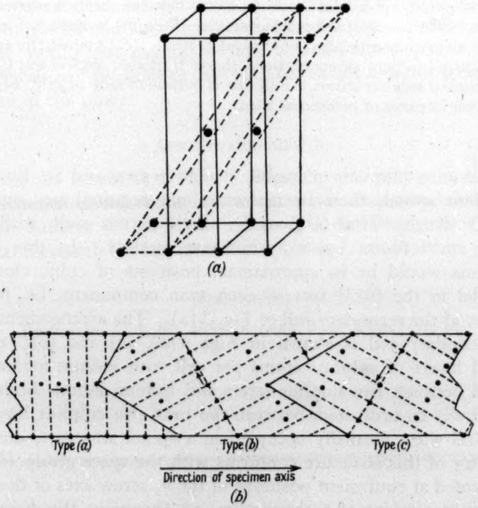

Fig. 3. (*a*) Secondary unit cell (dotted outline) having a centred base parallel to the (013) face of the tetragonal cell (full outline). (*b*) Orientation of the secondary cell in the three twin components; in each component the arrow represents the direction of the tetragonal *a* axis.

▲ Indium atom in tetrahedral coordination
△ Vacant tetrahedral site (occupied in the spinel structure)

Fig. 4. Atomic arrangement within the secondary cell. (*a*) Sequence of atomic sheets which are parallel to the centred base. Full lines A, B and C represent sheets of close-packed sulphur atoms, chain lines sheets of octahedrally co-ordinated indium atoms, and broken lines sheets of tetrahedrally co-ordinated indium atoms. (*b*) Octahedrally co-ordinated indium atoms between sheets A (dotted circles) and B full circles) of close-packed sulphur atoms. Full line is outline of top cell; broken line is cell perimeter in plane of octahedral sites. (*c*) Octahedrally and tetrahedrally co-ordinated indium atoms between sheets B (dotted circles) and C (full circles) of close-packed sulphur atoms. Full line is outline of base of cell; broken line is cell perimeter in plane of octahedral sites.

If one assumes the very plausible structure proposed by Rooymans, i.e. a cation-deficient spinel, then 16 molecules are required per unit cell giving a calculated density of $4{\cdot}60\ \mathrm{g\ cm^{-3}}$, which agrees well with a value of $4{\cdot}55 \pm 0{\cdot}02\ \mathrm{g\ cm^{-3}}$ found by a pyknometer method. In this structure the sulphur atoms would be in approximate positions of cubic close packing in layers parallel to the (013) face of each twin component, i.e. parallel to the centred faces of the secondary cell of Fig. 3 (*a*). The arrangement of the atoms within a secondary cell is shown in Figs 4 (*a*), (*b*) and (*c*); there are two close-packed layers of sulphur atoms per cell with indium atoms octahedrally co-ordinated between two sulphur layers and indium atoms, both octahedrally and tetrahedrally co-ordinated, between the next two sulphur layers. Four of the tetrahedral sites, normally occupied in a spinel structure, are now vacant. The symmetry of this structure conforms with the space group $I4_122$, with the vacancies located at equivalent positions of the 4_1 screw axes of the space group.

From the standpoint of the structure, no change in the disposition of the sulphur atoms or of any of the octahedrally co-ordinated indium atoms is required in crossing the boundary between one twin component and the next. Twinning takes place when the pattern of vacancy sites changes. This feature is clear if

Fig. 5, showing the slight change in the occupied tetrahedral sites at the twin boundaries, is considered in relation to Fig. 4 (*c*). In fact, if all the vacant sites normally occupied in a spinel were filled with indium atoms there would be no twinning phenomenon. This structural interpretation explains why only three components are found and also their relative orientation. Finally, as is actually observed, one would not expect to find a well-defined plane between two components because of the relative ease with which one individual could encroach on the domain of the other.

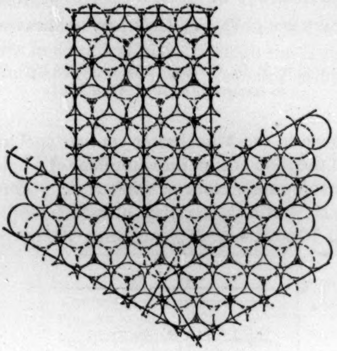

Fig. 5. Changes in the pattern of occupied tetrahedral sites at the twin boundaries.

ACKNOWLEDGMENTS

The authors are indebted to Miss J. Bleackley for preparing the specimens of β-In_2S_3 examined in this work.

The Manchester High Energy Magnetic Cosmic Ray Spectrograph

By J. E. R. HOLMES†, B. G. OWEN‡ and A. L. RODGERS§
Department of Physics, University of Manchester

Communicated by J. G. Wilson; MS. received 16*th May* 1960,
in revised form 10*th April* 1961

Abstract. Modifications to the Manchester counter spectrograph are described which have permitted the momentum measurement of single cosmic ray particles to a maximum detectable momentum of 1000 GeV/*c*. The measured output of the instrument was 20 particles per day of which approximately 50% had momentum exceeding 10 GeV/*c* and 2% exceeding 100 GeV/*c*.

§ 1. Introduction

The counter spectrograph at Manchester, described by Hyams *et al.* (1950) attained a maximum detectable momentum of about 20 GeV/*c*, a limit mainly set by the 4 cm diameter of a single counter. With this instrument Owen and Wilson (1955) measured the momentum spectrum of μ-mesons arriving vertically at sea level in the range 0·5 GeV/*c* to 20 GeV/*c*.

Consideration of counter spectrographs show that it is not easy to increase the maximum resolution by more than an order of magnitude by the use of smaller counters or by methods involving the overlapping of counters. To gain a greater increase in the momentum resolution suggests a different method of measuring the deflection of a particle trajectory. If cloud chambers are used for the purpose, it is possible to locate the particle trajectory to the order of the track width.

With this in mind, during 1952 flat horizontal cloud chambers were introduced at each of the three measuring levels of the Manchester spectrograph. The Geiger counter was thus replaced by a cloud chamber track as the fundamental mode of location of a particle trajectory. The counter trays were retained, although vertically displaced to make room for the cloud chambers, and served in a secondary role as the control system of the instrument. The particle trajectory at each horizontal measuring level was located with respect to a centimetre graticule ruled over the inner surface of the top glass plate of each cloud chamber. This surface formed one of the strict measuring planes and was coincident in each case with the original plane occupied by the counters, thus leaving the dimensions of the spectrograph unchanged.

We attempted to reach a maximum detectable momentum of about 1000 GeV/*c*. From the geometry of the spectrograph this implied measurement of particle deflections of about a third of a millimetre.

§ 2. THE SPECTROGRAPH CHARACTERISTICS

2.1. *Principle of the Spectrograph*

The spectrograph consists of a symmetrical arrangement of two deflecting magnetic fields and three horizontal measuring levels, symmetry being established about the middle measuring level.

The schematic representation of the instrument is shown in Fig. 1. A fast charged particle moves in a vertical plane through the horizontal magnetic fields having significant values of field only in the restricted similar regions H_1 and H_2.

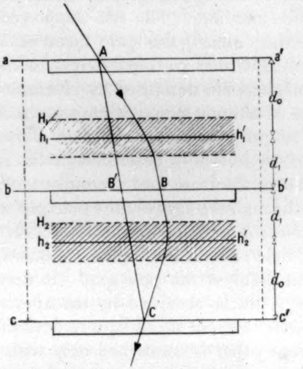

Fig. 1. The principle of trajectory deflection measurement.

The deflection of the particle trajectory is described by reference to the intersections A, B and C of the trajectory with the horizontal lines aa′, bb′, cc′ which are symmetrically placed relative to the field regions H_1 and H_2. The angular deflection θ of the particle trajectory in each magnetic field is given by

$$\theta = \int \frac{dl}{\rho} = \frac{300 \int H\,dl}{p} \qquad \ldots\ldots(1)$$

where ρ is the radius of curvature in centimetres from point to point of the trajectory of a singly charged particle of momentum p ev/c. The line integral of the magnetic field $\int H\,dl$ is taken throughout the whole of the region H_1 or H_2 from which significant contributions arise.

The momentum p of the particle is therefore given by

$$p = \frac{300 d_0 \int H\,dl}{\Delta} \qquad \ldots\ldots(2)$$

where $BB' = \Delta = d_0\theta$ is the deflection in centimetres referred to the middle measuring level.

The above expression assumes that the whole of the deflection θ occurs at the median lines h_1h_1' and h_2h_2' respectively, a description which is true only for a vertical trajectory and a symmetrical field distribution about the median line. The effect of departures from the ideal conditions is investigated in § 4.1, but it may be stated here that to within the precision of the present measurements the lines h_1h_1' and h_2h_2' are adequately defined by the horizontal planes of symmetry of the magnetic fields.

2.2. *Description of the Spectrograph*

The general features of the instrument are discussed here in so far as they are relevant to spectrum measurements at momenta exceeding the upper limit of the counter work. A more complete description of the design and performance is given in Hyams *et al.* (1950).

The three cloud chambers which are each enclosed in a light-tight box determine the points of intersection of the particle trajectory with the three planes aa′, bb′, cc′ respectively. Immediately below are the three counter layers which form the control system of the spectrograph. Counter alignment is achieved by a hanging plumb-line method. The two supported electromagnets of the Blackett type have vertical rectangular pole faces of 30 cm × 40 cm, with the smaller dimension vertical, which are separated by a distance of 9·5 cm. The characteristics of the magnets are described by Hyams *et al.*

'Defining' counters of cathode length 30 cm are placed in, and fill about 80% of, the gap width. The purpose of the counters is firstly to ensure that each accepted particle trajectory is totally described in air, minimizing the effect of particles being scattered in the iron, and secondly to exclude vertical particle trajectories which pass through the edges of the pole gap where $\int H\,dl$ falls rapidly. At full magnet excitation the defining counters exclude vertical particle trajectories whose integrated field value is more than 8% below that of the value corresponding to the central point of the pole gap. It may be shown that for all straight, i.e. high energy, tracks accepted by the aperture of the spectrograph and the defining counters, the root mean square deviation in $\int H\,dl$ is less than 1·5%. Since the present paper is concerned only with these 'straight' tracks, it may be concluded that, to within the accuracy of the present observations, all particles of a given momentum recorded by the chambers suffer the same deflection characterized by a unique value of $\int H\,dl$.

The weighted mean value of the magnet current over the duration of the spectrum determination (Holmes, Owen and Rodgers 1961) was 29·2 ± 0·4 A and corresponded to an integrated field of $(5{\cdot}97 \pm 0{\cdot}05) \times 10^5$ gauss cm. The value of d_0 is 149 cm and the equation relating the particle momentum p to the deflection Δ in the central plane of the spectrograph is

$$p = \frac{26{\cdot}8 \pm 0{\cdot}2}{\Delta}\ \text{GeV}/c, \qquad \ldots\ldots(3)$$

where Δ is measured in centimetres.

The deflection of the particle trajectory is defined in two stages. (i) At each measuring level the cloud chamber track is located with respect to a centimetre graticule ruled over the inner surface of the top plate of each chamber at a ruling pressure sufficient to provide adequate scattering of light by the chamber grid lines. This location establishes the point of intersection of the particle trajectory with each chamber grid. (ii) The three chamber grids are aligned with respect to one another thus establishing a three-dimensional coordinate system.

2.3. *Characteristics of the Cloud Chambers*

The design of the cloud chambers is governed by the necessity of keeping the additional scattering material in the particle beam at the measuring levels to a minimum, of conforming to the general geometry of the spectrograph, and of retaining sufficient accessibility. Further requirements are the reduction of gas motion and the production of comparable tracks in each of the three chambers.

The chambers are of light construction, the material in the particle beam consisting of 0·6 cm of plate glass (the top plate of the chambers) and 0·9 cm of Perspex which constitutes the material of the base and walls of the chamber. In addition the chambers are pressure controlled and require no back plate or piston.

The internal dimensions of each chamber are such as to provide adequate coverage of the respective counter trays. For the two extreme chambers the overall dimensions are 48 cm × 17 cm × 4·8 cm and cover the middle 14 of the 16 counters in the tray. The dimensions of the middle chamber are 32 cm × 15 cm × 4·8 cm and it spans the eight counters in this tray.

Consistent with their purpose the chambers are shallow, of sensitive depth 3·5 cm, and the gas expansion is downwards through a velvet covered perforated Perspex plate to the base of the chamber. The measuring plane adopted has the advantage that because the expansion is downwards, and therefore in the direction of the particle trajectory, this plane is one of zero movement at expansion.

To produce comparable tracks the chambers are connected in parallel to a common supply of gas. The gas used is saturated air produced by passing air through a mechanical filter to a large reservoir where it stands over distilled water. A fresh supply of gas is used after each expansion. The cloud chamber tracks are 1·10 ± 0·25 mm in width and correspond to an expansion time of 15 msec.

Satisfactory backgrounds of less than 10 drops per square centimetre of chamber grid may be obtained by using two cleaning expansions and a waiting interval of approximately 4 minutes. The total insensitive time is thus about 8 minutes, which is entirely permissible for the rate accepted by the geometry of the instrument in the momentum region investigated.

2.4. *Photography*

Figure 2 shows the photographic and illumination system of a single measuring unit which is comprised of a chamber CH and a horizontal layer of Geiger counters C. For compactness, and to keep associated apparatus out of the particle beam the chamber CH is photographed stereoscopically by the open shutter camera P through the plane mirror M inclined at $22\frac{1}{2}°$ to the vertical. Chamber illumination is provided by a line source of light at the focus of a cylindrical lens contained in the lamp box L. A parallel beam of light enters the chamber immediately below the top plate, of width sufficient to provide adequate illumination over the sensitive depth. Light scattered through 45° is used. The length of the projected track is about 2 cm and the juxtaposition of the stereoscopic photographs gives a mean angle between the projected tracks of about 10°.

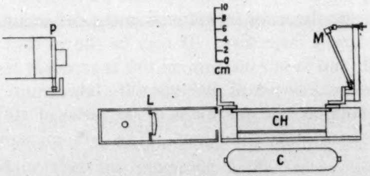

Fig. 2. Section through a single cloud chamber unit.

The point of intersection of the particle trajectory with the chamber grid is determined by finding the coordinate of the point of intersection of the stereoscopic tracks.

2.5. *Alignment of Chambers*

An optical method is used to align the three chambers with respect to each other. The top plate of each chamber extends beyond the sensitive chamber region in the 'longitudinal' direction (parallel to the pole faces of the magnets). For the chambers at the top and middle measuring levels brass plugs are cemented into the glass, one on each extension. For the top chamber a hole of 0·5 mm diameter is drilled into each plug and accurately located on the extension of the central line of the chamber grid whereas for the middle chamber there is a 5 mm aperture again located on the central line. A subsidiary grid is ruled on the bottom chamber glass.

Monochromatic light is passed through the small holes of the top level which then act as point sources of light. The light is diffracted by the 5 mm hole in the middle chamber extension and a Fresnel diffraction pattern is projected on to the subsidiary grid of the bottom chamber. The lines defined by the centre of the diffraction patterns and the point source of light are used as the reference lines from which all track locations are measured, in effect establishing a three-dimensional coordinate system.

The chambers are first mounted horizontally and an approximate alignment is achieved by hanging plumb-lines. The three chambers are then each adjusted the extra small amount until the centre of each diffraction pattern coincides with the central line of the bottom chamber. Subsidiary cameras photograph the diffraction patterns.

The system allows two degrees of freedom, one a translation of one chamber with respect to another and secondly a skewness of the chambers with respect to one another. It may be shown that the effect on the measured deflection of a particle trajectory by a pure translation is nullified by the symmetrical arrangement of measuring levels, and that in the general case where both conditions may exist, the effect is again zero for vertical particle trajectories. It is therefore only necessary to investigate the error introduced in the deflection as a function of the inclination of the particle trajectory. It may be shown that providing the angle of skewness is small (and in our instrument this is certainly less than 10^{-3} radian), and for a maximum inclination of 10°, then the maximum error introduced in the longitudinal deflection of a particle is of the order of 10^{-3} mm whilst that in the transverse direction is about 0·5 mm. The arrangement gave an alignment accuracy to $50\,\mu$.

The equation for the deflection of a particle is now related to the intersections A, B, C (Fig. 1) of the trajectory by the relation

$$\Delta = \mathrm{BB}' = \tfrac{1}{2}(T+B) - (M+M_c), \qquad \ldots\ldots(4)$$

where T, M, and B, refer respectively to the distances measured from the first grid line of the top, middle and bottom chambers and M_c is a correction factor relating the chamber grids with the three dimensional coordinate system defined by the diffraction alignment.

Equation (4) is combined with Eqn (2) to define the momentum of the incident particle.

§ 3. SELECTION OF EVENTS

A single event is characterized by the discharge of a set of three Geiger counters, one in each measuring level, which assigns each particle to a particular momentum category (Hyams *et al.* 1950), and by the particle deflection as measured by the cloud chambers. Strict criteria are applied to the acceptance of a particle trajectory in order that background effects may be reduced to a minimum. These considerations reduce the possibility of spurious observations below the already small value ($\sim 0{\cdot}1\%$) determined by Hyams *et al.* for the counter spectrograph.

3.1. *General Criteria of Acceptance*

That the expansion of the chambers is initiated by the discharge of a single counter in each of the measuring counter trays implies that a particular counter defines a region of the chamber where the track must be found. Tracks which lie outside this region are rejected, and only one track must lie within it. In addition the track width must be of the order of 1 mm, that is, its passage through the chamber must be contemporary with the expansion; furthermore the inclination of the track must not be greater than 10° to the vertical in the spectrograph.

3.2. *Selective Criterion*

In the plane parallel to the magnetic field the particle has nominally zero deflection. However, because of observational errors, scattering in the spectrograph and possible chamber distortion, the distribution of particle deflection in this direction is Gaussian of measured standard deviation $\pm 3{\cdot}0$ mm. Deflections of more than three times this standard deviation are rejected as arising from a spurious identification.

§ 4. FACTORS AFFECTING THE ACCURACY OF THE MEASURED PARTICLE DEFLECTION

The performance of the spectrograph is limited by errors which occur in the determination of particle momenta; in the paper by Holmes, Owen and Rodgers (1961) it is shown how these modify the measured sea level μ-meson spectrum at very high momenta.

The various sources of uncertainty in the spectrograph may be classified as follows.

4.1. *Geometrical Errors*

It was stated in § 2, that Eqn (2) is true only for a vertical trajectory and a symmetrical magnetic field distribution about the median line.

Measurements show that the magnetic fields are symmetrical about the median planes to within 2%. As the order of accuracy in the present measurements is never better than about 7%, only movements of h_1h_1' and h_2h_2' which arise from the inclination of the trajectory in the magnetic fields are considered. It may be shown that the vertical displacement of h_1h_1' from the plane of symmetry is given (Hyams *et al.* 1950) by

$$\delta = \frac{\int H\,dl}{2H_{\max}} \tan \tfrac{1}{2}\theta \sin \alpha, \qquad \ldots\ldots(5)$$

where $H_{\max}$ is the almost uniform field which extends over the major part of the pole gap, and where α is the inclination to the vertical of the incident trajectory.

In the present measurements $\int H\,dl = 6\times10^5$ gauss cm, $H_{\max} = 12\,500$ gauss and the maximum inclination of the particle trajectory is 10°. This leads to a maximum uncertainty in the location of h_1h_1' of $0{\cdot}014\Delta$ where Δ is the longitudinal deflection. The corresponding uncertainty in the longitudinal deflection is $0{\cdot}005\Delta^2\%$ and is negligible compared with the observational errors of measurement. To the precision of the present measurements therefore, the lines h_1h_1', h_2h_2' are adequately defined by the horizontal planes of symmetry of the magnetic fields.

Departure from the general symmetrical arrangements, either of measuring levels, or of inequality in deflecting magnetic fields, introduces an error in the measured particle deflection.

It may be shown that if the angular deflections in the two magnetic fields are θ and $\theta+\phi$ respectively and the middle measuring level is displaced by ϵ from the position of symmetry, then to the first order the error $\delta\Delta$ in the measured particle deflection is given by

$$\delta\Delta = \epsilon(\alpha-\theta) + \tfrac{1}{2}\phi d_0. \qquad \ldots\ldots(6)$$

The first term in the above expression represents the departure from geometrical symmetry whilst the second refers entirely to the inequalities in the angular deflections in the magnetic fields; the two terms are independent.

In the present work it has been possible to define the middle measuring level to within 0·7 mm from the plane midway between the top and bottom levels. For a particle incident at maximum inclination 10° and momentum greater than 10 GEV/c, the corresponding uncertainty in the particle deflection is 0·15 mm.

The difference in the field exciting current in each magnet may be controlled to less than 1%, corresponding to an uncertainty of 0·25% in the particle deflection, an amount small compared with the error introduced by the departure from geometrical symmetry.

Thus, within the accuracy of work undertaken, the measuring grids in each chamber are coincident with the symmetrical measuring levels aa′, bb′ and cc′ of Fig. 1, and a particle experiences equal deflections in the two magnetic fields.

4.2. *Scattering in the Spectrograph*

Following Eqn (15) of Hyams *et al.* (1950) the root mean square scattering deflection $(\delta\Delta)_s$ is proportional to the particle deflection, where both quantities are measured at the middle measuring plane of the spectrograph. A direct experimental determination of the scattering deflection has been derived from measurements of the half-width of the distribution of transverse deflections as a function of increasing particle momentum. For about a quarter of the period of the observations the spectrograph was run without any other scattering material in the particle beam than was necessary to determine the particle momentum. For the remainder of the time a subsidiary experiment involved the positioning of ancilliary apparatus in the spectrograph. The experimental determination gives ratios for $(\delta\Delta)_s/\Delta$ of $0{\cdot}022\pm0{\cdot}007$ and $0{\cdot}045\pm0{\cdot}005$ respectively under these two conditions. The ratios of the experimental scattering contribution to the expected scattering based on the William's formula are $0{\cdot}85\pm0{\cdot}27$ and $0{\cdot}9\pm0{\cdot}1$ respectively.

4.3. *Observational Errors*

Measurement errors are determined mainly by the geometry of photography. The errors in the point of intersection of the stereo-tracks projected on to the longitudinal and magnetic field directions vary over a single chamber with the angle made by the tracks to the chamber grid lines. For all cases the uncertainty in the location of a particle with respect to a chamber grid is greater in the magnetic field direction than in the longitudinal direction. The error in a particle deflection is calculated as a function of the trajectory displacement in the spectrograph. The measured distribution in deflections in the plane parallel to the magnetic field is used as an independent check on the calculated values.

For a particle which passes centrally through the spectrograph the error in measurement of the longitudinal deflection is 0·25 mm and corresponds to a maximum detectable momentum of 1000 GeV/*c*, whereas for the most unfavourable case of a particle which traverses vertically through the edge of the instrument the deflection error is 1·4 mm. The mean error averaged over the total aperture of the spectrograph is 0·9 mm and 70% of the particle deflections are subject to errors within the range 0·6 mm to 1·2 mm.

4.4. *Convective Gas Distortion*

An attempt has been made to determine the magnitude of the effect due to chamber gas movement before photography. Experimentally this may be indirectly inferred from the distribution of particle deflections in the direction parallel to the magnetic field. No great statistical accuracy may be placed on the conclusions, but it seems probable that convective gas distortion has a negligible effect on the measured particle momentum at least up to 300 GeV/*c* above which the paucity of measured particles becomes the controlling feature in spectrum determinations.

4.5. *Systematic Errors*

To provide an overall check on the presence of systematic errors in the measurement of particle deflections, observations were made both on zero magnetic field and of positive and negative deflections on reversed fields. These investigations showed that systematic effects were of negligible consequence compared to the observational errors of measurement.

§ 5. APPLICATION TO SPECTRUM DETERMINATIONS

It is for energetic particles that the additional information of the cloud chamber spectrograph is most important. There was, therefore, incorporated in the apparatus an electronic ‘ momentum selector ’, a device which in effect carries out the analytic operation by which particle momenta are determined in the counter spectrograph, and only passes an operating pulse to the cloud chamber system when the traversing particle falls into a desired momentum category. With the counter instrument statistical errors of 3% were achieved for momenta less than 10 GeV/*c* and thus it was unnecessary to re-investigate this momentum region. It was therefore important to record all particles of momentum appreciably greater than 10 GeV/*c* accepted by the geometry of the instrument, together with a sufficient number of particles of lower momentum to provide an overlap of the new data with the existing counter-determined spectrum. The selector bias was accordingly adjusted so that the selector only passed an operating pulse to the cloud chamber system when the traversing particle was recorded in momentum categories 0, 1, 2, and 3 (see Hyams *et al.* 1950, Table 4). Under these conditions the lower momentum limit of the cloud chamber spectrograph is approximately 3 GeV/*c* and effectively all particles of momentum greater than 10 GeV/*c* are recorded.

The rate of collection of particles accepted by the chambers is about 20 per day, of which 8 are of momentum greater than 10 GeV/*c*. Over an effective running period of 14 months, 4566 particles were recorded of which approximately 1800 were of momentum greater than 10 GeV/*c* and 70 were in excess of 100 GeV/*c*. The operating efficiency over this period, including maintenance time, was 70%.

Measurements of the Momentum Spectrum and Charge Ratio of Cosmic Ray Muons at Sea Level in the Momentum Range 10 GeV/c–1000 GeV/c

By J. E. R. HOLMES†, B. G. OWEN‡ and A. L. RODGERS§
Department of Physics, University of Manchester

Communicated by J. G. Wilson; MS. received 16*th May* 1960, *in revised form* 10*th April* 1961

Abstract. The momentum spectrum of single cosmic ray muons arriving at sea level in the north–south plane at 57° N geomagnetic latitude has been measured for near vertical incidence. Results are given which cover the momentum range 5 GeV/$c < p <$ 1000 GeV/c, and together with the earlier work of Owen and Wilson form a continuous spectrum from 0·5 GeV/c to 1000 GeV/c. The high momentum work is based on 1800 particles of momentum greater than 10 GeV/c.

The charge ratio of single muons arriving at sea level has been measured, for near vertical incidence, to an upper momentum limit of 100 GeV/c. The measurements are compared with those of other workers and together show evidence for a maximum in the sea level charge ratio in the momentum range 3 GeV/c to 7 GeV/c.

§ 1. Introduction

A particular application of the cloud chamber spectrograph, described in Holmes, Owen and Rodgers (1961), is to investigate the near-vertical sea-level spectrum and charge ratio of cosmic ray muons at appreciably higher momenta than could be attained using the original counter spectrograph of Hyams *et al.* (1950). With the counter instrument statistical errors of 3% were achieved in spectrum measurements for momenta less than 10 GeV/c and it was unnecessary to re-investigate this momentum region. It was therefore important to record effectively all particles of momentum greater than 10 GeV/c accepted by the aperture of the instrument together with a sufficient number of particles of lower momentum to provide an overlap of the new spectrum data with the existing counter spectrograph measurements of Owen and Wilson (1955). To achieve this performance the 'momentum selector' bias was adjusted so that the cloud chambers operated only when the traversing particle was recorded in counter momentum categories 0, 1, 2 and 3. Under these conditions the lower momentum limit of the cloud chamber spectrograph was approximately 3 GeV/c and all particles of momentum appreciably greater than 10 GeV/c were recorded. Over an effective running period of 14 months, during the years 1953–55, 4566 particles were recorded of which 1800 have momenta greater than 10 GeV/c and 70 momenta greater than 100 GeV/c.

All particles were collected within 10° from the vertical in the north–south plane, and within 2° in the east–west plane.

§ 2. The Principle of Spectrum Measurements

A particle traversal is characterized by the discharge of three Geiger counters which assign the particle to a momentum category covering a relatively wide momentum range, Hyams *et al.* (1950). Within the category n of nominal deflection Δ_n defined by the measured deviation for a trajectory passing through the axes of the three counters concerned, the deflection spectrum $S_n(\Delta)$ is the product of the incident deflection spectrum $S(\Delta)$ and the quantity $P(\Delta-\Delta_n)$ which is a purely geometrical expression for the relative collecting efficiency of a set of three counters as a function of the difference of deviation from the nominal deflection of the counter geometry. The particle deflections measured by the use of the three cloud chambers consist of observations of $S_n(\Delta)$ within the separate momentum categories.

The relative efficiency of collection K_n for particles of a given momentum category is a factor which is defined by the aperture of instrument. The total counting rate in a single momentum category is composed of counts from a number of 'channels' each of which is defined by the three Geiger counters concerned in a single event. Essentially the unit of counting is such a channel, and the differing relative efficiencies of collection K_n from one momentum category to another arise because different numbers of unit channels are available for the various momentum categories.

In the present instrument a further channel bias is produced by the operation of the 'momentum selector'. Ideally the selection output pulses should be constant in the same momentum category, but in practice the actual selection pulses are distributed about the nominal pulse for the category and those categories whose output selection pulses are near to the chosen bias value are in part rejected. There is thus no sharp cut off in momentum category selection, and for the fixed value of bias used during the present investigation, whilst appreciably all category 0 particles were recorded, the acceptance factors R_n for categories 1, 2 and 3 were 85%, 50% and 20% respectively. Under these conditions the normalized deflection spectrum is

$$S_n(\Delta)=K_nR_nS(\Delta)P(\Delta-\Delta_n). \qquad \ldots\ldots(1)$$

The momentum spectrum $S(p)$ is related to the incident deflection spectrum by

$$S(\Delta)\sim p^2S(p). \qquad \ldots\ldots(2)$$

§ 3. Calculation of the Sea-level Spectrum

3.1. *Methods of Spectrum Determination*

It is apparent from Eqn (1) that if observations are made within a single momentum category, the incident particle deflection spectrum may be calculated in arbitrary units independently of the category normalization factors, as both K_n and R_n affect a single momentum category as a whole.

Following Owen and Wilson (1955) the incident spectrum is derived by comparing the observed distribution of particle deflections in a single momentum category with the expected distribution of deflections in that category for an assumed incident spectrum. The comparison spectrum used is identical with the one used in the Owen and Wilson investigation and refers to a muon differential generation spectrum for a unique height of production and given by

$$S(p)\,dp\sim p^{-2\cdot 85}\,dp.$$

Whilst the application of the comparison spectrum in the present investigation is somewhat different from that in the earlier work, this spectrum was found still to be a convenient approximation.

Measured particle deflections are allocated to their respective counter categories and are grouped into suitable deflection ranges. The deflection distribution in a counter category is normalized to the intensity per unit of deflection, giving a differential deflection distribution for each category. The distribution expected on the basis of the incident comparison spectrum is calculated for each counter category and normalized to the same number of observations. The errors in normalization in no case exceed 1%. Fig. 1 shows the observed distributions for categories 0, 1, 2 and 3 together with the smoothed expected distribution for the comparison spectrum.

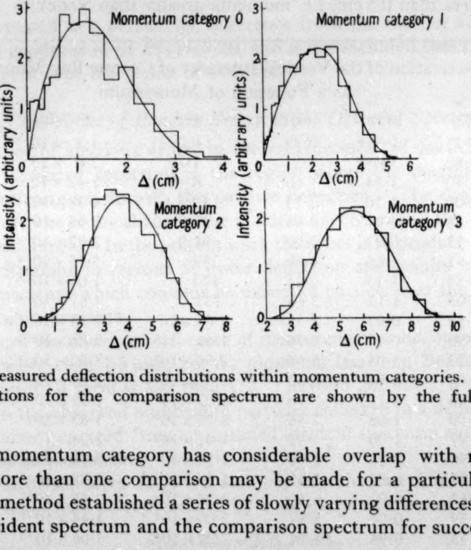

Fig. 1. The measured deflection distributions within momentum categories. The expected distributions for the comparison spectrum are shown by the full lines.

As each momentum category has considerable overlap with neighbouring categories, more than one comparison may be made for a particular deflection range. The method established a series of slowly varying differences between the measured incident spectrum and the comparison spectrum for successive deflection ranges.

Two methods are used to calculate the incident spectrum and these afford a convenient check on the interpretation of the measured data. In the first method the ratio of the observed number of particles to the integrated product of the comparison spectrum and the efficiency factor in a deflection range is multiplied by the integrated area of the comparison spectrum. This gives the incident spectrum in terms of the numbers of particles observed in a deflection range, and thus the corresponding momentum range. The observed intensities are normalized to unit momentum interval and give the differential momentum spectrum in histogram form and arbitrary units. The derived spectrum is fitted to the original counter spectrum of Owen and Wilson by normalizing to the same number of particles over the whole region of overlap. The statistical error in this normalization is 2·5%.

The second method of deriving the incident spectrum is to assume that the ratio of the observed number to the expected number of particles in a deflection range may be defined at a particular deflection in the range. This ratio is multiplied by the comparison spectrum at the chosen deflection to give the incident differential deflection spectrum. Conversion to the differential momentum spectrum is made by Eqn (2).

The choice of the deflection at which the whole of the contribution in a deflection range is plotted requires knowledge of the mean slope of the spectrum over the deflection interval considered. A method of successive approximations is used and the deflection is chosen so that the area under the histogram cell is equal to that under the smoothed curve of known slope which is assumed constant over the deflection interval considered. It may be shown that because of the shape of the incident spectrum the procedure is only important for particle deflections less than 0·5 cm, i.e. momenta greater than 50 GeV/*c*.

Table 1. Derivation of the Vertical Intensity of Cosmic Ray Muons at Sea Level as a Function of Momentum

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
0·23	0·23	1·71†	0·39	0·022	$4{\cdot}8 \times 10^{-13}$	48	1160
1·0	0·80	1·64†	1·31	1·27	$2{\cdot}8 \times 10^{-11}$	20	271

† Corrected for a total random error of 0·9 mm, $\alpha_T = 0{\cdot}75$.

(1) The mean deflection in the deflection range concerned Δ (mm), (2) The corresponding value of the comparison spectrum $S(\Delta)$, (3) The measured conversion factor including correction due to observational errors, (4) Differential deflection spectrum, i.e. product of (2) and (3), $S(\Delta)$, incident, (5) Differential momentum spectrum in arbitrary units $S(p)$, incident unnormalized, (6) Differential momentum spectrum in particles $\mathrm{cm}^{-2}\ \mathrm{sec}^{-1}\ \mathrm{sterad}^{-1}$ $(\mathrm{MeV}/c)^{-1}$ normalized to Rossi, $S(p)$, incident, (7) Statistical uncertainty: standard deviation of $S(p)$ (%), (8) Mean momentum p (GeV/*c*).

The measured data derived by this method are presented in Table 1. The spectrum is normalized to the counter spectrum of Owen and Wilson over the whole region of overlap by comparing the observed points with the smoothed curve of these workers. The comparison is displayed in Fig. 2 where the observed

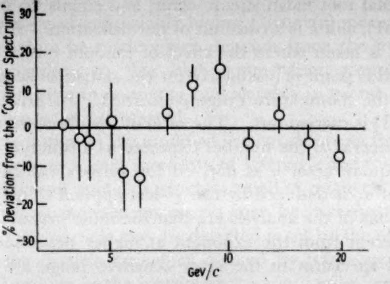

Fig. 2. Comparison with the counter spectrum of Owen and Wilson (1955).

points are expressed as a percentage difference from the counter spectrum. A χ^2-test gives a goodness of fit $P(\chi) = 0{\cdot}20$, and it is concluded that there is satisfactory agreement over the region of overlap.

3.2. *The Effect of Random Errors on the Observed Spectrum*

The presence of spurious errors in the measurement of particle deflections modifies the measured spectrum in the region where the magnitude of these errors becomes comparable with the particle deflection. The degree of modification is a function of the shape of the incident spectrum and the magnitude of the total random errors. In the present work the effect is to produce a net transfer of particle deflections to regions of lower deflection and results in a measured momentum spectrum which contains an excess of particle over the true incident spectrum at high momenta.

The effect of the observational error of measurement is negligible for particle deflections greater than 1·5 mm, i.e. for momenta less than 200 GeV/*c*. At this value the correction term is less than 1%. Beyond 200 GeV/*c*, a comparison is made between the observed numbers of particles collected in a deflection interval with the number expected from an assumed incident spectrum and the observational error of measurement.

Over the error-sensitive range it is assumed that the true differential spectrum $S(\Delta_T)$ of particles may be represented by a simple power law of the form

$$S(\Delta_T)\,d\Delta_T = K\Delta_T^{\alpha_T}\,d\Delta_T$$

where Δ_T is the true deflection and α_T is the true exponent in this range. K is a constant of normalization. The observation that over a relatively large range at higher deflections (lower momenta) the differential spectrum may be represented by a simple power law allows confidence to be placed in this assumption. A further assumption is that the random errors are normally distributed. This is in part justified by the observation that the residual particle deflections parallel to the magnetic field direction also follow such a distribution. Under these conditions the observed differential deflection spectrum $S(\Delta_0)$ is related to the true differential spectrum $S(\Delta_T)$ by

$$S(\Delta_0) = k\int_0^\infty S(\Delta_T)\exp\frac{1}{2}\left(-\frac{\Delta_0-\Delta_T}{\sigma}\right)^2 d\Delta_T \qquad \ldots\ldots(3)$$

where σ is the total root mean square error, and equals 0·9 mm (Holmes, Owen and Rodgers 1961), and k is a constant of normalization. A normalization point in the spectrum is taken where the effect of random errors is negligible. The actual choice of this point is insensitive for the statistical accuracy of the present observations in the momentum range concerned. In practice numerical integration of Eqn (3) is carried out. The ratio of the observed number of particles in a deflection interval to the number expected as a function of the exponent α_T and the mean square error σ is derived for various values of α_T. The most probable value of α_T is deduced by the χ^2-test applied to the comparison.

The conclusions of the analysis are that the most probable value of α_T is not significantly different from the exponent at higher deflections, and corrections to the measured spectrum in the error sensitive range are relevant to a true exponent $\alpha_T = 0{\cdot}75 \pm 0{\cdot}03$.

The uncertainty in the correction term due to a corresponding uncertainty in the total root mean square error is in no case greater than the statistical uncertainty in the groups affected, and only in the highest momentum group does the absolute correction exceed the statistical uncertainty.

The method is of course insensitive to any singularities in the spectrum which may occur at momenta greater than 200 GeV/c. It is however, commensurate with the paucity of events recorded in the error sensitive region.

§ 4. SEA-LEVEL CHARGE RATIO OF HIGH ENERGY MUONS

4.1. *Introduction*

Extended measurements of the momentum variation in the charge ratio of muons arriving vertically at sea level have been made by Owen and Wilson (1951) using the Manchester magnetic spectrograph described in Hyams *et al.* (1950), by Caro, Parry and Rathgeber (1951) and Moroney and Parry (1954) from observations on the Melbourne spectrograph, by Filosofo, Pohl and Pohl-Ruling (1954) from measurements using a magnetic lens at various depths underground, and by Pine, Davisson and Greisen (1959) who have used a cloud chamber magnetic spectrograph.

The results of Owen and Wilson, and those of Filosofo, Pohl and Pohl-Ruling, show that the charge ratio increases with meson momenta from about 1·17 at 1 GeV/c to about 1·26 at 5 GeV/c and that at higher momenta a slight decrease seems to occur. The results of Pine, Davisson and Greisen show stronger evidence of a decrease for momenta greater than 20 GeV/c. The observations of Caro, Parry and Rathgeber and Moroney and Parry, though statistically inferior to those of Owen and Wilson and Filosofo, Pohl and Pohl-Ruling corroborate an increase in the charge ratio at low meson momentum for the vertical muon component and are not inconsistent with a decrease at higher momenta.

The use of Geiger counter spectrographs and depth methods to study the behaviour of the charge ratio at momenta considerably greater than 10 GeV/c is limited by the maximum resolution of counter spectrographs and by the rate of collection of data at great depths. A further limitation with counter spectrograph measurements is that because particles are assigned to counter categories it is only possible to examine the general behaviour of particles over a relatively broad momentum range. In the Manchester counter instrument, because of the variation of the geometrical efficiency factor over a single category, the observed spectrum of particle deflections in category 1 contains a 3% contamination of particles of opposite sign of appreciably higher (70 GeV/*c*) mean momentum. A correction must therefore be made which depends upon the mean value of the charge ratio corresponding to this high momentum group, and an extrapolation of the charge ratio to momenta considerably in excess of the maximum detectable momentum must be inferred.

The increased resolution of the modified system allows an investigation of the charge ratio to be made to meson momenta of 100 GeV/*c* and the limit is imposed by the rate of collection of particles which is small at momenta greater than this value. Relatively small momentum ranges may be investigated and the limit to which the sign of the particle may be detected is set by the observational error in the location of the particle trajectory defined by reference to a set of three measuring cloud chambers in the instrument.

4.2. *Measurements with the Spectrograph*

The application of the instrument to charge ratio measurements is relatively simple since the ratio of the numbers of particles of opposite sign collected in a given time is independent of the variation of instrumental efficiency with momentum. Charge ratio observations were recorded continuously and concurrently with the collection of spectrum data and the direction of the magnetic field was reversed at frequent intervals to ensure that equal numbers of deflections of opposite sign were recorded. It is expected that the particles recorded were essentially muons, the proton component being negligible at the energies under consideration.

4.3. *Factors affecting the Observed Charge Ratio*

A correction to the observed charge ratio of the highest momentum group is imposed by the limit to which the sign of a measured particle deflection can be detected. This leads to an analogous correction to that of the earlier counter work, and depends upon the value of the charge ratio at the limits of measurement. As such a correction is uncertain to an extent to which the charge ratio at the limit of measurement is uncertain, two extreme possibilities are taken, i.e. that either the charge ratio at the higher momenta remains appreciably the same as the last measured point, or that it falls to unity at higher momenta. No evidence exists for an increase in the charge ratio and it is assumed that the true value lies between the two limits. It may be shown that the true value of the charge ratio in the highest momentum group is greater than the observed value by 0·6% if the charge ratio at high momentum is assumed to remain at the value of the last measured point, and is within 0·1% of the observed value if the charge ratio falls to unity. Both corrections are negligible compared with the statistical accuracy of the measured ratio.

The possibility of an electronic bias associated with the operation of the momentum selector was investigated and it was concluded that within the momentum categories used in the measurements the effect of such a bias would have negligible effect on the measured values of the charge ratio.

4.4. *Experimental Results*

Observations were collected within separate momentum categories for reversed magnetic fields and the measured values of the charge ratio are presented in Table 2. Columns (3) and (4) of this table show the charge ratios in the

relevant categories for reversed magnetic fields and column (5) is the weighted mean value for the momentum range concerned.

It has further been possible to check experimentally the numbers of particles of opposite sign which, because of the geometrical efficiency factor, appear in category 1 (Hyams *et al.* 1950). Reversed field observations show this fraction to be 2·86% and 2·78% respectively and give a mean value of 2·8 ± 0·4% which agrees well with the expected value.

§ 5. CONCLUSIONS

The description of the measured spectrum in terms of the comparison spectrum used by Owen and Wilson is given in Fig. 3 in an extended form of Fig. 2 of their paper (Owen and Wilson 1955, p. 413). The adopted form of the

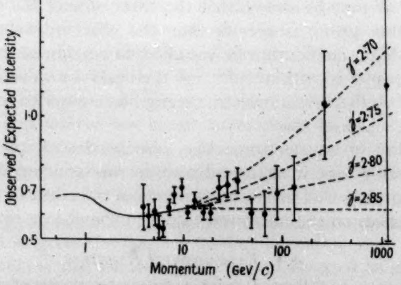

Fig. 3. Ratio of the observed intensity to the intensity expected based upon a muon differential generation spectrum $S(p)\,dp \sim p^{-\gamma}\,dp$. The full curve represents the counter spectrum of Owen and Wilson (1955).

differential spectrum of single muons arriving vertically at sea-level at 57° N geometric latitude is shown in Fig. 4, where the present results are combined with those of Owen and Wilson to form a continuous spectrum for

$$0{\cdot}5 \text{ GeV}/c < p < 1000 \text{ GeV}/c.$$

The corrections to the measured spectrum arising because particles are in general collected from a direction inclined to the vertical, which varies for different momentum categories, are negligible in the present work where the lowest momentum particles are recorded in category 3 of mean zenith angle 3°.

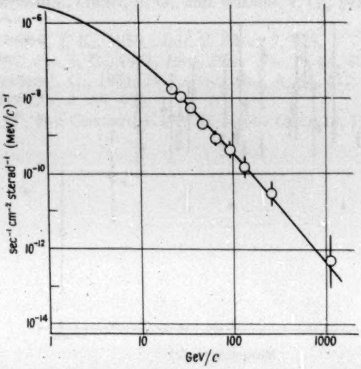

Fig. 4. The differential momentum spectrum of vertically incident muons at sea level.

The spectrum is essentially composed of muons. The electron component is eliminated as in the work of Owen and Wilson (1955), and the evidence on the proton component (Mylroi and Wilson 1951 and Barrett *et al.* 1952) indicates that the sea level proton flux in the momentum range investigated is less than 0·1% of that of the total sea level flux. From the expected form of the pion spectrum at sea level it is concluded that unless the pion cross section for nuclear interaction falls to a very small fraction of the geometric value, pions contribute a negligible proportion of the total sea level flux up to the highest measured momentum.

The fact that the spectrum described here is composed of single unaccompanied muons does not exclude the possibility of there existing a high momentum bias, which would act to reject an increasing fraction of the sea level component if the probability that a muon is accompanied by a shower increases with momentum. No experimental information may be gained from the records because of the impossibility of identifying the muons in such cases. The chance that two muons arising by decay of parents produced in the same primary collision and arriving simultaneously within the aperture of the spectrograph is negligibly small at the energies considered. It is further expected that the density of the soft component at sea level is low enough to make no substantial corrections to the observed rates at the highest momentum recorded.

Compared with the results of other workers the measured spectrum is in agreement with the more recent investigations of Ashton *et al.* (1960) and of

Pine, Davisson and Greisen (1959) over the whole of the momentum range below 200 GeV/*c*. It does not agree however with the earlier work of Caro, Parry and Rathgeber (1951), particularly above a momentum of 20 GeV/*c*.

In relation to charge ratio measurements the emphasis of the present work is primarily to study the behaviour at momenta in excess of 10 GeV/*c*. In Fig. 5 the present measurements are displayed together with the results of Owen and Wilson and those of later workers.

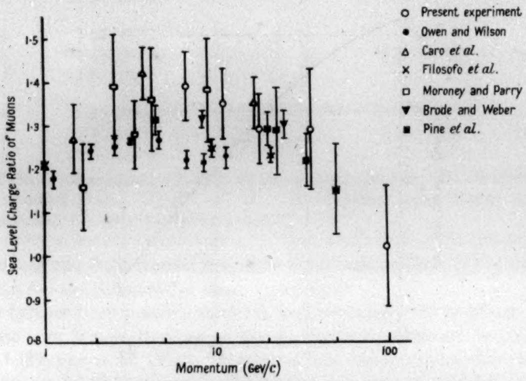

Fig. 5. Collected observations of the charge ratio of muons arriving vertically at sea level.

Taken alone the present investigation suggests that the sea-level charge ratio of vertically incident muons decreases with increasing momentum greater than 7 GeV/*c*. The measured points are in reasonable agreement with the observations of Pine *et al.* and of Brode and Weber (1955) above a momentum of 20 GeV/*c*, but are however approximately 10% greater than the Owen and Wilson and the Filosofo work.

On the basis of the evidence presented in Fig. 5 it would appear that the sea-level charge ratio passes through a broad maximum in the momentum range 3 GeV/*c* to 7 GeV/*c* but that only the general shape of the curve may be inferred.

ACKNOWLEDGMENTS

The authors wish to thank Professor P. M. S. Blackett and Professor G. D. Rochester for the support given and the facilities provided, Dr. A. W. Wolfendale for his interest and advice and Dr. D. A. Eyeions for help in the routine testing of the spectrograph. They are grateful to the technical staff of the Physical Laboratories, in particular to Mr. R. E. Bradford for the construction of parts of the apparatus and to Mrs. S. Holden for assistance in the measurement of track records.

One of us (A. L. R.) is indebted for a Further Education Training Scheme grant enabling him to do part of the work.

Low Temperature Electric Field Effects in Semiconductors†

BY V. V. PARANJAPE

Department of Theoretical Physics, University of Liverpool

Communicated by H. Fröhlich; MS. received 30*th August* 1960, *in final form* 10*th April* 1961

Abstract. Germanium shows at liquid helium temperature a very strong rise in conductivity with field strength at about 2 v cm^{-1}. This process has been investigated theoretically on the basis of electron temperature concept. The variation of the density of electrons with field is calculated considering excitation of donors into the conduction band by impact ionization and phonon absorption as well as reverse processes. It is shown that the current, though strongly field dependent, is always stable and an expression for current density as an explicit function of the field strength is obtained. Good agreement with experiments supports the validity of this theory.

---

§ 1. INTRODUCTION

THE variation of current with electric field in germanium has been a subject of extensive experimental investigation in recent years (Ryder 1953, Gunn 1957, Bray and Mendelssohn 1957). In general it is observed that the current obeys Ohm's law up to a certain value of the field strength, but deviations occur beyond this value. Shockley (1951) has proposed a theory and has shown that the mobility μ_L of the current carriers in a covalent semiconductor varies with the field F, according to the law

$$\mu_L = \mu_L(T_0)\left[\left(\frac{32}{3\pi}\right)^{1/2} \frac{s}{F\mu_L(T_0)}\right]^{1/2} \qquad \ldots\ldots (1.1)$$

where $\mu_L(T_0)$ is the mobility of the current carriers at vanishing field and s is the velocity of sound in the crystal, provided the scattering of the current carriers is due to the acoustical modes of the lattice vibrations and the field F satisfies the condition $F\mu_L(T_0) \gg s$. If the density of the current carriers $n(T_0)$ is independent of the electric field the expression for the current density J in view of (1.1) is

$$J = Fen(T_0)\mu_L(T_0)\left[\left(\frac{32}{3\pi}\right)^{1/2} \frac{s}{F\mu_L(T_0)}\right]^{1/2} \qquad \ldots\ldots (1.2)$$

where e is the charge of a current carrier.

Ryder (1953) investigating experimentally the field effects in a fairly pure n-type germanium at temperature 77°K and above found that the current density is proportional to $F^{1/2}$ as is predicted by the theoretical relation (1.2). However, the constant of proportionality was not in agreement with this relation. On the other hand Sclar and Burstein (1957) working at liquid helium temperatures observed that the current variation with the field was completely different from (1.2). These authors have reported that for a fairly pure n-type germanium at liquid helium temperature the current obeys Ohm's law up to a field strength of about 2 v cm^{-1} while for a small increase in the applied voltage above 2 v cm^{-1} the current increases by several orders of magnitude. This rapid increase ceases at about 4 v cm^{-1} and for higher values of the field strength the current is proportional to $F^{1/2}$. Sclar and Burstein refer to this behaviour as 'low temperature breakdown' because of its similarity with the rising current observed in semiconductors at intrinsic breakdown fields. These authors have also estimated theoretically, on the basis of a simple model, the magnitude of this breakdown field at which a steep rise in the current is observed. In the opinion of the present author however, this field dependence of the current at low temperatures cannot be denoted as a breakdown process. We emphasize this point because the processes involved in the low temperature field dependence and in intrinsic breakdown are quite distinct. Intrinsic breakdown results from a state of instability of the current carriers under the action of the breakdown field, whereas in the case of low temperature field dependence the current though strongly field dependent, is always stable. Furthermore at intrinsic breakdown, in view of the instability of the current, no theoretical expression for the current density can be obtained. It is the object of the present paper to provide a theoretical explanation for this low temperature field dependence and obtain an expression for the current density as a unique and continuous function of the field strength.

---

† Based on report L/T 406 of the British Electrical and Allied Industries Research Association.

The basic idea of our theory lies in the use of electron temperature concept first introduced by Fröhlich (1947 a, b). He has shown that electrons in a semiconductor under the action of a field can establish among themselves an equilibrium energy distribution corresponding to an electron temperature T, which is always greater than the lattice temperature T_0. Making use of this idea, Shockley calculated the effect of the field on the mobility of electrons and obtained the relation (1.1). The consequent expression (1.2) for the current density J follows if the density of electrons is constant. At liquid helium temperatures however we cannot expect the density of the free electrons to remain constant with the field as may be seen from the following argument. Consider a crystal† of n-type germanium having a donor impurity concentration of about 10^{14} cm^{-3}. At these low temperatures the number of free electrons will be small, about 10^7–10^8 cm^{-3}, whereas the number of electrons bound to the donor sites will be of the order of 10^{14} cm^{-3}. Under the action of an electric field the free electrons would assume a Maxwellian energy distribution at an electron temperature $T > T_0$ and would also tend to establish temperature equilibrium with the bound electrons. This is counteracted by the lattice vibrations which try to maintain equilibrium with the bound electrons at temperature T_0. These two opposing effects acting on the bound electrons determine their number density and consequently also that of the free electrons. These effects can be discussed in terms of the following processes:

Process 1, in which a free electron having a kinetic energy greater than the donor ionization energy can ionize a donor and create an additional free electron.

Process 2, in which a bound electron is ionized by the absorption of a lattice quantum of energy greater than the donor ionization energy.

---

† Even though the calculation of this paper is referred to n-type germanium, the results obtained are valid for any covalent semiconductor, provided the ionization energy of donors is less than Θ(Θ = Debye temperature).

In order to satisfy the principle of detailed balancing the reverse of these processes must occur. These reverse processes relate to the capture of a free electron by a donor. These two processes, each with its reverse, are taken into account in § 3 in order to determine the free electron density as a function of the lattice and electron temperatures. In § 4 we obtain the expression for the current density, by considering the effect of the field on both the mobility and the density of the free electrons. The results obtained in § 4 are discussed and compared with experiment in § 5. The necessary preliminary discussion for the development of the theory is given in § 2.

§ 2. Preliminary Considerations

Fröhlich has considered the effect of an electric field on the energy distribution of the electrons in a series of papers. (Fröhlich 1947 a, Fröhlich 1947 b, Fröhlich and Paranjape 1956). He has shown that the electron–electron interactions play a very important role in determining the energy distributions of electrons in the presence of an electric field. By considering a simple free electron model (i.e. without inter-electron interactions) he and Stratton (1957) have shown that for a field F however small, the sufficiently fast electrons continuously gain energy from the field and would be indefinitely accelerated leading to a non-stationary energy distribution. This can only be avoided by considering electron–electron interactions which bring about a stationary distribution. These authors show that the energy gained from the field is randomized as a result of electron–electron interactions. The average energy of the free electrons which exceeds the vibrational energy of the lattice can therefore be represented in terms of an electron temperature T. Stratton has treated in detail the problem of inter-electronic collisions in semiconductors by considering various ranges of the electron density. He has concluded that even at low densities when the influence of inter-electronic collisions may not be predominant the field dependence of the average energy and of the mobility of electrons is practically the same as that obtained by using the electron-temperature concept. In this paper although we are dealing with very low electron densities, the use of electron-temperature concept will not therefore introduce any serious error in our calculations. To determine T we proceed as follows: We denote the rate of gain of energy by the free electrons from the field by A and the rate of loss of energy by the electrons to the lattice by B. For the steady state the condition

$$A = B \qquad \ldots\ldots (2.1)$$

must be satisfied. On the basis of the electron-temperature concept Stratton has calculated A and B and has obtained an explicit form of Eqn (2.1) which read

$$A = F^2 en(T)\mu(T) = \frac{32}{3\pi}\frac{n(T)es^2}{\mu_{\mathrm{L}}(T_0)}\left[\frac{T}{T_0}\right]^{3/2}\left[1-\frac{T_0}{T}\right] = B \quad \ldots\ldots (2.2)$$

where $n(T)$ is the free electron density at electron temperature T and $\mu(T)$ is the effective mobility of the electons at T. Eqn (2.2) is called the energy balance equation and is used to determine T for a given field F. When the field F is increased T would also increase and this would in general affect the electrical properties of the crystal. In this section we consider the effect of electron temperature on the mobility of electrons. For any mechanism of electron scattering, if we know the mobility of an electron of a given energy then the corresponding average mobility at electron temperature T can be obtained by the usual procedure of averaging. It can be shown that the variation with T of mobility, due solely to scattering by the acoustical modes of the lattice is given by

$$\mu_L(T) = \mu_L(T_0)\left(\frac{T_0}{T}\right)^{1/2}. \qquad \ldots\ldots(2.3)$$

The corresponding expression for the mobility $\mu_I(T)$ due to the ionized impurity scattering, which can be obtained with the help of the Conwell and Weisskopf (1950) formula, is

$$\mu_I(T) = \mu_I(T_0)\left[\frac{T}{T_0}\right]^{3/2}\frac{n_I(T_0)}{n_I(T)} \qquad \ldots\ldots(2.4)$$

where $n_I(T)$ is the number density of the ionized impurity at T. It should be remembered that (2.4) is an approximate formula, since we have neglected the terms varying slowly with energy in the Conwell and Weisskopf formula.

Using (2.1) if we eliminate T from (2.3) and (2.4) we will get the expression for the mobility variation with the field. This procedure can be applied in a straightforward manner to lattice scattering; it results in relation (1.1). But for ionized impurity scattering elimination of T is not possible at the present stage since we do not know the electron temperature dependence of $n_I(T)$. We shall derive this quantity in the next section.

§ 3. ELECTRON DENSITY

As a model for our calculations consider a crystal of n-type germanium, containing a donor impurity of N_D per cm^3 and an acceptor impurity of N_A per cm^3. From the requirement of electrical neutrality one can calculate, using elementary statistical mechanics the number density $n(T_0)$ of free electrons in such a crystal. In this paper we are only interested in low temperature, so low in fact that the density of holes in the valence band is negligible compared with the free electron density.

Defining $n_b(T_0)$ and $n_I(T_0)$ as the density of the bound electrons and the density of ionized donors respectively, then the charge neutrality requires that

$$n(T_0) = n_I(T_0) - N_A \qquad \ldots\ldots(3.1)$$

where

$$n_I(T_0) = N_D = n_b(T_0). \qquad \ldots\ldots(3.2)$$

Relations (3.1) and (3.2) are fundamental and are valid even under the influence of an electric field.

In the absence of an external electric field, there is complete thermal equilibrium between free electrons, bound electrons and the lattice at any temperature T_0. If we measure the energy ϵ of an electron from the bottom of the conduction band, then the probability $\Phi(\epsilon)$ of finding an electron with a positive or negative value of ϵ obeys the equation

$$\Phi(\epsilon) = \left[\exp\left(\frac{-\xi+\epsilon}{kT_0}\right)+1\right]^{-1} \qquad \ldots\ldots(3.3)$$

where ξ is the Fermi energy. For a non-degenerate semiconductor $-\xi \gg kT_0$, (k = Boltzmann's constant), and in terms of $n(T_0)$

$$\exp\left(\frac{\xi}{kT_0}\right) = \frac{n(T_0)h^3}{2(2m\pi kT_0)^{3/2}}.$$

From (3.3) follows

$$n_b(T_0) = N_D\left[\exp\left(-\frac{\xi+I}{kT_0}\right)+1\right]^{-1}$$

on the assumption that the donors have a single ionization energy I. Having obtained $n_{\rm b}(T_0)$ we may determine $n(T_0)$ and $n_{\rm i}(T_0)$ from Eqns (3.1) and (3.2). Hence the ratio $[n_{\rm i}(T_0)/n_{\rm b}(T_0)]$ whose value we require later, is given by

$$\frac{n_{\rm i}(T_0)}{n_{\rm b}(T_0)}=\exp\left(-\frac{\xi+I}{kT_0}\right). \qquad \ldots\ldots(3.4)$$

In the presence of an electric field the thermal equilibrium of the crystal is disturbed. However, if the crystal is maintained in a heat bath of temperature T_0, one may assume that the lattice is maintained at a temperature T_0 while the electron temperature T will be in excess of T_0.

We denote the energy distribution of free electrons in the conduction band, under the action of the field by $f(\epsilon)$. Since they are assumed to reach equilibrium amongst themselves at temperature $T (T > T_0)$, $f(\epsilon)$ can be represented by Fermi–Dirac distribution function at T. This distribution will be valid in the conduction band only for electrons with $\epsilon > 0$. Thus $f(\epsilon)=[\alpha^{-1}\exp(\epsilon/kT)+1]^{-1}$ where α is a normalizing factor. If $\alpha^{-1}\exp(\epsilon/kT_0)\gg 1$ which is true for non-degenerate semiconductors, we have

$$f(\epsilon)\simeq\exp\left(\frac{-\epsilon}{kT}\right) \qquad \ldots\ldots(3.5)$$

α the normalizing factor, is obtained by using the condition

$$\int_0^\infty f(\epsilon)\rho(\epsilon)d\epsilon=n(T)$$

where $\rho(\epsilon)$ is the density of states per unit range of energy for the free electrons. As is well known $\rho(\epsilon)=4\pi(2m)^{3/2}(\epsilon)^{1/2}/h^3$ so that

$$\alpha=\frac{n(T)h^3}{2(2m\pi kT)^{3/2}}=\frac{n(T)}{n(T_0)}\left(\frac{T_0}{T}\right)^{3/2}\exp\left(\frac{\xi}{kT_0}\right). \qquad \ldots\ldots(3.6)$$

When $T=T_0$, $\alpha=\exp(\xi/kT_0)$ as is expected.

Since $f(\epsilon)$ as given by (3.5) is only valid for $\epsilon\geqslant 0$ we cannot determine $n_{\rm b}(T)$ from it, as we could in the field free case. To determine $n_{\rm b}(T)$ and hence $n(T)$ and $n_{\rm i}(T)$ one has to consider in detail the rates of change of $n(T)$ due to processes 1 and 2 introduced in § 1. If we denote the rate of change of $n(T)$ due to process 1 and its reverse by $[dn(T)/dt]_{\rm c}$ and that due to process 2 and its reverse by $[dn(T)/dt]_{\rm L}$ then the total rate of change $[dn(T)/dt]_{\rm total}$ is equal to $[dn(T)/dt]_{\rm c}+[dn(T)/dt]_{\rm L}$. For the electron density to be time independent, we must have

$$\left[\frac{dn(T)}{dt}\right]_{\rm total}=\left[\frac{dn(T)}{dt}\right]_{\rm c}+\left[\frac{dn(T)}{dt}\right]_{\rm L}=0. \qquad \ldots\ldots(3.7)$$

We shall first consider process 1 with its reverse and obtain $[dn(T)/dt]_{\rm c}$. In process 1 an electron with an energy ϵ greater than the donor ionization energy can ionize a donor and produce an additional free electron. If ϵ is the energy of the initiating electron and the final energies of the resulting electrons are ϵ_1 and ϵ_2 then energy conservation requires that $\epsilon=\epsilon_1+\epsilon_2+I$.

Here $[dn(T)/dt]_{\rm c}$ is expressed as a sum of the rates of increase and decrease of $n(T)$ by the process 1 and its reverse by the equation

$$\left[\frac{dn(T)}{dt}\right]_{\rm c}=an_{\rm b}(T)-bn_{\rm i}(T). \qquad \ldots\ldots(3.8)$$

Using the energy distribution function (3.5) with (3.6) for the electrons at electron temperature T it can be shown that a and b are related to T by the relation

$$\left[\frac{a}{b}\right]=[\alpha]^{-1}\exp\left[\frac{-I}{kT}\right]$$
$$=\left[\frac{n_1(T_0)}{n_b(T_0)}\right]\left[\frac{n(T_0)}{n(T)}\right]\left[\frac{T}{T_0}\right]^{3/2}\exp\left[-\left(\frac{I}{kT}\right)+\left(\frac{I}{kT_0}\right)\right]. \qquad \ldots\ldots(3.9)$$

The quantities a and b are expressible in terms of the cross section $\sigma_C(\epsilon|\epsilon_1, \epsilon_2)$ for the process 1 and its reverse. If we define an average cross section by

$$\sigma_C(\epsilon)=\int_0^{\epsilon-I}\sigma_C(\epsilon|\epsilon_1, \epsilon_2)\rho(\epsilon_1)d\epsilon_1 \Big/ \int_0^{\epsilon-I}\rho(\epsilon_1)d\epsilon_1 \qquad \ldots\ldots(3.10)$$

then clearly

$$a=\int_I^\infty f(\epsilon)\sigma_C(\epsilon)v(\epsilon)\rho(\epsilon)\,d\epsilon \qquad \ldots\ldots(3.11)$$

where $v(\epsilon)$ is the velocity of the electron of energy ϵ. For hydrogen-like impurity (Mott and Massey 1952)

$$\sigma_C(\epsilon)=\frac{0{\cdot}285\pi e^4}{DI\epsilon}\log\frac{\epsilon D}{0{\cdot}012I} \qquad \ldots\ldots(3.12)$$

where D is the dielectric constant. Eqn (3.12) is obtained by Born's approximation and is valid for $\epsilon \gg I$, but it gives a fair order of magnitude for $\epsilon \geqslant I$. Using (3.12) in (3.11) one obtains

$$a=\frac{16\pi}{h^3}\alpha m\sigma_C(I)IkT\exp\left(\frac{-I}{kT}\right) \qquad \ldots\ldots(3.13)$$

where $\sigma_C(I)$ is the ionization cross section for an electron of energy $\epsilon \simeq I$. With the value of a from (3.13) and the ratio $[a/b]$ from (3.9) one can readily obtain

$$b=\frac{16m\pi}{h_3}\alpha^2\sigma_C(I)IkT. \qquad \ldots\ldots(3.14)$$

We now turn to process 2, in which a bound electron absorbs a lattice quantum of energy $\epsilon+I$; it is thus transferred to the conduction band into a state of energy ϵ. Conversely a free electron of energy ϵ emits a lattice quantum of energy $\epsilon+I$ and is captured. Since this process involves the emission and absorption of a lattice quantum (phonon) the cross section for ionization and recombination respectively can be written as

$$\sigma_{LE}(\epsilon)=\sigma_L(\epsilon)\exp\left(\frac{I+\epsilon}{kT_0}\right)\left[\exp\left(\frac{I+\epsilon}{kT_0}\right)-1\right]^{-1}\left.\begin{matrix}\text{emission of phonon}\\ \text{recombination of an electron,}\end{matrix}\right\} \qquad \ldots\ldots(3.15a)$$

$$\sigma_{LA}(\epsilon)=\sigma_L(\epsilon)\left[\exp\left(\frac{I+\epsilon}{kT_0}\right)-1\right]^{-1}\left.\begin{matrix}\text{absorption of phonon}\\ \text{ionization of donor,}\end{matrix}\right\} \qquad \ldots\ldots(3.15b)$$

the quantity $[\exp\{(I+\epsilon)/kT_0\}-1]^{-1}$ represents the temperature dependence of the number of phonons of energy $\epsilon+I$ which is involved in the interaction. $\sigma_L(\epsilon)$ is independent of T_0 but depends on the properties of the crystal. When $kT_0 \ll I$ (as is the case at liquid helium temperature), $\sigma_{LE}(\epsilon)$ is almost equal to $\sigma_L(\epsilon)$ so that $\sigma(\epsilon)$ can be interpreted as the electron recombination cross section at low temperatures. Here $[dn(T)/dt]_L$ can be written as a sum of the rates of increase and decrease of $n(T)$ by process 2 and its reverse by

$$\left[\frac{dn(T)}{dt}\right]_{\mathrm{L}} = cn_{\mathrm{b}}(T) - dn_{\mathrm{i}}(T) \qquad \ldots\ldots(3.16)$$

where c and d are related to the cross section $\sigma_{\mathrm{L}}(\epsilon)$ through the following relations

$$c = \int_0^{k\Theta - I} \left[\exp\left(\frac{I+\epsilon}{kT_0}\right) - 1\right]^{-1} \sigma_{\mathrm{L}}(\epsilon) v(\epsilon) \rho(\epsilon) d\epsilon \qquad \ldots\ldots(3.17)$$

and

$$d = \int_0^{k\Theta - I} f(\epsilon) \exp\left(\frac{I+\epsilon}{kT_0}\right) \left[\exp\left(\frac{I+\epsilon}{kT_0}\right) - 1\right]^{-1} \sigma_{\mathrm{L}}(\epsilon) v(\epsilon) \rho(\epsilon) d\epsilon. \qquad \ldots\ldots(3.18)$$

To determine c and d it is necessary to know the energy dependence of $\sigma_{\mathrm{L}}(\epsilon)$. Lax (1959) and Frood (1959) have calculated $\sigma_{\mathrm{L}}(\epsilon)$ on the basis of different models and have obtained different results, but both of these authors agree that $\sigma_{\mathrm{L}}(\epsilon)$ should increase as ϵ decreases. Making use of this fact we define $\sigma_{\mathrm{L}}(\epsilon)$ by the relation

$$\sigma_{\mathrm{L}}(\epsilon) = \sigma_{\mathrm{L}}(kT_0)(kT_0/\epsilon)^{\beta} \qquad \ldots\ldots(3.19)$$

where β is treated as an arbitrary but positive numerical parameter From (3.5), (3.17), (3.18) and (3.19) it is seen that

$$\frac{c}{d} = (\alpha)^{-1} \left(\frac{T}{T_0}\right)^{\beta - 2} \exp\left(\frac{-I}{kT_0}\right) \qquad \ldots\ldots(3.20)$$

provided $I \gg kT_0$ and $k\Theta - I \gg kT$. Substituting the value of α from (3.6) into Eqn (3.20) we get

$$\frac{c}{d} = \frac{n_{\mathrm{i}}(T_0)}{n_{\mathrm{b}}(T_0)} \frac{n(T_0)}{n(T)} \left[\frac{T}{T_0}\right]^{(2\beta - 1)/2}. \qquad \ldots\ldots(3.21)$$

From (3.19) and (3.21) we can see that at $T = T_0$

$$\frac{n_{\mathrm{i}}(T_0)}{n_{\mathrm{b}}(T_0)} = \left[\frac{a}{b}\right]_{T_0} = \left[\frac{c}{d}\right]_{T_0}$$

so that

$$\frac{n_{\mathrm{i}}(T_0)}{n_{\mathrm{b}}(T_0)} = \left[\frac{a+c}{b+d}\right]_{T_0}. \qquad \ldots\ldots(3.22)$$

Consider now the integral (3.17) for c. Using Eqn (3.19) we evaluate the integral for c and obtain

$$c = \frac{16m\pi}{h^3} \sigma_{\mathrm{L}}(kT_0) Q \exp\left(\frac{-I}{kT_0}\right) (kT_0)^2 \qquad \ldots\ldots(3.23)$$

where Q is a numerical factor independent of T and is defined by

$$Q = \int_0^{(k\Theta - I)/kT_0} \exp(-x) x^{1-\beta} \, dx.$$

With the knowledge of the values of the ratio $[c/d]$ from (3.20) and of c from (3.23) the value of d is found as

$$d = [16m\pi/h^3][\alpha][kT_0]^2[\sigma_{\mathrm{L}}(kT_0)Q][T_0/T]^{\beta-2}. \qquad \ldots\ldots(3.24)$$

Substituting the values of a, b, c and d from (3.13), (3.14), (3.23) and (3.24) into (3.8) and (3.16) condition (3.7) can be written as

$$\frac{n_{\mathrm{i}}(T)}{n_{\mathrm{b}}(T)} = (\alpha^{-1}) \left[\frac{\alpha\sigma_{\mathrm{c}}(I) kT \exp(-I/kT) + \exp(-I/kT_0)(kT_0)^2 \sigma_{\mathrm{L}}(kT_0) Q}{\alpha\sigma_{\mathrm{c}}(I) IkT + (T_0/T)^{\beta-2}(kT_0)^2 \sigma_{\mathrm{L}}(kT_0) Q}\right]. \qquad \ldots\ldots(3.25)$$

For the sake of convenience we write (3.25) in the form

$$\frac{n_l(T)}{n_b(T)} = (\alpha)^{-1}\left[\frac{a'+c'}{b'+d'}\right] \qquad \ldots\ldots (3.26)$$

where a', b', c' and d' stand for the respective terms in (3.25). It should be remembered that a', b', c' and d' are obtained from a, b, c and d by the removal of a common factor.

We attempt to solve (3.26) approximately for different ranges of electron temperature T and consider in each range only one predominant term from the numerator and denominator of the right-hand side of the Eqn (3.25). At liquid helium temperature, α is very small so that we expect that a' and b' would be very much smaller than c' and d' respectively for a range of electron temperature $T_0 < T < T_1$ where T_1 is to be determined. On the basis of this and with the known electron temperature dependence of a', b', c' and d' we divide the electron temperature T into the following three ranges:

Case I.	$T_0 < T < T_1$	when	$c' \gg a'$	and	$d' \gg b'$
Case II.	$T_1 < T < T_2$	when	$a' > c'$	and	$d' > b'$
Case III.	$T_2 < T$	when	$a' \gg c'$	and	$b' > d'$

The electron temperatures T_1 and T_2 are determined by the conditions $[a']_{T_1} = [c']_{T_1}$ and $[b']_{T_2} = [d']_{T_2}$ respectively.

In case I, we neglect a' and b' from the Eqn (3.26) and writing $n_l(T)$ and $n_b(T)$ in terms of $n(T)$ from (3.1) and (3.2), Eqn (3.26) can be written as

$$\frac{N_A + n(T)}{N_D - N_A - n(T)} = \frac{2(2m\pi kT)^{3/2}}{n(T)h^3}\left[\frac{T}{T_0}\right]^{\beta-2} \exp\left(\frac{-I}{kT_0}\right). \qquad \ldots\ldots (3.27)$$

This quadratic equation in $n(T)$ has the solution

$$n(T) = \tfrac{1}{2}\{-(N_A + x) + [(N_A + x)^2 - 4x(N_A - N_D)]^{1/2}\} \qquad \ldots\ldots (3.28)$$

where

$$x = \frac{2(2m\pi kT_0)^{3/2}}{h^3}\left(\frac{T}{T_0}\right)^{(2\beta-1)/2} \exp\left(\frac{-I}{kT_0}\right).$$

Simplifying the relation (3.28) for the condition $x \ll N_A$ and $N_A{}^2 > 4xN_D$ we obtain

$$n(T) = \frac{2N_D}{N_A}\left[\frac{2m\pi kT_0}{h^3}\right]^{3/2} \exp\left(\frac{-I}{kT_0}\right)\left(\frac{T}{T_0}\right)^{(2\beta-1)/2}.$$

In case II we neglect c' and b' in Eqn (3.26) and solving for $n(T)$ we obtain

$$n(T) + N_A = \frac{N_D[T/T_0]^{\beta-1}[\sigma_c(I)/\sigma_L(kT_0)Q][I/kT_0]\exp(-I/kT)}{1 + [T/T_0]^{\beta-1}[\sigma_c(I)/\sigma_L(kT_0)Q][I/kT_0]\exp(-I/kT)}. \qquad \ldots\ldots (3.30)$$

The relation (3.30) can be simplified for the condition

$$1 \gg \left(\frac{T}{T_0}\right)^{\beta-1} \frac{\sigma_c(I)}{\sigma_L(kT_0)Q}\,\frac{I}{kT_0} \exp\left(\frac{-I}{kT}\right) \qquad \ldots\ldots (3.31)$$

giving

$$n(T) + N_A = N_D\left(\frac{T}{T_0}\right)^{\beta-1} \frac{\sigma_c(I)}{\sigma_L(kT_0)Q}\,\frac{I}{kT_0} \exp\left(\frac{-I}{kT}\right). \qquad \ldots\ldots (3.32)$$

For case III, we solve the Eqn (3.26) for $n(T)$ neglecting c' and d' and obtain

$$n(T)=\tfrac{1}{2}\{-(N_A+y)+[(N_A+y)^2-4y(N_A-N_D)]^{1/2}\} \quad \ldots\ldots(3.33)$$

where

$$y=[2(2m\pi kT)^{3/2}/h^3]\exp(-I/kT).$$

The relation (3.33) may be simplified to

$$n(T)=\frac{2N_D}{N_A}\left(\frac{2m\pi kT}{h^2}\right)^{3/2}\exp\left(\frac{-I}{kT}\right) \quad \ldots\ldots(3.34)$$

for the conditions

$$y \ll N_A \quad \text{and} \quad N_A{}^2 \gg 4yN_D \quad \ldots\ldots(3.35)$$

§ 4. RESULTS

In this section we make use of the results obtained in the previous sections to derive an expression for the current density J, as a function of F, the applied potential gradient. By definition

$$J=n(T)e\mu(T)F. \quad \ldots\ldots(4.1)$$

From Eqns (2.3) and (2.4) we therefore have

$$J=n(T_0)e\mu_L(T_0)\left[\frac{n(T)}{n(T_0)}\right]\left[\frac{T_0}{T}\right]^{1/2}F \quad \text{for acoustical mode scattering} \quad \ldots\ldots(4.2)$$

and

$$J=n(T_0)e\mu_I(T_0)\left[\frac{n(T)}{n(T_0)}\right]\left[\frac{n_I(T)}{n_I(T_0)}\right]\left[\frac{T}{T_0}\right]^{3/2}F \quad \text{for ionized impurity scattering.} \quad \ldots\ldots(4.3)$$

Using (2.2) to eliminate T from (4.2) and (4.3), we shall find J as an explicit function of F. Before carrying out this calculation of J, we first discuss Eqn (2.2) which relates T with F. Unfortunately T is not an experimentally observable quantity so that one cannot confirm the correctness of (2.2) by direct experimental observations. By observing the field dependence of conductivity at temperature 77°K and above Gunn (1957) and several other authors have concluded, that Eqn (2.2) is only qualitatively correct. To get quantitative agreement with experiments the right-hand side of (2.1) must be increased by a factor of the order of 10. Physically this means that the electrons should lose energy to the lattice at a rate ten times greater than that given by B in Eqn (2.2). We do not attempt to give any explanation for this discrepancy but for the purpose of this paper multiply the right-hand side of (2.1) by an arbitrary numerical parameter g and determine its value from higher temperature measurements. If the scattering is due to the acoustical modes then Eqn (2.2) can now be written as

$$F^2\mu_L{}^2(T_0)=\frac{32}{3\pi}s^2\left(\frac{T}{T_0}\right)^2\left(\frac{T-T_0}{T}\right)g. \quad \ldots\ldots(4.4)$$

When the electric field is large enough to satisfy $F\mu_L(T_0)>\gamma s$ where $\gamma=(32g/3\pi)^{1/2}$, then (4.4) can be simplified to give

$$\frac{T}{T_0}=\frac{F\mu_L(T_0)}{\gamma s}+\tfrac{1}{2}. \quad \ldots\ldots(4.5)$$

With the help of (4.5) we may now write the current density J due to acoustical scattering for the three cases defined in § 3.

Case I.

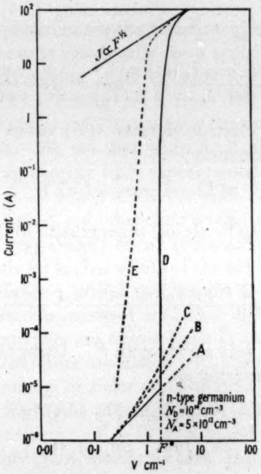
For a field range of $F_1 > F > (\gamma s)/\mu_L(T_0)$ where

$$F_1 = \frac{\gamma s}{\mu_L(T_0)}\left[\frac{T_1}{T_0} - \frac{1}{2}\right] \qquad \ldots\ldots(4.6)$$

we have the current density J as

$$J = [F\mu_L(T_0)e]\,\frac{N_D}{N_A}\,\frac{2(2m\pi kT_0)^{3/2}}{h^3}\exp\left(\frac{-I}{kT_0}\right)\left[\frac{F\mu_L(T_0)}{\gamma s} + \frac{1}{2}\right]^{\beta-1} \qquad \ldots\ldots(4.7)$$

provided the conditions for the validity of (3.29) are satisfied.



The variation of the current with the field. Curves A, B and C represent the case I with $\beta = 1$, 3/2 and 2 respectively, while the curves D and E represent the cases II and III respectively.

Case II.

For a field range of $F_2 > F > F_1$ where

$$F_2 = \frac{\gamma s}{\mu_L(T_0)}\left[\frac{T_2}{T_0} - \frac{1}{2}\right] \qquad \ldots\ldots(4.8)$$

the current density J is

$$J = [F\mu_L(T_0)e]\left[N_D\left\{\frac{F\mu_L(T_0)}{\gamma s} + \frac{1}{2}\right\}^{(2\beta-3)/2} \times \frac{\sigma_C(I)}{\sigma_L(kT_0)Q}\,\frac{I}{kT_0}\exp\left\{-\frac{I}{kT_0}\left(\frac{F\mu_L(T_0)}{\gamma s} + \frac{1}{2}\right)^{-1}\right\} - N_A\right] \qquad \ldots\ldots(4.9)$$

provided the condition (3.31) is satisfied.

Case III.

For a field range $F > F_2$, the current density J is

$$J = F\mu_L(T_0)e\frac{N_D}{N_A}\frac{2(2m\pi kT_0)^{3/2}}{h^3}\left[\frac{F\mu_L(T_0)}{\gamma s}+\frac{1}{2}\right]\exp\left\{\left(\frac{-I}{kT_0}\right)\left(\frac{F\mu_L(T_0)}{\gamma s}+\frac{1}{2}\right)^{-1}\right\} \qquad \ldots\ldots(4.10)$$

provided the condition (3.35) is satisfied, which gives the upper limit of F for the validity of (4.10).

An expression for the current density J, when the scattering is due to ionized impurities can be obtained in a similar way. We shall not give the exact expressions here, but derive only approximate results from the cases II and III where the results are interesting. Substituting (2.4) in (2.2), we obtain the relation between T and F as

$$\frac{F^2\mu_I(T_0)\mu_L(T_0)}{s^2\gamma^2} = \frac{n_i(T)}{n_i(T_0)} = \frac{N_A+n(T)}{N_A+n(T_0)}. \qquad \ldots\ldots(4.11)$$

For cases II and III the electron density $n(T)$ varies exponentially with T, so that one can write approximately

$$n(T) = X\exp(-I/kT) \qquad \ldots\ldots(4.12)$$

where X may be assumed to be almost independent of T. Substituting (4.12) in (4.11), we obtain

$$kT = \frac{I}{\log X} - \log\left[\frac{F^2\mu_I(T_0)\mu_L(T_0)\{N_A+n(T_0)\}}{(\gamma s)^2} - N_A\right]. \qquad \ldots\ldots(4.13)$$

This means that kT varies very slowly with F. Using this property we may write J for ionized impurity scattering as

$$J = F^3\mu_I{}^2(T_0)\mu_L(T_0\ eN_A/s^2\gamma^2 \qquad \ldots\ldots(4.14)$$

provided $n(T) < N_A$ and $[F^2\mu_I(T_0)\mu_L(T_0)/s^2\gamma^2] \gg 1$.

When $n(T) > N_A$, the current density J can be expressed as

$$J = Fe\mu_I(T_0)[n(T_0)+N_A] \qquad \ldots\ldots(4.15)$$

so that the current is proportional to the field F. From Eqns (4.14) and (4.15) we can see that no strong field dependence is expected on the basis of this theory when the impurity scattering predominates.

§ 5. DISCUSSION

In § 3 we have obtained expressions for the variation of the free electron density with electron temperature for three separate ranges denoted by cases I, II and III. Each case is defined by considering only one of the two processes by which the ionizations of the donors or the recombinations of the free electrons take place. For case I both the ionization and the recombination is due to the process 2 (lattice interaction) and we obtained a rise in $n(T)$ with T as proportional to $(kT)^{(2\beta-1)/2}$. For case II, $n(T)$ rises rapidly with T as $\exp(-I/kT)$ when the ionization of the donors is due to process 1 (impact ionization) and the recombination of the free electrons by process 2. In case III the process 1 completely predominates and is therefore associated with a complete thermal equilibrium of the free and the bound electrons. In this case $n(T)$ increases exponentially till it almost reaches the saturation value of N_D. The transition temperatures T_1 and T_2 can be defined using (3.25) by the following equations

$$\left(\frac{T_1}{T_0}\right)^{\beta-1} \exp\left(\frac{-I}{kT_1}\right) = \frac{N_A}{N_D} \frac{\sigma_L(kT_0)Q}{\sigma_C(I)} \frac{kT_0}{I} \qquad \ldots\ldots(5.1)$$

and

$$\alpha\sigma_C(I) IkT_2 = \left(\frac{kT_0}{kT_2}\right)^{\beta-2} (kT_0)^2 \sigma_L(kT_0)Q \qquad \ldots\ldots(5.2)$$

respectively.

In § 4, we obtained expressions for the variation of current density J with field F. We illustrate these results graphically for a typical example of a fairly pure n-type germanium crystal having $N_D = 10^{14}\,\text{cm}^{-3}$, $N_A = 5 \times 10^{12}\,\text{cm}^{-3}$ and with $(I/kT_0) = 25$ (i.e. $T_0 \simeq 4\,°\text{K}$). Fixing $\gamma = 6$ from the experiments of the field dependence of the conductivity at 77 °K, we have drawn for case I three curves for three different values of β. We see that when $\beta = 1$, the current is proportional to the field, which is in agreement with experimental observation by Sclar and Burstein. This value of $\beta = 1$ which lies in the same range as the values obtained theoretically by Lax and Frood, may therefore be the correct value. For cases II and III the current rises very steeply as exp (constant/F) for a very narrow range of the field strength F while for higher values of the field the current is proportional to $F^{1/2}$. The $F^{1/2}$ field dependence of the current indicates complete ionization of donors and is therefore consistent with (1.1). The transitional field strength of F_1, below which the currents are ohmic (case I) and above which the current rises rapidly (case II) is therefore associated with the critical field F^* (the breakdown field, in the terminology of Sclar and Burstein).

F^* is obtained from Eqn (4.6) with the use of (5.1) which determines T_1 the transition electron temperature. $T_1 = 12\,°\text{K}$ is found if we set $\sigma_C(I) = 10^{-11}\,\text{cm}^2$ and $\sigma_L(kT_0)Q = 10^{-12}\,\text{cm}^2$ (Lax 1959). From Eqn (4.6) $F^* = 1{\cdot}8\,\text{v}\,\text{cm}^{-1}$ is then obtained when the mobility of electrons in germanium at 4·2 °K is assumed to be $2{\cdot}7 \times 10^6\,\text{cm}^2\,\text{v}^{-1}\,\text{sec}^{-1}$ a value proposed by Sclar and Burstein. F^* has been obtained in agreement with the experimental value, by making use of the experimental value of γ at 77 °K and the above values for the cross section and the mobility. In our theory at the field strength F^* the impact ionization (process 1) just begins to surpass ionization by phonons (process 2) while recombination is still predominantly due to phonons. Sclar and Burstein incorrectly neglect the latter, i.e. they consider process 1 for both ionization and recombination according to our case III. This would lead to a much lower field F^* than found by our theory.

ACKNOWLEDGMENTS

The author wishes to thank Professor H. Fröhlich for his guidance at all stages of the work, and Dr. B. K. P. Scaife for his help in the preparation of the manuscript. The financial help from the Electrical Research Association is gratefully acknowledged.

Formulae for Non-degenerate Rayleigh–Schrödinger Perturbation Theory in any order

By R. HUBY

Department of Theoretical Physics, University of Liverpool

MS. received 13th February 1961

Abstract. It is shown that Bloch's solution for the *n*th order perturbation of the energy and the eigenvector in the Rayleigh–Schrödinger perturbation theory of non-degenerate, discrete levels can be expressed in a different form, of a kind suggested by Brueckner, and some advantages of the latter form are presented.

---

§ 1. INTRODUCTION

The many-body problem has stimulated interest in the systematic formulation of the higher order terms in Rayleigh–Schrödinger perturbation theory for discrete energy levels, i.e. the determination of the discrete eigenstates and eigenvalues of a Hamiltonian:

$$H = H_0 + H' \qquad \ldots\ldots(1)$$

(the sum of an unperturbed operator H_0 and a perturbing one H') in the form of series in ascending powers of H'. The case most studied has been that of a system of many particles the interactions between which constitute H', and important perturbation developments appropriate to this particular case have been made (e.g. Goldstone 1957). However, some attention has also been paid to the formulation of the solution to the general problem (1). Bloch (1958) has presented an elegant formulation, which leads to a quite simple expression for the *n*th order energy or state vector when the problem is 'non-degenerate' (i.e. when we study the shift of a non-degenerate unperturbed energy level). A different prescription for writing down the energy shifts in the first few perturbation orders (again for the non-degenerate problem) had been suggested by Brueckner (1955), but it was not clear how this was to be generalized correctly to any arbitrary order. The purpose of this paper is to show that the prescription of Brueckner for the energy can in fact, with small modifications, be extended up to any arbitrary order; and that it can also be adapted to yield formulae for the state vectors to any order. This is achieved by showing that the formulae proved by Bloch can be expressed alternatively in Brueckner's form.

Brueckner's type of formula has some advantage in the ease with which it can be visualized and applied.

§ 2. BLOCH'S FORMULATION

Let us first summarize the relevant results of Bloch (see also Messiah 1960). We consider some unperturbed, discrete eigenvalue of H_0, say E_0, which in the first instance may perhaps be degenerate, its eigenvectors spanning a g-dimensional subspace Ω_0 of the total state space. Let P_0 be the operator of projection on to Ω_0 and Q_0 the projector on to the orthogonal sub-space:

$$Q_0 = 1 - P_0. \qquad \text{......(2)}$$

Next, we define the 'energy denominator' operator:

$$\frac{Q}{a} = \frac{1}{E_0 - H_0} Q_0. \qquad \text{......(3)}$$

Now we assume that there are g independent, exact eigenvectors of H which, if the perturbation H' were reduced to zero, would tend to unperturbed vectors lying within the subspace Ω_0. Let these exact eigenvectors of H be $|\alpha\rangle$, $|\beta\rangle, \dots (g)$, (all normalized); and let the corresponding eigenvalues of H be $(E_0 + E_\alpha)$, $(E_0 + E_\beta), \dots (g)$. We denote by $|\alpha\rangle_0$ the projection of $|\alpha\rangle$ on to Ω_0:

$$|\alpha\rangle_0 = P_0 |\alpha\rangle. \qquad \text{......(4)}$$

Bloch works with an operator U, defined so that its product with each of these projections $|\alpha\rangle_0$, $|\beta\rangle_0, \dots$ is the corresponding exact eigenket of H:

$$|\alpha\rangle = U |\alpha\rangle_0, \qquad \text{......(5)}$$

while the product of U with any vector in the sub-space orthogonal to Ω_0 vanishes. He obtained a perturbation expansion of U:

$$U = \sum_{n=0}^{\infty} U^{(n)}, \qquad \text{......(6)}$$

where

$$U^0 = P_0, \qquad \text{......(7)}$$

and

$$U^{(n)} = \sum{}' S^{k_1} H' S^{k_2} H' \dots S^{k_n} H' P_0 \quad (n > 0). \qquad \text{......(8)}$$

Here

$$S^0 = -P_0, \qquad \text{......(9)}$$

$$S^k = \left(\frac{Q_0}{a}\right)^k = \left(\frac{1}{a}\right)^k Q_0 \quad (k > 0) \qquad \text{......(10)}$$

and $\sum'$ means a sum taken over all non-negative integers $k_1, k_2, \dots k_n$ which satisfy

$$\sum_{i=1}^{n} k_i = n \qquad \text{......(11)}$$

and

$$\sum_{i=1}^{p} k_i \geqslant p \quad (\text{all } p \text{ from } 1, 2, \dots \text{ to } n-1). \qquad \text{......(12)}$$

In the non-degenerate case ($g = 1$) the energy shift can be found immediately with the aid of U. Writing the energy as a perturbation series:

$$E_0 + E_\alpha = E_0 + \sum_{n=1}^{\infty} E_\alpha^{(n)}, \qquad \text{......(13)}$$

we have

$$E_\alpha^{(n)} = \langle 0 | H' U^{(n-1)} | 0 \rangle, \qquad \text{......(14)}$$

where $|0\rangle$ is the *normalized* unperturbed state vector proportional to $|\alpha\rangle_0$. Also the eigenvector of H in a perturbation series (but not normalized to unity), i.e.

$$N|\alpha\rangle = |0\rangle + \sum_{n=1}^{\infty} |\alpha^{(n)}\rangle, \qquad \text{......(15)}$$

is given by

$$|\alpha^{(n)}\rangle = U^{(n)}|0\rangle. \qquad \ldots\ldots(16)$$

Each of the perturbation terms $|\alpha^{(n)}\rangle$ is orthogonal to $|0\rangle$, and so the normalization factor N may be written $\langle 0|\alpha\rangle^{-1}$. N is to be determined, to any chosen perturbation order, after evaluating the right-hand side of (15) to the appropriate order, by calculating the length of this vector.

§ 3. THE FORMULATION AFTER BRUECKNER

We deal only with the non-degenerate case.

It is well known that, if the lowest order non-vanishing correction to the energy in the perturbation series (13) is $E_\alpha^{(n)}$, then this is given by

$$E_\alpha^{(n)} = \left\langle 0\left|H' \frac{Q_0}{a} H' Q_0 \frac{Q_0}{a} H' \ldots \frac{Q_0}{a} H'\right|0\right\rangle \qquad \ldots\ldots(17)$$

(where the bracket contains n factors H'); but on the other hand, if there exist lower order non-vanishing corrections to the energy, then the formula for $E_\alpha^{(n)}$ contains certain additional terms†. When (17) is expanded in terms of the matrix elements of H', e.g.

$$\left\langle 0\left|H' \frac{Q_0}{a} H' \frac{Q_0}{a} H'\right|0\right\rangle = \sum_{i,j\neq 0} \frac{\langle 0|H'|j\rangle\langle j|H'|i\rangle\langle i|H'|0\rangle}{(E_0-E_j)(E_0-E_i)}, \qquad \ldots\ldots(18)$$

this introduces intermediate unperturbed states $|i\rangle$, $|j\rangle$, etc., which are all different from the initial state $|0\rangle$. On the other hand, the additional terms that can appear in $E_\alpha^{(n)}$ contain factors in which $|0\rangle$ itself occurs as an intermediate state. For example, the full formula for $E_\alpha^{(3)}$ comprises in addition to (17) the term

$$-\left\langle 0\left|H' \frac{Q_0}{a^2} H'\right|0\right\rangle\langle 0|H'|0\rangle = -\sum_{i\neq 0} \frac{\langle 0|H'|i\rangle\langle i|H'|0\rangle\langle 0|H'|0\rangle}{(E_0-E_i)^2}. \qquad \ldots\ldots(19)$$

Brueckner pointed out that, in the first few perturbation orders, the additional terms such as (19) in $E_\alpha^{(n)}$ can be constructed schematically from the basic term of (17) as follows. Writing (19) for instance, as

$$-\left\langle 0\left|H' \frac{Q_0}{a} \langle H'\rangle \frac{Q_0}{a} H'\right|0\right\rangle,$$

we insert around the inner factors H' in (17) one or more pairs of bra–ket brackets, which signify taking a diagonal matrix element with respect to the state $|0\rangle$—also a change of sign may be required.

The correct generalization of this procedure to any order is as follows.

Rule 1. *To find the nth order energy perturbation of the level* E_0, *viz.* $E_\alpha^{(n)}$, *we first write down the basic matrix element* (17). *We then add to this all other expressions which can be obtained from it by inserting any number of pairs of bra–ket brackets around the inner* H' *factors*‡. *The bra and ket of a pair may be separated*

---

† More precisely, additional terms enter, not in the next higher order above the first non-vanishing one, but only in the next order after that.

‡ By an ' inner ' H' factor we mean any H' other than the first or the last.

by any number of link factors

$$H' \frac{Q_0}{a} H' \frac{Q_0}{a} \ldots H',$$

and brackets may lie within brackets, but one bra–ket pair may not straddle another, and no brackets may touch. Finally the sign $(-1)^\nu$ *is attached to the expression, where* ν *is the number of bra–ket pairs inserted in it. Each bra–ket pair signifies that we form the expectation value of the operator which it encloses, in the state* $|0\rangle$.

Afterwards, any bra–ket pair together with its contents, since they constitute a pure number, may be removed bodily as a factor outside the original expression As an illustration, $E_\alpha^{(5)}$ is

$$\begin{aligned}
E_\alpha^{(5)} = {} & \left\langle 0\middle| H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \middle|0\right\rangle \\
& - \left\langle 0\middle| H' \frac{Q_0}{a} \langle H' \rangle \frac{Q_0}{a} H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \middle|0\right\rangle - \ldots \\
& - \left\langle 0\middle| H' \frac{Q_0}{a} \left\langle H' \frac{Q_0}{a} H' \right\rangle \frac{Q_0}{a} H' \frac{Q_0}{a} H' \middle|0\right\rangle - \ldots \\
& - \left\langle 0\middle| H' \frac{Q_0}{a} \left\langle H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \right\rangle \frac{Q_0}{a} H' \middle|0\right\rangle \\
& + \left\langle 0\middle| H' \frac{Q_0}{a} \langle H' \rangle \frac{Q_0}{a} \langle H' \rangle \frac{Q_0}{a} H' \frac{Q_0}{a} H' \middle|0\right\rangle + \ldots \\
& + \left\langle 0\middle| H' \frac{Q_0}{a} \left\langle H' \frac{Q_0}{a} \langle H' \rangle \frac{Q_0}{a} H' \right\rangle \frac{Q_0}{a} H' \middle|0\right\rangle. \qquad \ldots\ldots(20)
\end{aligned}$$

(14 terms)

$$\begin{aligned}
= {} & \left\langle 0\middle| H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \middle|0\right\rangle \\
& - \left\langle 0\middle| H' \frac{Q_0}{a^2} H' \frac{Q_0}{a} H' \frac{Q_0}{a} H' \middle|0\right\rangle \langle 0|H'|0\rangle \\
& \vdots \\
& + \left\langle 0\middle| H' \frac{Q_0}{a^2} H' \middle|0\right\rangle \left\langle 0\middle| H' \frac{Q_0}{a^2} H' \middle|0\right\rangle \langle 0|H'|0\rangle.
\end{aligned}$$

The correctness of this prescription is proved in the appendix.

A similar prescription (also proved in the appendix) can be made for the perturbation of the state vector. Let us consider the nth order term in the series (15) for the eigenvector of H. We write down first a 'basic' term (cf. (17))

$$\frac{Q_0}{a} H' \frac{Q_0}{a} H' \ldots \frac{Q_0}{a} H' |0\rangle, \qquad \ldots\ldots(21)$$

(where there are n factors H'), and this is in fact the correct formula for $|\alpha^{(n)}\rangle$ provided that all the energy corrections of order less than n vanish. Otherwise, however, certain terms must be added to (21). The general rule for formulating these terms is

Rule 2. *To find the nth order perturbation of the state vector* $|0\rangle$, *we first write down the ket that is displayed in* (21), *and then add to it all the expressions which* *can be obtained from it by inserting any number of bra–ket pairs around the H' factors other than the last. The rules for arranging and interpreting the brackets are the same as those in Rule* 1, *and again the sign* $(-1)^{\nu}$ *is to be attached to an expression, where* ν *is the number of inserted bra–ket pairs.*

The perturbed vector thus obtained is the one normalized as in (15) and (16). As an illustration, $|\alpha^{(4)}\rangle$ is

$$\begin{aligned}
|\alpha^{(4)}\rangle &= \frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'|0\rangle \\
&\quad -\frac{Q_0}{a}\langle H'\rangle\frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'|0\rangle \\
&\quad \vdots \\
&\quad +\frac{Q_0}{a}\Big\langle H'\frac{Q_0}{a}\langle H'\rangle\frac{Q_0}{a}H'\Big\rangle\frac{Q_0}{a}H'|0\rangle. \\
&\qquad\qquad\qquad\qquad\qquad \text{(14 terms)} \\
&= \frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'|0\rangle \\
&\quad -\frac{Q_0}{a^2}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'|0\rangle\langle 0|H'|0\rangle \\
&\quad \vdots \\
&\quad +\frac{Q_0}{a^2}H'|0\rangle\Big\langle 0\Big|H'\frac{Q_0}{a^2}H'\Big|0\Big\rangle\langle 0|H'|0\rangle.
\end{aligned}$$

§ 4. COMMENTS ON THE FORMULATION AFTER BRUECKNER

From (14) and (16) there is a simple relation between $E_\alpha^{(n)}$ and $|\alpha^{(n-1)}\rangle$:

$$E_\alpha^{(n)} = \langle 0|H'|\alpha^{(n-1)}\rangle. \qquad \ldots\ldots (22)$$

This shows that Rule 1 follows directly from Rule 2, the formula for $E_\alpha^{(n)}$ being closely related to that for $|\alpha^{(n-1)}\rangle$ (both, for instance, having the same number of terms).

The formulation given in Rules 1 and 2 is most helpful when the energy corrections vanish below a certain order, say the nth. It is evident from Rule 1 that the necessary and sufficient condition for this is the vanishing of all brackets of the form

$$\Big\langle 0\Big|H'\frac{Q_0}{a}H'\ldots H'\Big|0\Big\rangle$$

which contain fewer than n factors H'. This greatly simplifies the construction of the formulae for energies and state vectors of order higher than n: in following Rules 1 and 2 we have simply to exclude all expressions which contain brackets enclosing fewer than n factors H'. For instance, if the lowest non-vanishing energy correction is the third, then $E_\alpha^{(5)}$ is given by

$$\begin{aligned}
E_\alpha^{(5)} &= \Big\langle 0\Big|H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'\Big|0\Big\rangle \\
&\quad -\Big\langle 0\Big|H'\frac{Q_0}{a}\Big\langle H'\frac{Q_0}{a}H'\frac{Q_0}{a}H'\Big\rangle\frac{Q_0}{a}H'\Big|0\Big\rangle.
\end{aligned}$$

Brueckner's original formulation indeed differed slightly from ours of § 3, because he exploited this kind of simplifications as follows. The original problem of (1) is replaced formally by

$$H = \{H_0 + \langle 0|H'|0\rangle\} + u,$$

where

$$u = H' - \langle 0|H'|0\rangle,$$

and u is now treated as the perturbing operator. The unperturbed energy becomes $(E_0 + \langle 0|H'|0\rangle)$, but all the unperturbed states $|i\rangle$ remain unaltered, as does the operator Q_0/a. The first order energy perturbation $\langle 0|u|0\rangle$ now certainly vanishes, and so when the perturbation formulae are written down according to Rules 1 and 2, all expressions containing brackets $\langle u\rangle$ can be excluded.

APPENDIX

Starting from Bloch's formula for $U^{(n)}$ (Eqn. (8)), we assert that this can be constructed by the following Rule:

Rule 3. *To find $U^{(n)}$, we first write down*

$$\frac{Q_0}{a} H' \frac{Q_0}{a} H' \ldots \frac{Q_0}{a} H' P_0, \qquad \ldots\ldots(\text{A.1})$$

(*containing n factors H′*), *and then add to it all the expressions which can be formed from it by inserting any number of bra–ket pairs around the H′ factor other than the last. The rules for arranging and interpreting the brackets are the same as those of Rule* 1, *and again the sign* $(-1)^\nu$ *is to be attached to an expression, where* ν *is the number of inserted bra–ket pairs.*

Once Rule 3 has been proved, Rules 1 and 2 will follow trivially from it by applying (14) and (16) respectively.

First we show that any single one of the expressions prescribed by Rule 3 is equal to one of the terms in Bloch's series (8). A typical expression in Rule 3 may be written.

$$v = (-1)^\nu \frac{Q_0}{a} \overset{(1)}{H'} \frac{Q_0}{a} \overset{(2)}{H'} \ldots \overset{(i)}{H'} \frac{Q_0}{a} \langle \overset{(i+1)}{H'} \ldots \overset{(i+m)}{H'} \rangle \frac{Q_0}{a} \overset{(i+m+1)}{H'} \ldots \overset{(n)}{H'} P_0 \qquad \ldots\ldots(\text{A.2})$$

$$\equiv (-1)^\nu O_1 \langle O_2\rangle O_3 P_0 = (-1)^\nu O_1 \langle O_2\rangle O_3 |0\rangle\langle 0|,$$

where it is to be understood that the bra beside O_2 is the one closest to the left end of the whole expression and the ket beside O_2 is the proper partner of this bra. That is to say, O_1 contains no bra–ket pairs, but both O_2 and O_3 may do so. Now let us lift out the numerical factor $-\langle O_2\rangle$ and replace it between $|0\rangle$ and $\langle 0|$ in the last form of (A.2)

$$v = (-1|)^{\nu-1} O_1 O_3 |0\rangle\langle 0| - O_2|0\rangle\langle 0|$$

$$= (-1)^{\nu-1} O_1 O_3 (-P_0) O_2 P_0$$

$$= (-1)^{\nu-1} \frac{Q_0}{a} \overset{(1)}{H'} \frac{Q_0}{a} \overset{(2)}{H'} \ldots \overset{(i)}{H'} \frac{Q_0}{a_2} \overset{(i+1)}{H'} \ldots \overset{(n-m)}{H'}\; S^0 \overset{(n-m+1)}{H'} \ldots \overset{(n)}{H'} P_0. \qquad \ldots\ldots(\text{A.3})$$

Comparing this final expression with the first expression in (A.2) the changes can be described as follows:

(i) In the chain of operators (interspersed with brackets)

$$\frac{Q_0}{a}\overset{(1)}{H'}\frac{Q_0}{a}\ldots\overset{(n)}{H'},$$

the factor Q_0/a which stood originally just to the right of $\overset{(n-m)}{H'}$ has been shifted leftwards into the place just to the right of $\overset{(i)}{H'}$, converting this factor into Q_0/a^2, while the place vacated has been refilled with S^0.

(ii) The number of bra–ket pairs has been reduced by one, and the positions of the remaining brackets have been altered.

(iii) The factor $(-1)^\nu$ has been altered so as still to correspond to the remaining number of bra–ket pairs. This process is now to be repeated successively, first seeking the nearest complete bra–ket pair to the left end of the expression, and then shifting it to the extreme right end. At each step the number of bra–ket pairs falls by one, and a factor Q_0/a is shifted leftwards, its vacant place being taken by S^0. Eventually, all the brackets will have gone, and we shall have an expression of the form in (8), which we denote v':

$$v' \equiv v, \qquad \ldots\ldots\text{(A.4)}$$

though it remains to verify that (11) and (12) are satisfied.

Since the total power of $1/a$ in the expression has been conserved, the k's in v' satisfy (11). The chain of operators in the original expression (A. 2) (forgetting for the moment the brackets and sign factor) is of the form of a term in (8), with

$$\sum_{i=1}^{p} k_i = p.$$

Now in the process of going from v to v', the shift of factors Q_0/a has always been leftwards; hence the k_i's in v' satisfy (12).

We proceed to the converse: to show that any single one of the terms in Bloch's formula (8) is equal to one of the expressions prescribed by Rule 3. A typical term in (8) may be rewritten

$$w' = S^{l_n}\overset{(n)}{H'}S^{l_{n-1}}\overset{(n-1)}{H'}\ldots S^{l_1}\overset{(1)}{H'}P_0, \qquad \ldots\ldots\text{(A.5)}$$

where, because of (11) and (12)

$$\sum_{i=1}^{n} l_i = n, \qquad \ldots\ldots\text{(A.6)}$$

$$\sum_{i=1}^{q} l_i \leqslant q, \quad \text{(all } q \text{ from 1 } to\ n-1). \qquad \ldots\ldots\text{(A.7)}$$

We may write

$$\begin{aligned} w' &= -S^{l_n}\overset{(n)}{H'}S^{l_{n-1}}\ldots\overset{(i+1)}{H'}\frac{Q_0}{a^{l_i}}\overset{(i)}{H'}\ldots H'P_0\overset{(m)}{H'}\ldots\frac{Q_0}{a}\overset{(1)}{H'}P_0 \\ &\equiv -O_4\frac{Q_0}{a^{l_i}}O_5P_0O_6P_0 = -O_4\frac{Q_0}{a^{l_i}}O_5|0\rangle\langle 0|O_6|0\rangle\langle 0|, \qquad \ldots\ldots\text{(A.8)} \end{aligned}$$

where (i) the inner P_0 which has been written down explictly represents the S^0 nearest to the right end of the expression in (8), (ii) the factor Q_0/a^{l_i} which has been written down explicitly is the factor S^{l_i} nearest to the right end for which $l_i > 1$. Because of (A.7) all the l values contained in O_6 are unity.

Now, let us lift out the numerical factor $\langle 0|O_6|0\rangle$ and replace it between O_4 and O_5 thus:

$$w' = -O_4 \frac{Q_0}{a^{l_i-1}} \langle 0|O_6|0\rangle \frac{Q_0}{a} O_5 |0\rangle\langle 0|$$

$$= -S^{l_n}\overset{(n)}{H'}S^{l_{n-1}}\ldots\overset{(i+1)}{H'}\frac{Q_0}{a^{l_i-1}}\left\langle \overset{(i)}{H'}\frac{Q_0}{a}\overset{(i-1)}{H'}\ldots\overset{(i-m+1)}{H'}\right\rangle\frac{Q_0}{a}\overset{(i-m)}{H'}\ldots\overset{(1)}{H'}P_0. \qquad \ldots\ldots(\text{A.9})$$

Comparing this with the original expression in (A.8), the changes can be described as follows:

(i) In the chain of operators, from the factor Q_0/a^{l_i} which, having $l_i > 1$, lies nearest to the right end, one factor Q_0/a has been extracted and has been shifted rightwards to replace a S^0 factor, and the remaining S^0 factors right of $\overset{(i+1)}{H'}$ (if any) have been interchanged with some Q_0/a factors.

(ii) A bracket of the type prescribed in Rule 3 has been inserted to the right of $\overset{(i+1)}{H'}$.

(iii) The expression has been multiplied by (-1).

The process is now to be repeated successively, first lifting out everything to the right of the S^0 factor nearest to the right end (again because of (A.7) this section always contains only a string of Q_0/a factors to first power) and setting it down leftwards inside the first factor Q_0/a^{l_i} from the right end which has $l_i > 1$. This eventually results in the disappearance of all S^{l_i} factors with $l_i \neq 1$, and indeed we get an expression of the type prescribed by Rule 3, which we denote w:

$$w \equiv w'. \qquad \ldots\ldots(\text{A.10})$$

We have now proved that every expression v in Rule 3 equals a term v' in Bloch's (8), and conversely every expression w' in (8) equals a term w in Rule 3. Furthermore, if we follow the first procedure for converting v into v', and then the second procedure for converting v' back into a Rule 3 type expression, it can be seen that the result obtained is the original v. This is because the second procedure, starting from v', just reverses step by step the first process which ended in v'. This result finally establishes a 1 : 1 identity between all the individual expressions in Rule 3 and all the terms in (8), so that they both yield the same sum $U^{(n)}$.

H_2^+ : A Problem in Perturbation Theory

By P. D. ROBINSON
Mathematical Institute, Oxford

Communicated by C. A. Coulson; *MS. received 27th February* 1961,
in revised form 17th April 1961

Abstract. A résumé is given of how accurately perturbation theory (using a ground-state hydrogen-like atom perturbed by a point charge) predicts the 1sσ and 2pσ energies of H_2^+ and HeH^{2+}. Corresponding delta-function models are discussed; here it is possible to test the convergence of the perturbation expansions. The models indicate that the series for the 1sσ energy is divergent for H_2^+ at large values of the internuclear separation R but convergent for HeH^{2+}; this explains why the H_2^+ series is inaccurate and the HeH^{2+} series accurate. Both series converge for small R. The 2pσ energies are represented by divergent series which are asymptotically convergent if R is sufficiently large. A 'resonance' correction is justified for the H_2^+ series, giving an accurate 1sσ energy for all R and an improved 2pσ energy.

---

§ 1. Introduction

Exact electronic energies of H_2^+ have been found numerically for given values of the internuclear separation R (Bates, Ledsham and Stewart 1953), but it is desirable to express these energies directly as functions of R. An obvious approach is to use a perturbation method and regard the ion as a hydrogen atom perturbed by a proton, but the resulting energies are not accurate even at quite large values of R (Dalgarno and Lewis 1956). This is in contrast to the situation with the heteronuclear ion HeH^{2+} where accurate energies can be obtained using similar techniques, and so H_2^+ poses a problem in perturbation theory.

A physical reason for the poor results with H_2^+ is the so-called 'resonance' degeneracy in the limit of infinite R. To take the simplest case, both the ground state (1sσ) and the first excited state (2pσ) of H_2^+ have each to be represented for large R by a 1s hydrogen atom perturbed by a proton; the resulting iterated energy cannot be a good approximation to two different exact energies simultaneously, and so the method must be inaccurate for one or both of the states. With HeH^{2+} the nuclei have different charges, and the 1sσ and 2pσ energies are represented by two different perturbation expansions.

The central part of this paper is devoted to a mathematical investigation of the conventional perturbation theory approach with the help of a one-dimensional delta-function model for H_2^+ introduced by Frost (1956). Here a transcendental equation for the exact energies is used as a yardstick to test the convergence of corresponding perturbation results. It is, unfortunately, necessary to employ some kind of simplified model, because formulae giving exact energies as functions of R are not available for H_2^+ itself. The reasons for the shortcomings of perturbation theory in the case of Frost's model should be similar to those for the actual ion.

Firstly, however, we give a résumé of the perturbation treatment for the 1sσ and 2pσ states of both H_2^+ and HeH^{2+}, and the paper is completed by the justification of a simple 'resonance' correction to the H_2^+ perturbation series. This yields accurate formulae for the 1sσ energy at all R values and for the 2pσ energy when R is greater than $4a_0$.

§ 2. PERTURBATION TREATMENT FOR THE 1sσ AND 2pσ STATES

The electronic energy of a hydrogen-like atom of nuclear charge Z in its ground state perturbed by a point charge q situated at a distance R away from the nucleus can be formally written

$$E = E_0 + qE_1 + q^2E_2 + O(q^3). \qquad \ldots\ldots(1)$$

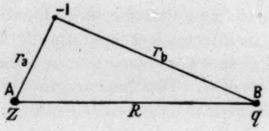

Fig. 1

Here $E_0 = -\frac{1}{2}Z^2$ in ordinary atomic units. Using conventional perturbation theory with $-q/r_b$ as the perturbation to the Hamiltonian (see Fig. 1), it can be shown (Dalgarno and Lynn 1957, Robinson 1958) that if we write

$$t = ZR$$

then

$$E_1 = Z\left[-\frac{1}{t} + \left(1+\frac{1}{t}\right)e^{-2t}\right],$$

and

$$\begin{aligned} E_2 = \frac{5}{2t^2} &+ \left(1-\frac{1}{t}\right)^2 e^{2t}\,\mathrm{Ei}^*(2t) - \left(1+\frac{1}{t}\right)^2 e^{-2t}\,\mathrm{Ei}(2t) \\ &+ \left[1+\frac{2}{t}-\frac{3}{t^2}+\frac{4}{t}\left(1+\frac{1}{t}\right)e^{-2t}\right]\mathrm{Ei}^*(2t) \\ &+ \left[2\left(1+\frac{1}{t}\right)^2(K+\ln 2t) - 2 - \frac{4}{t} - \frac{5}{t^2} - \left(1+\frac{1}{t}\right)^2 e^{-2t}\,\mathrm{Ei}(2t)\right]e^{-2t} \\ &+ \left[2\left(1+\frac{1}{t}\right)^2(K+\ln 2t) + 2t + \frac{7}{2} + \frac{4}{t} + \frac{5}{2t^2}\right]e^{-4t}, \end{aligned}$$

K being Euler's constant. It is possible in principle to evaluate further terms in the series (1), but the labour involved in finding even E_3 would be very considerable; good approximations are available for these higher orders (Dalgarno and Lewis 1956, Dalgarno and Stewart 1956 b).

In Table 1, the expression $E_0 + qE_1 + q^2E_2$ with $Z=2$ and $q=1$ is compared with the exact 1sσ energy of HeH^{2+} at different values of R, and the same expression with $Z=1$ and $q=2$ is compared with the exact 2pσ energy. These exact values were computed by Bates and Carson (1956). It seems likely from the table that the 1sσ perturbation series converges to the true 1sσ energy for all values of R. It has been shown by Dalgarno (1956) that the first three terms of the series do give the true result in the limit of zero R; this can be verified by considering the limiting values of E_1 and E_2. We also see from the table that the 2pσ series is probably asymptotically convergent to the true 2pσ energy for sufficiently large R.

† See § 5.

The results for H_2^+ are displayed in Table 2. This time there is only one 'perturbed' energy, i.e. $E_0+qE_1+q^2E_2$ with $Z=q=1$. For large R, this is a good approximation to the *mean* of the 1sσ and 2pσ energies (cf. Dalgarno and Lewis 1956), and for small R it again seems likely that the perturbation series converges to the exact 1sσ energy. It is possible that this also occurs for large R, but if so then the convergence will be slow and many more terms than three in the series (1) will be needed. Dalgarno and Lewis included E_3 and E_4 (in approximate form) without apparent improvement.

If a perturbation expression for the 2pσ energy is required which is valid for small R, then an unperturbed hydrogenic wave function must be used which tends to the appropriate 2p function as R tends to zero. We shall not discuss such a problem here as we are primarily concerned with behaviour at large R values.

§ 3. FROST'S DELTA FUNCTION MODELS

(*a*) *Hydrogen-like atom.* This one-dimensional model of the atom consists of an electron moving along the x axis with a potential of $-\lambda\delta(x)$ replacing the true $-Z/|x|$, $\delta(x)$ being the usual delta-function. This potential is the limiting case of a square well potential centred on the origin, of depth U and width a, as U tends to infinity and a tends to zero whilst the product

$$aU=\lambda$$

is kept constant (see Fig. 2). We call the quantity λ the *strength* of the well, although such a term is sometimes used to mean a^2U. The model has just one bound state with energy

$$E=-\tfrac{1}{2}\lambda^2, \qquad \ldots\ldots(2)$$

and normalized wave function

$$\psi=\lambda^{1/2}\exp(-\lambda|x|);$$

it is thus analogous to the ground state of the hydrogen-like atom if λ is replaced by Z.

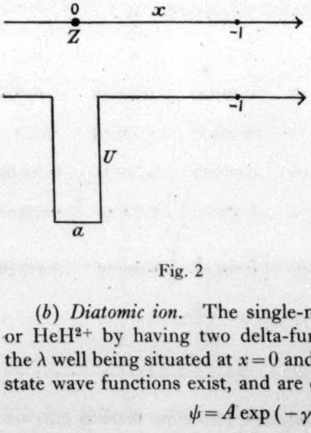

Fig. 2

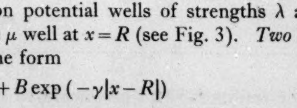

Fig. 3

(*b*) *Diatomic ion.* The single-nucleus model is extended to represent H_2^+ or HeH^{2+} by having two delta-function potential wells of strengths λ and μ, the λ well being situated at $x=0$ and the μ well at $x=R$ (see Fig. 3). *Two* bound state wave functions exist, and are of the form

$$\psi=A\exp(-\gamma|x|)+B\exp(-\gamma|x-R|)$$

where the two possible values for γ are roots of the equation

$$\gamma^2-(\lambda+\mu)\gamma+\lambda\mu[1-\exp(-2\gamma R)]=0. \qquad \ldots\ldots(3)$$

A and B are specified in terms of γ and R, and the energy eigenvalues are given by

$$E=-\tfrac{1}{2}\gamma^2 \qquad \ldots\ldots(4)$$

in each case.

We denote the two possibilities for γ by γ_1 and γ_2, where, from (3), γ_1 is the (positive) root of

$$2\gamma_1=\lambda+\mu+[(\lambda-\mu)^2+4\lambda\mu\exp(-2\gamma_1 R)]^{1/2}, \qquad \ldots\ldots(5)$$

and γ_2 is the non-zero root of the similar equation

$$2\gamma_2 = \lambda + \mu - [(\lambda - \mu)^2 + 4\lambda\mu \exp(-2\gamma_2 R)]^{1/2}. \qquad \ldots\ldots(6)$$

We shall suppose, without loss of generality, that $\lambda \geqslant \mu$. It is clear that γ_1 is the greater value for γ, and thus from (4) yields the ground state of the system. The limiting values of γ_1 as R tends to infinity or to zero are, from (5), respectively λ and $\lambda + \mu$; Eqns (2) and (4) therefore indicate that for large or small R values the ground-state energy approximates to that of a single-well system with strength λ or $\lambda + \mu$ accordingly. This situation is an exact analogue of what happens with the 1sσ state of the diatomic ion, with the nuclear charges Z and q replaced by delta-function wells λ and μ, and with the limiting cases of ground-state hydrogen-like atoms replaced by single-well systems.

γ_2 gives the only bound excited state of the system. This state can be compared with the first excited state (2pσ) of the diatomic ion. The behaviour is analogous for large R when γ_2 approximates to μ, showing that the electron is concentrated round the μ well; with the ion the electron is concentrated round the charge q. But the analogy breaks down at small values of R. γ_2 decreases to zero as R decreases to $(\lambda + \mu)/4\lambda\mu$, and is negative when R is less than this value, showing that the model has then only one bound state. However, the model can still be used for testing perturbation theory at large R values.

In §§ 3.1 and 3.2 we give certain series expansions for γ_1 and γ_2, and in § 3.3 we see to what extent the corresponding energies found from them agree with energies derived from perturbation theory. The case of equal wells is considered in § 3.4.

3.1. *Ground State* ('1sσ'); $\lambda > \mu$

In order to test the perturbation theory we need an expansion for γ_1 in powers of μ. We see from (5) that γ_1 tends to λ as μ tends to zero, and it can in fact be proved (see Appendix A) that

$$\gamma_1 = \lambda + \mu a_1(\lambda) + \mu^2 a_2(\lambda) + \ldots + \mu^n a_n(\lambda) + \ldots, \qquad \ldots\ldots(7)$$

where

$$a_n(\lambda) = \frac{\lambda^n}{n!}\left[\frac{d^{n-1}}{d\gamma^{n-1}}\left\{\frac{1}{\lambda} + \frac{e^{-2\gamma R} - 1}{\gamma}\right\}^n\right]_{\gamma=\lambda} = \sum_{s=0}^{n} \frac{\lambda^s}{s!(n-s)!}\frac{d^{n-1}}{d\lambda^{n-1}}\left\{\frac{e^{-2\lambda R} - 1}{\lambda}\right\}^s.$$

The first three coefficients are:

$$a_1(\lambda) = e^{-2\lambda R},$$

$$a_2(\lambda) = [1 - (2\lambda R + 1)e^{-2\lambda R}]\frac{e^{-2\lambda R}}{\lambda},$$

$$a_3(\lambda) = [1 - (4\lambda R + 3)e^{-2\lambda R} + 2(3\lambda^2 R^2 + 3\lambda R + 1)e^{-4\lambda R}]\frac{e^{-2\lambda R}}{\lambda^2}.$$

The radius of convergence ρ of the series (7) is discussed in Appendix A. It is not possible to find ρ explicitly as a function of R, but a partly qualitative graph is shown in Fig. 4. The series converges whenever μ is less than ρ, i.e. under the following circumstances: (*a*) if $\mu < \nu$, for all values of R; (*b*) if $\nu < \mu < \lambda$, for R sufficiently small or sufficiently large, but not in the intermediate region; (*c*) if $\mu \geqslant \lambda$, only for R sufficiently small. Thus when

$\lambda>\mu$, (7) will converge for all values of R save possibly for those in some intermediate region. The crucial difference between the cases $\lambda>\mu$ and $\lambda=\mu$ is that in the latter case the series (7) can *never* be convergent for large values of R.

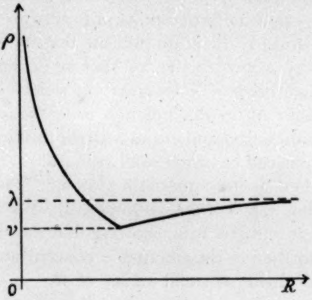

Fig. 4

There is an alternative series expansion for γ_1 in powers of $\exp(-2\lambda R)$ which is valid for large R. Since γ_1 tends to λ as R tends to infinity, (5) gives, by iteration:

$$\gamma_1=\lambda+\left(\frac{\lambda\mu}{\lambda-\mu}\right)e^{-2\lambda R}-\left[2R+\frac{1}{\lambda-\mu}\right]\left(\frac{\lambda\mu}{\lambda-\mu}\right)^2 e^{-4\lambda R}$$
$$+2\left[3R^2+\frac{3R}{\lambda-\mu}+\frac{1}{(\lambda-\mu)^2}\right]\left(\frac{\lambda\mu}{\lambda-\mu}\right)^3 e^{-6\lambda R}+\mathrm{O}(e^{-8\lambda R}). \qquad \ldots\ldots(8)$$

It is interesting to compare expansions (7) and (8). If (8) is expanded further in ascending powers of μ (permissible since $\mu<\lambda$), then it coincides exactly with (7), correct to order μ^4.

3.2. *Excited State* ('2pσ'); $\lambda>\mu$

There is no valid convergent expansion for γ_2 in ascending powers of λ which would correspond to series (7) for γ_1. We cannot let λ tend to zero in (6), because $\lambda>\mu$. There is, however, an analogue of (8) which will be valid for large R. Since γ_2 tends to μ as R tends to infinity, (6) gives:

$$\gamma_2=\mu-\left(\frac{\lambda\mu}{\lambda-\mu}\right)e^{-2\mu R}-\left[2R-\frac{1}{\lambda-\mu}\right]\left(\frac{\lambda\mu}{\lambda-\mu}\right)^2 e^{-4\mu R}$$
$$-2\left[3R^2-\frac{3R}{\lambda-\mu}+\frac{1}{(\lambda-\mu)^2}\right]\left(\frac{\lambda\mu}{\lambda-\mu}\right)^3 e^{-6\mu R}+\mathrm{O}(e^{-8\mu R}). \qquad \ldots\ldots(9)$$

(9) is the same as (8) with λ and μ interchanged.

The formal expression

$$\gamma_2=\mu+\lambda a_1(\mu)+\lambda^2 a_2(\mu)+\lambda^3 a_3(\mu)+\mathrm{O}(\lambda^4, e^{-6\mu R}) \qquad \ldots\ldots(10)$$

can be obtained by dividing out the coefficients of the powers of $e^{-2\mu R}$ in (9), but this can never give a convergent series since $\lambda>\mu$. All that can be said for it is that a finite number of its terms give the correct value μ for γ_2 in the limit of infinite R.

3.3. *Perturbation Treatment*

We now treat the two-well model as a single well of strength λ situated at $x=0$ perturbed by a second well of strength μ at $x=R$ (see Fig. 3), and develop an expression for the energy in the form

$$E=E_0+\mu E_1+\mu^2E_2+\mu^3E_3+\mathrm{O}(\mu^4). \qquad \ldots\ldots(11)$$

The unperturbed energy and wave function are those of the single-well model, i.e.

$$E_0=-\tfrac{1}{2}\lambda^2 \quad \text{and} \quad \psi=\lambda^{1/2}\mathrm{e}^{-\lambda|x|},$$

and the perturbation to the Hamiltonian is $-\mu\delta(x-R)$. The first-order correction to the energy is therefore

$$E_1=-\int_{-\infty}^{\infty}\psi\delta(x-R)\psi\,dx=-\lambda\mathrm{e}^{-2\lambda R}.$$

The sum-rule technique of Dalgarno and Lewis (1955, see also Dalgarno and Stewart 1956a) is employed to evaluate E_2 and E_3; details are given in Appendix B. The results are:

$$E_2=-[1-(2\lambda R+\tfrac{1}{2})\mathrm{e}^{-2\lambda R}]\mathrm{e}^{-2\lambda R},$$

$$E_3=-[1-2(2\lambda R+1)\mathrm{e}^{-2\lambda R}+(6\lambda^2R^2+4\lambda R+1)\mathrm{e}^{-4\lambda R}]\frac{\mathrm{e}^{-2\lambda R}}{\lambda}.$$

Substituting these expressions in (11), we have

$$E=-\tfrac{1}{2}\lambda^2\left[1+2\frac{\mu}{\lambda}\mathrm{e}^{-2\lambda R}+2\left(\frac{\mu}{\lambda}\right)^2\{1-(2\lambda R+\tfrac{1}{2})\mathrm{e}^{-2\lambda R}\}\mathrm{e}^{-2\lambda R}\right.$$
$$\left.+2\left(\frac{\mu}{\lambda}\right)^3\{1-2(2\lambda R+1)\mathrm{e}^{-2\lambda R}+(6\lambda^2R^2+4\lambda R+1)\mathrm{e}^{-4\lambda R}\}\mathrm{e}^{-2\lambda R}+\mathrm{O}(\mu^4)\right]. \qquad \ldots\ldots(12)$$

It can be verified that if series (7) for γ_1 is substituted in $E=-\tfrac{1}{2}\gamma^2$, then the resulting formula for the energy is identical with (12), to order μ^4. Thus, on the evidence of the first four terms in the perturbation expansion, the ground-state energy of the two-well model is accurately represented by perturbation theory provided that μ is less than ρ, so that series (7), and therefore also series (11), is convergent.

If the two-well model is regarded as a well of strength μ perturbed by a larger well of strength λ, expression (12) will be obtained with λ and μ interchanged. So the energy predicted for the excited state by perturbation theory will be that derivable from (10); it will only be a poor asymptotic approximation to the true energy for large R, and will be meaningless for small R.

3.4. *The Case of Equal Wells*: $\lambda=\mu$

Here there is just the one perturbation series which has to represent both the '1sσ' and the '2pσ' energies, i.e. expression (12) with μ set equal to λ. But in this case series (7) can never be convergent for large R, as we saw in §3.1, and so (12) will not converge for large R either. It is merely a poor asymptotic approximation to both energies. When R is sufficiently small, however, (12) does converge to the true '1sσ' energy.

With equal wells, Eqns (5) and (6) defining γ_1 and γ_2 degenerate into

$$\gamma/\lambda = 1 \pm e^{-\gamma R},$$

giving the following approximate solutions for large R:

$$\gamma_1/\lambda = 1 + e^{-\lambda R} - \lambda R e^{-2\lambda R} + \tfrac{3}{2}\lambda^2 R^2 e^{-3\lambda R} \ldots, \qquad \ldots\ldots(13)$$

$$\gamma_2/\lambda = 1 - e^{-\lambda R} - \lambda R e^{-2\lambda R} - \tfrac{3}{2}\lambda^2 R^2 e^{-3\lambda R} \ldots. \qquad \ldots\ldots(14)$$

(13) and (14) replace (8) and (9), which are no longer valid when $\lambda = \mu$. Unlike (8) and (9), they contain odd powers of $\exp(-\lambda R)$, providing further evidence that series (7), which does not contain such powers, cannot be an accurate representation of γ_1 for large R.

§ 4. Results and Discussion

If it is permissible to carry over the results derived from the delta-function model to the genuine physical problem, then we can make the following assertions:

HeH^{2+}. In the 1sσ state the energy is represented by a perturbation series with $Z=2$ and $q=1$ (cf. $\lambda=2$, $\mu=1$) which is convergent either for all values of R, or possibly for all values of R except those in some 'intermediate' region. For the 2pσ state, the perturbation series with $Z=1$ and $q=2$ (cf. $\lambda=1$, $\mu=2$) is divergent at any fixed value of R but is asymptotically convergent for sufficiently large R. It can be said to represent the 2pσ energy only for such values of R. (The asymptotic convergence would seem to be better for HeH^{2+} itself than for the model. Perhaps this is because the contribution to the energy which is *not* exponentially decreasing is less trivial than with the model.)

H_2^+. The single perturbation series with $Z=q=1$ (cf. $\lambda=\mu=1$) merely converges to the 1sσ energy for small values of R. The series is divergent for large R, but it is asymptotically convergent to both the 1sσ and the 2pσ energies.

The question remains as to whether it is possible to 'improve' the perturbation series for H_2^+. A recent attempt at this has been made by Dalgarno and Lynn (1956). For the ground state they start with the 'best' LCAO wave function

$$\psi_1(\mathbf{r}_a) + \psi_1(\mathbf{r}_b),$$

and improve it with the set of functions

$$\psi_n(\mathbf{r}_a) + \psi_n(\mathbf{r}_b)$$

as a basis for the perturbation expansion, ψ_n being the *n*th hydrogenic wave function. However their approximations lead to an energy which is not accurate as R tends to zero. In § 5 we attempt to justify a simpler, more accurate formula, which merely adds a 'resonance' term on to the first three terms of the perturbation series (1).

§ 5. A 'Resonance' Correction

5.1. *A Modified Perturbation Expansion*

The primary aim is to find a good approximation to the energy of the 1sσ state of H_2^+ for large R. Following Dalgarno and Lynn, and writing

$$A_n = \psi_n(\mathbf{r}_a), \qquad B_n = \psi_n(\mathbf{r}_b)$$

(both functions being assumed normalized), we set

$$\psi = A_1 + B_1 + \sum_{n\neq 1} c_n(A_n + B_n)$$

in the wave equation

$$H\psi = E\psi. \qquad \ldots\ldots(15)$$

The Hamiltonian is (see Fig. 1 with $Z = q = 1$)

$$H = -\tfrac{1}{2}\nabla^2 - \frac{1}{r_a} - \frac{1}{r_b} = H^A - \frac{1}{r_b},$$

and as R tends to infinity then

$$E \rightarrow E_0{}^A;$$

H^A and $E_0{}^A$ are the Hamiltonian and ground-state energy for an isolated hydrogen atom with nucleus at A. We suppose the coefficients c_n to be small, since c_n tends to zero as R tends to infinity.

If (15) is premultiplied by $A_1{}^*$ and integrated, and the products of c_n with exponentially decreasing integrals are neglected, it is found that

$$(E - E_0{}^A)(1 + \langle A_1|B_1\rangle) = \left\langle A_1 \middle| -\frac{1}{r_b} \middle| A_1 \right\rangle + \left\langle A_1 \middle| -\frac{1}{r_b} \middle| B_1 \right\rangle + \sum_{n\neq 1} c_n \left\langle A_1 \middle| -\frac{1}{r_b} \middle| A_n \right\rangle. \qquad \ldots\ldots(16)$$

(Here $\langle A_1|B_1\rangle$ means $\int A_1{}^* B_1\, d\tau$, $\langle A_1| - 1/r_b|A_n\rangle$ means $\int A_1{}^*(-1/r_b)A_n\, d\tau$, etc.) Similarly, if we first premultiply (15) by $A_m{}^*$, we obtain

$$c_m = \frac{1}{E - \mathscr{E}_m} \left\langle A_m \middle| -\frac{1}{r_b} \middle| A_1 + \sum_{n\neq 1} c_n A_n \right\rangle + \mathrm{O}(\mathrm{e}^{-R}),$$

$\mathscr{E}_m$ being the energy of the hydrogenic function ψ_m. For large R, it follows that

$$c_m \simeq \frac{1}{\mathscr{E}_1 - \mathscr{E}_m} \left\langle A_m \middle| -\frac{1}{r_b} \middle| A_1 \right\rangle, \qquad \ldots\ldots(17)$$

since E tends to $\mathscr{E}_1$ ($\equiv E_0{}^A$) and c_n tends to zero as R tends to infinity.

Substitution of (17) into the last term of (16) gives precisely the second-order perturbation energy $E_2{}^A$. Also the first term on the right-hand side of (16) is the first-order energy $E_1{}^A$, and so we finally obtain

$$E = E_0{}^A + \left(E_1{}^A + E_2{}^A + \left\langle A_1 \middle| -\frac{1}{r_b} \middle| B_1 \right\rangle\right)(1 + \langle A_1|B_1\rangle)^{-1}. \qquad \ldots\ldots(18)$$

5.2. *The 'Resonance' Term*

E can be expressed more concisely in terms of a 'resonance' correction, Δ_+, defined by

$$\Delta_+ = \frac{\langle A_1 + B_1|H|A_1 + B_1\rangle}{\langle A_1 + B_1|A_1 + B_1\rangle} - \langle A_1|H|A_1\rangle.$$

This quantity is the difference in energy caused by having $A_1 + B_1$ rather than A_1 as wave function. Δ_+ simplifies to

$$\{(1 + \langle A_1|B_1\rangle)^{-1} - 1\}E_1{}^A + \left\langle A_1 \middle| -\frac{1}{r_b} \middle| B_1 \right\rangle (1 + \langle A_1|B_1\rangle)^{-1},$$

and using this in (18) we get

$$E = E_0{}^A + E_1{}^A + E_2{}^A(1 + \langle A_1|B_1\rangle)^{-1} + \Delta_+. \qquad \ldots\ldots(19)$$

Expression (19) has been derived on the assumption that R is large; the overlap integral $\langle A_1|B_1\rangle$ is exponentially decreasing, and so the difference between (19) and

$$E = E_0{}^{\mathrm{A}} + E_1{}^{\mathrm{A}} + E_2{}^{\mathrm{A}} + \Delta_+ \qquad \ldots\ldots(20)$$

will not be very great for large R. (20) has the advantage over (19) in that it correctly represents the $1s\sigma$ energy as R tends to zero, for Δ_+ then also tends to zero. The explicit form of Δ_+ is

$$-\frac{(-1/R+2R/3)\mathrm{e}^{-R}+(1+1/R)(1+R+R^2/3)\mathrm{e}^{-3R}}{1+(1+R+R^2/3)\mathrm{e}^{-R}};$$

it supplies some odd powers of e^{-R} which are lacking in the perturbation series. There was similar trouble with the delta-function model, as we saw in § 3.4. Values of (20) are given in Table 2, showing how accurately it represents the $1s\sigma$ energy for all values of R.

The $2p\sigma$ energy of $H_2{}^+$ is also quite well represented for large R by

$$E_0{}^{\mathrm{A}} + E_1{}^{\mathrm{A}} + E_2{}^{\mathrm{A}} + \Delta_- \qquad \ldots\ldots(21)$$

where Δ_- is defined as

$$\frac{\langle A_1-B_1|H|A_1-B_1\rangle}{\langle A_1-B_1|A_1-B_1\rangle} - \langle A_1|H|A_1\rangle,$$

$A_1 - B_1$ being the best LCAO wave function for this state. Values of (21) are also shown in Table 2.

We have expressed the formulae in this section in terms of energies referred to nucleus 'A'. This is purely arbitrary; 'A' and 'B' could be interchanged throughout.

5.3. *Resonance in the Heteronuclear Case*

It can be shown that the resonance corrections are less significant if the nuclear charges are different. Reverting to Fig. 1 with a charge Z at A and q ($<Z$) at B, the hydrogenic ground-state functions are

$$A_1 = \left(\frac{Z^3}{\pi}\right)^{1/2} \exp(-Zr_{\mathrm{a}}) \quad \text{and} \quad B_1 = \left(\frac{q^3}{\pi}\right)^{1/2} \exp(-qr_{\mathrm{b}});$$

the best LCAO function is of the form

$$\psi = A_1 + \theta(Z, q, R)B_1,$$

θ being found by minimizing the resulting energy. There are two values for θ, θ_+ (approximating to the $1s\sigma$ state), and θ_- (to the $2p\sigma$ state). The corresponding resonance corrections turn out to be of magnitude

$$\Delta_+ = \mathrm{O}(q^4), \qquad \Delta_- = \mathrm{O}(q^3),$$

if q is sufficiently small. Thus they should not appreciably affect the energy given by (1), where q^3 terms are already neglected. They are calculated for HeH^{2+}, and the difference they make to the perturbed energies is shown in Table 1.

Finally we remark that, as R tends to infinity, θ_+ tends to zero and θ_- tends to infinity provided $Z \neq q$, but $\theta_+ = 1$, $\theta_- = -1$ for all R if $Z = q$. Also if $Z = 1$ and $q = 1 - \epsilon$ where ϵ is small, it can be proved that

$$\theta_\pm = \pm 1 - \frac{3\epsilon}{2}\left(\frac{R-1}{2R^2-3}\right)\mathrm{e}^{R} + \mathrm{O}(\epsilon^2),$$

showing that, for large R, $\theta_\pm$ approach their $H_2{}^+$ values quite sharply as q gets close to 1. This indicates that the significance of the resonance correction increases markedly as the $H_2{}^+$ case is reached.

APPENDIX A

The Series for γ_1 in Powers of μ

Equation (3) can be written

$$\gamma = \lambda + \mu f(\gamma),$$

where

$$f(\gamma) = 1 + [e^{-2\gamma R} - 1]\frac{\lambda}{\gamma},$$

and hence a series in powers of μ can be developed for the root of (3) which tends to λ as μ tends to zero, i.e. for γ_1. There is in fact a Lagrange's expansion for γ_1 (see, for example, Goursat 1916) of the form (7), where

$$a_1(\lambda) = f(\lambda) \quad \text{and} \quad a_n(\lambda) = \frac{1}{n!}\left[\frac{d^{n-1}}{d\gamma^{n-1}}\{f(\gamma)\}^n\right]_{\gamma=\lambda}.$$

Following Goursat, if $M(r)$ is the greatest value of the function $|f(z)|$ on the circle $|z-\lambda| = r$ in the complex plane, then the radius of convergence ρ of the series (7) is in turn given by the greatest value of the function

$$y(r) = r/M(r), \qquad 0 \leqslant r \leqslant \infty.$$

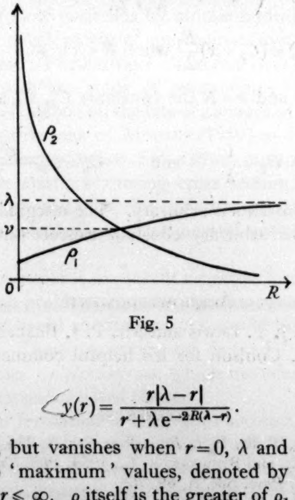

Fig. 5

In our case we obtain

$$y(r) = \frac{r|\lambda - r|}{r + \lambda e^{-2R(\lambda - r)}}.$$

$y(r)$ is never negative, but vanishes when $r = 0$, λ and ∞. It is a continuous function of r with two 'maximum' values, denoted by ρ_1 in the range $0 \leqslant r \leqslant \lambda$ and ρ_2 in the range $\lambda \leqslant r \leqslant \infty$. ρ itself is the greater of ρ_1 and ρ_2. It is impossible to find ρ_1 and ρ_2 directly, but analysis shows that:

(i) ρ_1 behaves like $(3 - 2\sqrt{2})\lambda\{1 + 2R\lambda(\sqrt{2} - 1)\}$ for small R, and like $\lambda[1 - 2e^{-\lambda R}]$ for large R;

(ii) ρ_1 is less than λ for all finite R;

(iii) ρ_2 behaves like $(1/2R)\ln(1/2R\lambda)$ for small R, and like $0{\cdot}14/R$ for large R. We thus arrive at the partly qualitative graphs of ρ_1 and ρ_2 as functions of R shown in Fig. 5, and hence also of ρ, in Fig. 4.

APPENDIX B

The Second- and Third-order Energy Corrections in § 3.3

If μV is the perturbation to the Hamiltonian (here $V = -\delta(x-R)$), and $F(x)$ is a physically acceptable solution of

$$\frac{d^2F}{dx^2} + 2\frac{dF}{dx}\frac{d}{dx}(\ln\psi) = V - E_1,$$

then Dalgarno *et al.* showed that the second- and third-order energy corrections are

$$E_2 = 2(\langle\psi|VF|\psi\rangle - E_1\langle\psi|F|\psi\rangle),$$
$$E_3 = 4(\langle\psi|VF^2|\psi\rangle - E_1\langle\psi|F^2|\psi\rangle - E_2\langle\psi|F|\psi\rangle).$$

Solving the differential equation for $F(x)$ and applying the necessary finiteness conditions to ψF at $x = \pm\infty$, it is found that

$$F(x) = (C_1 - x)\frac{E_1}{2\lambda} \text{ when } -\infty \leqslant x < 0;$$

$$F(x) = \left(C_2 + x - \frac{e^{2\lambda x}}{\lambda}\right)\frac{E_1}{2\lambda} \text{ when } 0 < x < R,$$

and

$$F(x) = (C_3 + x)\frac{E_1}{2\lambda} \text{ when } R < x \leqslant \infty.$$

For continuity at $x = 0$ and $x = R$ the constants C_1, C_2 and C_3 must satisfy the relations

$$C_1 = C_2 - \frac{1}{\lambda} \quad \text{and} \quad C_3 = C_2 - \frac{e^{2\lambda R}}{\lambda};$$

hence just one of the constants is arbitrary. The integrals required for E_2 and E_3 are elementary, and the arbitrary constant cancels out when the results are combined.

ACKNOWLEDGMENTS

I am grateful to Dr. J. T. Lewis and Mr. P. J. Bushell for useful discussions, and to Professor C. A. Coulson for his helpful comments on the manuscript.

Partial Wave Theory of Positron–Hydrogen Atom Collisions[†]

By K. SMITH
Argonne National Laboratory, Argonne, Illinois

MS. received 17*th April* 1961

Abstract. This paper is concerned with the derivation of the radial equations for positron–hydrogen atom collisions from the continuous state Hartree–Fock equations. The angular coefficients are expressed in terms of vector addition coefficients and Racah coefficients for any angular momentum state of the atomic systems: positronium and atomic hydrogen.

The boundary conditions are written in terms of the S-matrix and expressions are obtained for total and differential cross sections.

§ 1. Introduction

The scattering of slow positrons by atomic hydrogen is of interest in connection with the development of approximate methods for the treatment of collision problems. Furthermore, the recent developments of experimental technique associated with the study of positronium formation (Marder *et al.* 1956) focuses additional interest on the fate of a stream of positrons in a gas.

The variational calculations of Moussa (1959) and Spruch and Rosenberg (1960) show that at energies below 5 ev virtual positronium formation has an important effect on the elastic scattering cross section. In particular, Spruch and Rosenberg (1960) found that the positrons are *attracted* to the atom, in contradiction to those calculations which neglect positronium formation (Smith and Burke 1961).

The purpose of this paper is to present a concise formulation of the positron–hydrogen atom collision problem from the eigenfunction expansion point of view. Numerical calculations based on this approach would involve the *exact* solution of the radial equations. These equations are derived from the continuous state Hartree–Fock equations. Calculations, which included positronium formation, should resolve the discrepancy noted above.

When positronium formation is taken into account, the positron problem is more complicated than the electron problem (Percival and Seaton 1957). This is due to the positron–hydrogen atom problem being a two-centre problem.

The effect of electron–positron annihilation to form γ-rays has been neglected.

The radial equations are derived in § 2 and the potentials and kernels are analysed in § 3 and § 4, respectively. The formulae for the cross sections are given in § 5.

§ 2. Derivation of the Radial Equations

The Schrödinger equation for the positron–hydrogen atom problem cannot be solved exactly. Kohn (1948) has shown that the elements of the S-matrix, from

---

[†] Work performed under the auspices of the U.S. Atomic Energy Commission.

which the cross sections are calculated, can be computed to second order in the error in the wave function if the approximate wave function satisfies

$$\iint \Psi^*(H-E)\Psi \, d\mathbf{r}_1 \, d\mathbf{r}_2 = 0. \qquad \ldots\ldots (2.1)$$

Since spin-dependent forces will be neglected, the total orbital angular momentum **L** and the total spin **S** of the system are separately conserved; similarly for their z-components. Thus, a convenient representation to describe the collision process will be one which is diagonal in LM_LSM_S. Let this representation be denoted by

$$\Gamma = \alpha LM_LSM_S \qquad \ldots\ldots (2.2)$$

where α represents all the other quantum numbers required to specify the system: wave numbers and principal atomic quantum number. However, the various types of cross sections are more conveniently discussed in terms of a second representation.

$$\gamma = \alpha\, l_1 m_1 l_2 m_2 m_1{}^s m_2{}^s. \qquad \ldots\ldots (2.3)$$

The two representations are related by a unitary transformation, labelled $(\gamma|\Gamma)$.

The approximate functions considered here are

$$\Psi(1,2) \simeq \sum_{\Gamma} \psi_\Gamma(\mathbf{r}_1 s_1, \hat{\mathbf{r}}_2 s_2) \frac{F_\Gamma(r_2)}{r_2} + \sum_{\Delta} \phi_\Delta(\boldsymbol{\rho} S, \hat{\mathbf{R}}) \frac{G_\Delta(R)}{R}, \qquad \ldots\ldots (2.4)$$

where Δ is a representation of the Γ-type; $\boldsymbol{\rho}$ is the internal coordinate of positronium, while R is the relative coordinate of positronium and proton.

The continuous state Hartree–Fock equations

$$\iint \psi_\Gamma{}^*(H-E)\Psi \, d\mathbf{r}_1 \, d\hat{\mathbf{r}}_2 = 0 \qquad \ldots\ldots (2.5)$$

$$\iint \phi_\Delta{}^*(H-E)\Psi \, d\boldsymbol{\rho} \, d\hat{\mathbf{R}} = 0 \qquad \ldots\ldots (2.6)$$

are obtained by substituting Eqn (2.4) into Eqn (2.1), with

$$\psi_\gamma = \psi_{nl_1m_1}(\mathbf{r}_1) Y_{l_2m_2}(\hat{\mathbf{r}}_2) X(s_1, m_1{}^s) X(s_2, m_2{}^s) \qquad \ldots\ldots (2.7)$$

and

$$\phi_\delta = \phi_{mp_1q_1}(\boldsymbol{\rho}) Y_{p_2q_2}(\hat{\mathbf{R}}) X(S, M_S). \qquad \ldots\ldots (2.8)$$

ψ_γ and ϕ_δ are related to ψ_Γ and ϕ_Δ, respectively, by the unitary transformations, which are given explicitly by Percival and Seaton (1957). Putting $\nu = nl_1l_2$ and $\mu = mp_1p_2$, Eqns (2.5) and (2.6) reduce to the radial equations

$$\left[\frac{d^2}{dr_2{}^2} + k_n{}^2 - \frac{l_2(l_2+1)}{r_2{}^2}\right] F_\nu(r_2) = \sum_{\nu'} V_{\nu\nu'}(r_2) F_{\nu'}(r_2) + \sum_{\mu'} \int_0^\infty K_{\nu\mu'}(r_2, R) G_{\mu'}(R) \, dR \qquad \ldots\ldots (2.9)$$

and

$$\left[\frac{d^2}{dR^2} + \kappa_m{}^2 - \frac{p_2(p_2+1)}{R^2}\right] G_\mu(R) = \sum_{\mu'} V_{\mu\mu'}(R) G_\mu(R) + \sum_{\nu} \int_0^\infty K_{\mu\nu}(R, r_2) F_\nu(r_2) \, dr_2 \qquad \ldots\ldots (2.10)$$

with

$$k_n{}^2 = \frac{2m}{\hbar^2}(E - E_n) \quad \text{and} \quad \kappa_m{}^2 = \frac{4m}{\hbar^2}(E - E_m). \qquad \ldots\ldots (2.11)$$

§ 3. THE DIRECT INTERACTIONS V

The function $V_{\nu\nu'}$ is just that which arises in the electron–hydrogen atom problem, but opposite in sign, and has been evaluated by Percival and Seaton (1957).

The direct interaction of positronium with the proton vanishes if only the S-states of positronium are taken into account. In general

$$V_{\mu\mu'} = -\frac{8m}{\hbar^2}\sum_l \delta_{l\,\mathrm{odd}} f_l(p_1 p_2, p_1' p_2'; L)\, y_l(P_{mp_1}, P_{m'p_1'}; 2R), \qquad \ldots\ldots(3.1)$$

where f_l and y_l are defined by Percival and Seaton (1957). For even values of l the direct interaction vanishes.

§ 4. THE KERNELS K

According to Eqns (2.5)–(2.10), the kernels are defined by

$$K_{\nu\mu}(r_2, R) \equiv \frac{16mr_2}{\hbar^2}\int\!\!\int\left(-\frac{\hbar^2}{4m}\nabla_R^{\,2} + E_m - E - \frac{e^2}{r_1} + \frac{e^2}{r_2}\right)\psi_\Gamma^{*}\,\phi_\Delta R\, d\hat{\mathbf{R}}\, d\hat{\mathbf{r}}_2 \qquad \ldots\ldots(4.1)$$

where

$$\nabla_R^{\,2} \equiv \left[\frac{d^2}{dR^2} - \frac{p_2(p_2+1)}{R^2}\right]$$

and

$$K_{\mu\nu}(R, r_2) \equiv \frac{32mR}{\hbar^2}\int\!\!\int\left(-\frac{\hbar^2}{2m}\nabla_2^{\,2} + E_n - E + \frac{e^2}{r_2} - \frac{e^2}{\rho}\right)\phi_\Delta^{*}\,\psi_\Gamma r_2\, d\hat{\mathbf{r}}_2\, d\hat{\mathbf{R}} \qquad \ldots\ldots(4.2)$$

where

$$\nabla_2^{\,2} \equiv \left[\frac{d^2}{dr_2^{\,2}} - \frac{l_2(l_2+1)}{r_2^{\,2}}\right].$$

The terms involving the Laplacian will be called the 'kinetic energy' terms and are analysed in §4.2; the remaining terms will be called the 'potential terms'.

4.1. *The Potential Terms*

In order to perform the angular integrations the representations will have to be written out explicitly, using Eqns (2.7) and (2.8), and the surface harmonic components of the bound state wave functions will have to be expanded using a theorem given by Moshinsky (1959):

Given

$$\mathbf{r} = \mathbf{x} + \mathbf{y}, \qquad \ldots\ldots(4.3)$$

then

$$r^L Y_{LM}(\hat{\mathbf{r}}) = \sum_{p,q}\left[\frac{(2L+1)!\,4\pi}{(2L-2p+1)!\,(2p+1)!}\right]^{1/2} \times (pL-pqM-q\,|\,LM)\,Y_{pq}(\hat{\mathbf{x}})\,Y_{L-pM-q}(\hat{\mathbf{y}})\,x^p y^{L-p}. \qquad \ldots\ldots(4.4)$$

The relation for $L=2$ has been used extensively by Bransden *et al.* (1958) in nucleon–deuteron scattering with tensor forces.

The angular dependence of the radial atomic functions can be extracted by defining the kernels

$$k^{\mathscr{L},i}_{nl_1,mp_1}(r_2, R) = \frac{1}{4\sqrt{2}}\int_{-1}^{1} d\eta\, Q_{nl_1}(r_1)\,Q_{mp_1}\!\left(\frac{\rho}{2}\right) a^i P_{\mathscr{L}}(\eta) \qquad \ldots\ldots(4.5)$$

where $Q \equiv R/r^l$, and R is the radial function defined by Pauling and Wilson (1935); $\eta \equiv \hat{\mathbf{r}}_2 . \hat{\mathbf{R}}$, and

$$r_1 = (4R^2 + r_2^{\,2} - 4Rr_2\eta)^{1/2}, \quad \rho = 2(R^2 + r_2^{\,2} - 2Rr_2\eta)^{1/2} \qquad \ldots\ldots(4.6)$$

$$a^1 = 1, \quad a^2 = 1/r_1, \quad a^3 = 1/\rho. \qquad \ldots\ldots(4.7)$$

After performing the angular integrations in Eqn. (4.1) the potential contributions to the kernels are

$$K^{\text{pot}}_{\nu\mu}(r_2, R) = \left[\left(-\kappa_m{}^2 + \frac{4}{r_2 a_0}\right) q_{\nu\mu}{}^1(r_2, R) - \frac{4}{a_0} q_{\nu\mu}{}^2(r_2, R)\right], \quad \ldots\ldots(4.8)$$

where a_0 is the Bohr radius of the H-atom, and

$$\begin{aligned} q^{i}_{nl_1l_2,mp_1p_2}(r_2, R) \equiv{} & 4[(2l_1+1)!\,(2p_1+1)!\,(2l_1+1)(2l_2+1)(2p_1+1)(2p_2+1)]^{1/2} \\ & \times (-1)^{l_2+p_2} R r_2 2^v r_2{}^{l_1+p_1} \sum_{v=0}^{l_1} \sum_{u=0}^{p_1} [(2u)!\,(2v)!\,(2p_1-2u)!\,(2l_1-2v)!]^{-1/2} \\ & \times \left(\frac{R}{r_2}\right)^{u+v} \sum_{\mathscr{L}} k^{\mathscr{L},i}_{nl_1,mp_1}(r_2, R)\, C(L, l_1l_2, p_1p_2, uv, \mathscr{L}), \end{aligned} \quad \ldots\ldots(4.9)$$

and

$$\begin{aligned} & C(L, l_1l_2, p_1p_2, uv, \mathscr{L}) \\ & \quad \equiv (2\mathscr{L}+1) \sum_{f,f'} (l_2 l_1 - v00\,|\,f0)(p_1 - u\mathscr{L}00\,|\,f0)(p_2 v00\,|\,f'0)(\mathscr{L}u00\,|\,f'0) \\ & \quad \times W(f'ufp_1 - u\,;\, \mathscr{L}p_1)\, W(vp_2fp_1\,;\, f'L)\, W(Lvl_2l_1 - v\,;\, fl_1). \end{aligned} \quad \ldots\ldots(4.10)$$

For Eqn (4.2) the potential contributions are

$$K^{\text{pot}}_{\mu\nu}(R, r_2) = 4\left[\left(-k_n{}^2 + \frac{2}{r_2 a_0}\right) q_{\nu\mu}{}^1(r_2, R) - \frac{2}{a_0} q_{\nu\mu}{}^3(r_2, R)\right]. \quad \ldots\ldots(4.11)$$

4.2. *Kinetic Energy Terms*

The first term in Eqn (4.1) can be written as

$$\begin{aligned} K^{\text{k.e.}}_{\nu\mu}(r_2, R) = -4 \iint & R r_2\, d\hat{\mathbf{R}}\, d\hat{\mathbf{r}}_2 (\gamma\,|\,\Gamma)(\delta\,|\,\Delta) Y^*_{l_2m_2}(2) Y_{p_2q_2}(\hat{\mathbf{R}}) Y_{\mathscr{L}M_{\mathscr{L}}}(2) \\ & \times (\nabla_R{}^2)_{r_2} \left[k^{\mathscr{L},1}(r_2, R) Y^*_{\mathscr{L}M_{\mathscr{L}}}(\hat{\mathbf{R}})\, r_1{}^{l_1} Y^*_{l_1m_1}(\hat{\mathbf{r}}_1) \left(\frac{\rho}{2}\right)^{p_1} Y_{p_1q_1}(\hat{\boldsymbol{\rho}})\right]. \end{aligned}$$

The solid harmonics, with arguments $\hat{\mathbf{r}}_1$ and $\hat{\boldsymbol{\rho}}$ are then expanded using theorem (4.4), and the angular integrations are performed to give

$$K^{\text{k.e.}}_{\nu\mu}(r_2, R) = -q_{\nu\mu}{}^4(r_2, R), \quad \ldots\ldots(4.12)$$

where

$$q_{\nu\mu}{}^4(r_2, R) \equiv \left[\frac{d^2}{dR^2} - \frac{p_2(p_2+1)}{R^2}\right] q_{\nu\mu}{}^1(r_2, R). \quad \ldots\ldots(4.13)$$

The angular integrations in the kinetic energy term of Eqn (4.2) can be performed to give

$$K^{\text{k.e.}}_{\nu\mu}(R, r_2) = 4 q_{\nu\mu}{}^5(r_2, R), \quad \ldots\ldots(4.14)$$

where

$$q_{\nu\mu}{}^5(r_2, R) \equiv \left[\frac{d^2}{dr_2{}^2} - \frac{l_2(l_2+1)}{r_2{}^2}\right] q_{\nu\mu}{}^1(r_2, R). \quad \ldots\ldots(4.15)$$

In conclusion it is seen that the kernels for Eqns (2.9) and (2.10) are given by the sum of Eqns (4.8) and (4.12) and the sum of Eqns (4.11) and (4.14) respectively.

It should be pointed out that spin does not enter into the problem at all, since there is no mechanism present to cause spin flip (which is effected by particle exchange in the corresponding electron problem).

§ 5. CROSS SECTIONS

The formulae for the cross sections for any collision process in which two particles collide and two particles emerge have been given by Blatt and Biedenharn

(1952) and corrected in the phase factors by Huby (1954). The method of Blatt and Biedenharn will be used here to derive the total, and differential, cross sections for transitions from level nl_1 to level $n'l_1'$ of atomic hydrogen and from level nl_1 of atomic hydrogen to level $m'p_1'$ of positronium.

In the asymptotic region the most general wave function (see Eqn (2.4)) with total quantum numbers L and M_L in channel α will have the form

$$\Psi^{LM_L} \simeq y_L^{M_L}(\hat{\mathbf{r}}, \hat{\mathbf{r}}_\alpha) R_\alpha(r)\{A_\alpha^{LM_L} \exp[-i(k_\alpha r_\alpha - \tfrac{1}{2}l_\alpha \pi)] - B_\alpha^{LM_L} \exp[i(k_\alpha r_\alpha - \tfrac{1}{2}l_\alpha \pi)]\}/r_\alpha \qquad \ldots\ldots(5.1)$$

with the S-matrix defined by

$$B_{\alpha'}^{LM_L} \equiv \sum_{\alpha''} S_{\alpha',\alpha''}^{L} A_{\alpha''}^{LM_L}, \qquad \ldots\ldots(5.2)$$

and the real derivative matrix, $\mathscr{R}$, defined by

$$S \equiv (1 + i\mathscr{R})/(1 - i\mathscr{R}). \qquad \ldots\ldots(5.3)$$

The analysis proceeds analogously to that of Blatt and Biedenharn to give the differential cross section for excitation of the H atom

$$\frac{d\sigma_{n'l_1', nl_1}(\hat{\mathbf{r}}_2)}{d\Omega} = \frac{(-1)^{l_1'-l_1}}{4k_n{}^2(2l_1+1)} \sum_v P_v(\cos\theta) B_v(n'l_1', nl_1), \qquad \ldots\ldots(5.4)$$

where

$$B_v(n'l_1'; nl_1) \equiv \sum_{Ll_2l_2'} \sum_{\mathscr{L}t_2t_2'} T^{L}_{n'l_1 l_2', nl_1l_2} T^{\mathscr{L}*}_{n'l_1 l_2', nl_1t_2} Z(l_2Lt_2\mathscr{L}; l_1v) Z(l_2'Lt_2'\mathscr{L}; l_1'v) \qquad \ldots\ldots(5.5)$$

and the T-matrix and Z-coefficients (without the i-factor (Huby 1954)) are defined by Blatt and Biedenharn.

The total cross section is obtained by integrating Eqn (5.4) over all solid angles to give

$$\sigma_{n'l_1', nl_1} = \frac{1}{k_n{}^2(2l_1+1)} \sum_{Ll_2l_2'} T^{L}_{\nu'\nu} T^{L*}_{\nu'\nu}(2L+1). \qquad \ldots\ldots(5.6)$$

The total and differential cross sections for positronium formation, into the state $m'p_1'$, $d\sigma_{m'p_1', nl_1}(\hat{\mathbf{R}})$ and $\sigma_{m'p_1', nl_1}$, respectively, are identical to Eqns (5.4)–(5.6) with $n'l_1'l_2'$ replaced by $m'p_1'p_2'$.

Abstract. The univalent ions Fe^{1+}, Co^{1+} and Ni^{1+} have been produced by ultra-violet or x-irradiation of impure MgO crystals. The electron spin resonance spectra of these ions are compared with those of the isoelectronic ions Co^{2+}, Ni^{2+} and Cu^{2+} which they resemble closely. The spectra of Fe^{1+}, Co^{1+} and Ni^{2+} show line-width effects which may be interpreted as being due to the presence of small distortions in the cubic crystal lattice. A detailed report of the $3d^9$ configuration in a cubic field is given. There is a transition at low temperature from an isotropic to an anisotropic spectrum, presumably due to the 'freezing in' of Jahn–Teller distortions. Observation of hyperfine structure from ^{61}Ni has made it possible to estimate the nuclear moment by comparison with the observed hyperfine structure from Co^{1+}. The ease of formation and stability of these univalent ions is shown to be related to the concentration of positive ion vacancies and to the concentration of trapped hole centres.

§ 1. INTRODUCTION

ELECTRON spin resonance has proved to be a valuable technique for investigating iron-group impurity ions in single crystals of magnesium oxide (Wertz and Auzins 1957, Low 1957b, c, 1958a, b, c). With the exception of titanium and copper, all the iron-group elements have been studied in one or more valence states, and the majority of the results indicate crystalline electric fields having very nearly perfect cubic symmetry. The only ions so far found in non-cubic surroundings are trivalent chromium (Wertz and Auzins 1957, Griffiths and Orton 1959) and iron (Orton, unpublished). Some of these ions are associated with defects (probably positive ion vacancies) in nearest-neighbour or next-nearest-neighbour positive ion sites. There is evidence, however, that some of the 'cubic' ions show very small departures from exactly cubic symmetry (Low 1960a).

There have also been some studies of the effects of irradiation with neutrons (Wertz *et al.* 1957) and with x-rays or ultra-violet light (Wertz *et al.* 1958, 1959) which may aid in the interpretation of optical absorption, photoconductivity and luminescence data. It is apparent that any acceptable theory of the behaviour

[||] Now at the Mullard Research Laboratories, Redhill, Surrey.

of MgO under irradiation must take into account the part played by impurity ions. These are important centres for the production and trapping of electrons, and it has not yet proved possible to obtain crystals so pure that impurity effects may be neglected.

The purpose of this paper is threefold: to report the observation of some new resonance spectra in MgO; to present further evidence concerning small departures from exactly cubic surroundings, and to consider some features of the role played by impurity ions in electron transfers due to ultra-violet or x-irradiation.

§ 2. EXPERIMENTAL

The magnesium oxide crystals used in these experiments were obtained from the Norton Company (Canada), the General Electric Company (U.S.A.) and the Infrared Development Company (England). Attempts to diffuse impurities into single crystals of MgO at temperatures up to 1500°c have not led to uniform distribution. In general, only a thin surface layer was obtained, and prolonged heating did little to improve the distribution. The samples containing cobalt were doped in the melt (General Electric Company) and were rose-coloured. For the other impurities it was possible to find crystals which had appropriate concentrations as received, and these crystals were nearly colourless. Some samples used in the Cu^{2+} studies were made from doped powders. Powdered MgO (Fisher, electronic grade) was added to concentrated solutions of $CuCl_2$ and subsequently dried and heated to the maximum temperature attainable with an oxygen–gas flame.

The electron spin resonance measurements were nearly all made at 9·2 Gc/s; a few were carried out at 6·8 Gc/s and at 23 Gc/s. In some of the work the spectrometer employed bolometer detection in a balanced circuit of the type described by Feher (1957); most of the rest was carried out with transmission cavities with 200 kc/s modulation and crystal detection. The *g*-values were usually determined with a proton resonance probe, measuring both radio-frequency and microwave frequencies with a Hewlett–Packard 524D counter and its accessories. Samples were irradiated with a low-pressure mercury vapour lamp emitting most of its energy at 4·9 ev (2537 Å) or with x-rays from tubes operated at 50 to 100 kv.

§ 3. THE ELECTRON SPIN RESONANCE SPECTRA

After x- or ultra-violet irradiation of MgO crystals containing iron, cobalt and nickel in divalent form we have detected electron spin resonance spectra which may be attributed to the corresponding univalent ions Fe^{1+}, Co^{1+} and Ni^{1+}. The relevant parameters describing these spectra are collected in the Table together with the corresponding values for the isoelectronic ions, Co^{2+}, Ni^{2+} and Cu^{2+} in the same lattice. The *g*-values and hyperfine constants A are in all cases isotropic.

The spectra attributed to Fe^{1+} and Ni^{1+} consist of single isotropic lines having widths of order 1 gauss. Co^{1+} shows the expected eight-line hyperfine structure from ^{59}Co ($I=7/2$), the line-width in this case being approximately 20 gauss. At large microwave powers sharp ($\Delta H \sim 1$ gauss) lines appear, superposed on the

Configuration	Ion	Temp. (°K)	g	A (cm$^{-1}\times 10^4$)	Reference
$3d^7$	Co^{2+}	20	$4{\cdot}278\pm0{\cdot}001$	$97{\cdot}8\pm0{\cdot}2$	Low (1958 c)
	Fe^{1+}	20	$4{\cdot}15\ \pm0{\cdot}01$	—	This paper

† Low (1958 b) found $g=2{\cdot}227\pm0{\cdot}002$ at 77°K, but we believe this value to be more accurate (see text).

centre of each Co^{1+} hyperfine component. These may be attributed to double quantum transitions by comparison with the Ni^{2+} spectrum which shows a similar behaviour (Orton, Auzins and Wertz 1960 a), and provide fairly conclusive evidence of the correct assignment of this spectrum to Co^{1+}. It may be mentioned here that the presence of the sharp double-quantum lines enables one to measure the g-values of Co^{1+} and Ni^{2+} with considerable accuracy. On this account we feel justified in preferring our g-value for Ni^{2+} to that measured previously by Low (1958 b). We may also feel confident of the correct interpretation of the Ni^{1+} line on account of the low temperature transition discussed in § 5.1 and the fact that this spectrum occurs only in crystals showing resonance from Ni^{2+} prior to irradiation.

The assignment of the $g=4{\cdot}15$ line to Fe^{1+} depends on the similarity of g-value and spin–lattice relaxation time to those of Co^{2+}. In one crystal containing Co^{2+} both spectra were examined together. On increasing the temperature slowly from 20°K the widths of both lines increased rapidly until it was no longer possible to detect resonance. In fact, the new line disappeared first, indicating a slightly shorter T_1 than for Co^{2+} but the difference was very small. The ions most likely to exhibit this behaviour are Fe^{1+} and Ni^{3+} (V, Cr, Mn, Co and Cu all being ruled out by the absence of hyperfine structure), and the latter may fairly be excluded by the observation of this line in crystals showing no resonance from Ni^{2+} prior to irradiation. It has been detected (with various intensities) in nearly all crystals examined, a fact consistent with the occurrence of iron as an impurity in all crystals available to us.

Further evidence in favour of these interpretations is provided by the results of Bleaney and Hayes (1957), Hayes (1958) and Hayes and Jones (1958) who found the ions Fe^{1+}, Co^{1+} and Ni^{1+} after irradiation of NaF crystals containing the corresponding divalent ions. It may be argued that univalent ions would be more stable in NaF than in MgO; however, the question of charge compensation and stabilization will be taken up later.

3.1. *Covalent Bonding*

For the ions Co^{2+} and Ni^{2+} in MgO, Low (1958 c, b) has shown that there is appreciable covalent bonding between them and the neighbouring oxygen ions. Using the observed g-values of the Table, it is tempting to try to compare the extent of covalency for the univalent ions with their divalent analogues. The

g-values of the three configurations in octahedral crystal field are given by

$$3d^7 \qquad g=3\cdot33+\alpha k-\frac{15}{2}\frac{\lambda}{\Delta} \qquad \ldots\ldots(1\,a)$$

$$3d^8 \qquad g=2-\frac{8\lambda}{\Delta} \qquad \ldots\ldots(1\,b)$$

$$3d^9 \qquad g=2-\frac{4\lambda}{\Delta}, \qquad \ldots\ldots(1\,c)$$

where α takes account of the small admixture of ^{4}P states into the ^{4}F ground state of $3d^7$, k is the orbital reduction factor (Stevens 1953), λ is the spin–orbit coupling constant for the ion in the crystal and Δ measures the splitting of the orbital levels by the crystal field. The effects of covalency appear in k and λ (Low 1960 b).

In order to calculate k or λ from the measured g-value, it is obviously necessary to know Δ. It appears probable that Δ may vary appreciably between two isoelectronic ions having different nuclear charges (cf. the cubic field splitting constants of Mn^{2+} and Fe^{3+} in MgO, Low 1957 a) and there is too much uncertainty involved in trying to estimate it. Reliable values may only be obtained from measurements of the appropriate optical spectra and this is also true of α. We have not yet attempted such measurements on the univalent ions as these are present in small concentration ($\sim 10^{-4}$) and their spectra may be confused by much stronger bands from other impurity ions.

Rough calculations using reasonable values of Δ and α seem to indicate that the amount of covalency for each univalent ion is probably about the same as for the corresponding divalent one.

§ 4. SYMMETRY OF THE CRYSTAL FIELD

The isotropic nature of the spectra and the absence of fine structure indicates that the ions Fe^{1+}, Co^{1+} and Ni^{1+} are situated in surroundings having cubic symmetry. The same has been found for several other iron-group ions in MgO, in particular, the corresponding divalent ions from which they are derived (Low 1960 a, Low 1958 b, c). However, the observed line-widths suggest that in several cases there are very small departures from exactly cubic symmetry. We shall discuss the evidence for this provided by the spectra of Ni^{2+} and Fe^{1+}.

In both cases the line-width is found to be dependent on the orientation of the external magnetic field H relative to the crystal axes. For Fe^{1+} the widths with H along the directions [111], [110] and [100] are in the ratios 1 : 3 : 6, and for Ni^{2+} the corresponding ratios are 1 : 1·1 : 1·5. The precise widths vary from crystal to crystal. With H along the [111] direction, the Fe^{1+} width ranges from 0·8 to 3 gauss at X band and the corresponding Ni^{2+} variation is between approximately 30 and 40 gauss. At K band ($\nu=23$ Gc/s) the Fe^{1+} widths are approximately 2·5 times greater, suggesting a direct proportionality between ΔH and ν, but in all cases the ratios 1 : 3 : 6 for the principal directions are maintained. There is no detectable variation of the Ni^{2+} width with frequency.

4.1. *Interpretation of Line-widths for Fe^{1+} and Ni^{2+}*

We shall consider three possible causes of these line-width variations: aggregation of impurity ions, Jahn–Teller distortions of the $[MO_6]$ complex (Jahn and Teller 1937) and distortion of the crystal lattice due to dislocations or other faults.

The first possibility, attributing the widths to dipole–dipole interaction, may be disposed of at once on the grounds that it is impossible, in this way, to explain the frequency dependence of ΔH in the Fe^{1+} spectrum. It is also inconsistent with the very small width of the Ni^{2+} double quantum line. The other two possibilities both depend essentially on a distortion of the O^{2-} octahedron surrounding the magnetic centre and may be treated together.

(*a*) Fe^{1+}.

Consider the simple case of an Fe^{1+} ion in approximately cubic surroundings but with one of its neighbours displaced very slightly so as to produce a small tetragonal component of crystal field. Abragam and Pryce (1951) showed that the g-value of the ground-state doublet will be anisotropic with $g_{\parallel}$ and $g_{\perp}$ lying on either side of g_0 (the value in cubic field) and $g_{\parallel}-g_0 \simeq 2(g_0-g_{\perp})$. Using this result and taking into account the three ions in unit cell (corresponding to the tetragonal axis being along any one of the cubic axes), we may represent the spectrum along each of the principal directions as shown in Fig. 1. The height of a line represents the intensity of absorption, the solid lines arising from tetragonal field of one sign and the dotted ones from opposite sign. It is necessary to include tetragonal components of both signs to account for the observed symmetry of the line shape.

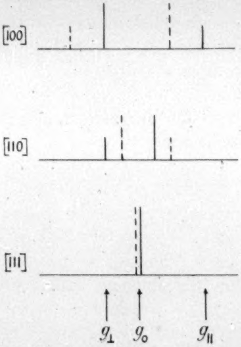

Fig. 1. Reconstruction of the Fe^{1+} line-width along principal directions. The solid lines represent absorption from ions with tetragonal crystal field components of one sign, dotted lines from those of opposite sign.

We now postulate a large number of distortions distributed according to a function $f(\Delta g)$ having a maximum value for $\Delta g=0$ and falling to zero with a half-power width of order $10^{-2}g_0$ (corresponding to $\Delta H \sim 10$ gauss at X band). It may be seen from Fig. 1 that the observed variations of line-width (i.e. the ratios 1 : 3 : 6) are reproduced approximately. In particular, the variation of line-width with operating frequency is accounted for since

$$\Delta H \simeq \frac{H_0}{g_0}\Delta g = \frac{h\Delta g}{g_0^2\beta}\nu. \qquad \ldots\ldots(2)$$

(*b*) Ni^{2+}.

The occurrence of a small tetragonal component of crystal field will produce small zero-field splittings ΔE between the $S_z = 0$ and $S_z = \pm 1$ levels of the Ni^{2+} ground state. By assuming a spread of these values, this situation will give rise to a line-width $\Delta H \sim \Delta E / g\beta$ for $\Delta M = \pm 1$ transitions, while affecting the double quantum transition ($\Delta M = \pm 2$) only by an amount $\sim (\Delta H)^2 / H_0$. Taking $\Delta H \sim 50$ gauss, this term is less than 1 gauss at X band; this contribution is less than the commonly observed dipolar width for 3d group ions in MgO and is consistent with the observed double quantum line-width of the order of 1 gauss. That the width of the broad Ni^{2+} line does result from zero-field splittings is supported by two pieces of evidence.

We observe a resonance line at approximately half the field of the main one, having an unusual shape. There is a sharp cut-off at the high field side and much more gradual tailing off to low field. A similar line was observed by Low (1960 a) in the spectrum of Fe^{2+} in MgO and, as he shows, the shape may be explained satisfactorily on the assumption that there is a spread of ground-state splittings. The transition probability for this line is zero in exactly cubic field which accounts for the sharp cut-off on the high field side.

Further evidence is provided by the intensity of absorption in the 'two frequency' double quantum experiment we have already described (Orton, Auzins and Wertz 1960 a). In a three-level system such as this, a double quantum absorption may only be observed if the level separations are in approximately the same ratio as the two frequencies absorbed. Thus, absorption of two quanta at the same frequency requires equally spaced levels and will occur for ions in cubic crystal field. If the frequencies differ, the level spacings must be unequal, which implies the existence of a ground state splitting, and the intensity of absorption obviously depends on the number of ions having the appropriate splitting.

In a series of measurements with the two frequencies ν_A and ν_B differing by increasing amounts we have compared the intensity of absorption I of quanta $h(\nu_A + \nu_B)$ with that of $2h\nu_A$ and $2h\nu_B$ (I_0). The ratios of I/I_0 are represented by

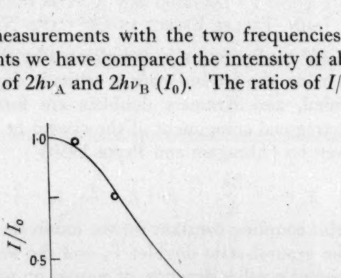

Fig. 2. Results of the 'two frequency' double quantum experiment for three values of $|\nu_A - \nu_B|$. The experimental points show the relative intensity of absorption of quanta $h\nu_A + h\nu_B$ and the solid curve represents the observed shape of the broad Ni^{2+} line.

the experimental points in Fig. 2 where the solid line indicates the shape of the broad Ni^{2+} line. The close agreement between the relative intensity of absorption of $\nu_A + \nu_B$ and the broad line shape provides good evidence for interpreting the latter as arising from a spread of splittings.

(*c*) *Tetragonal distortions.*

A simple model of tetragonal distortions along the crystal cubic axes would require the line-width along [110] and [111] directions to be much smaller than that observed. The experimental values may be taken as evidence either of the actual symmetry being rhombic, or the axes of distortion not coinciding exactly with [100] type directions (or, possibly, both).

It is not possible to decide with certainty between the Jahn–Teller effect and crystal imperfections as the origin of the proposed distortions, but the weight of evidence is probably in favour of the latter. As the ground-state doublet contains orbital wave-functions, the $3d^7$ configuration might be expected to show a Jahn–Teller distortion but the considerable variation of ΔH from one crystal to another provides fairly strong evidence against its existence in Fe^{1+}. It may also be noted that we have not observed any corresponding line-width variation in the spectrum of Co^{2+}, as might be expected if its origin lay in the Jahn–Teller effect. Finally, one does not expect there to be any appreciable Jahn–Teller distortion for the $3d^8$ configuration, whereas both Ni^{2+} and Co^{1+} spectra show evidence of departure from exactly cubic symmetry.

Perhaps the greatest difficulty with the crystal imperfection theory is that of explaining the occurrence of distortions close to [100] type directions, whereas this could be done in a straightforward fashion in terms of the Jahn–Teller effect. A detailed investigation of specific models may yield a plausible explanation in terms of imperfections but we shall not attempt it here†.

§ 5. JAHN–TELLER EFFECT IN Cu^{2+} AND Ni^{1+}

The theory of the $3d^9$ configuration is complicated by the fact that, in cubic (and trigonal) crystal fields, the ground state is orbitally degenerate. When the spin $(S=\frac{1}{2})$ is included, two Kramers doublets are formed and these are separated only by a tetragonal component of the crystal field. The *g*-values of these doublets are given by (Abragam and Pryce 1950)

$$(a)\ g_{\parallel}=2-\frac{8\lambda}{\Delta},\quad g_{\perp}=2-\frac{2\lambda}{\Delta},\qquad (b)\ g_{\parallel}=2,\quad g_{\perp}=2-\frac{6\lambda}{\Delta},\qquad \ldots\ldots(3)$$

where λ is the spin–orbit coupling constant for the ion in the crystal and Δ is the separation between the ground-state doublet Γ_3 and the next higher level (the triplet Γ_5). The measured *g*-value depends, of course, on which of the Kramers doublets is lower, i.e. on the sign of the tetragonal field. For ions in cubic (or trigonal) surroundings one expects to find a Jahn–Teller distortion resulting in separation of the doublets (Van Vleck 1939).

5.1. *Low Temperature Transitions*

Bleaney, Bowers and Trenam (1955) examined a number of cupric salts in which the Cu^{2+} ion is in approximately octahedral surroundings but with a small trigonal distortion. They found that, below a certain temperature (which varied for different salts), the spectrum showed tetragonal symmetry. There were three ions in the unit cell, corresponding to three mutually perpendicular directions of the tetragonal axis. The observed g-values were $g_{\parallel} \simeq 2{\cdot}45$, $g_{\perp} \simeq 2{\cdot}10$, indicating that the doublet (*a*) is lowest. Öpik and Pryce (1957) have shown that this is to be expected in most cases. At these low temperatures it is assumed that the Jahn–Teller distortions are 'frozen in'. Ludwig and Woodbury (1959) have observed a similar effect in the electron spin resonance spectrum of nickel as an impurity in germanium.

---

† The referee of this paper makes the suggestion: "A complex imperfection such as $Fe^{1+}O^{2-}Mg^{2+}O^{2-}Fe^{3+}$ would appear quite plausible."

Above the transition temperature they found the g-value to be very nearly isotropic. Abragam and Pryce (1950) explained this as due to a rapid oscillation between the three distorted configurations (each having equal energy), resulting in an average g-value of $2-4\lambda/\Delta$. This interpretation is expected to apply to Ni^{1+} and Cu^{2+} in cubic field and leads one to look for a transition temperature below which the Jahn–Teller distortions are 'frozen in' as found by Bleaney *et al.*

Both spectra were found to be isotropic at temperatures down to 4°K, but at 1·2°K these were no longer detectable and had been replaced by anisotropic spectra as expected. However, the 'low temperature' spectra are not, at the moment, understood. The anticipated model would assume tetragonal distortions occurring along [100] type directions but it does not seem possible to fit this to the experimental results. Further work is planned to analyse these results.

5.2. *Line-width of Cu²⁺*

Further evidence for the existence of an oscillating Jahn–Teller effect at temperatures above 4°K is provided by the line-widths of the Cu^{2+} spectrum. The widths of the four hyperfine lines decrease as one goes to higher field (see Fig. 3) and the amplitudes correspondingly increase. A reasonably good fit to the observed spectrum at 77°K was obtained by using a reconstruction of four

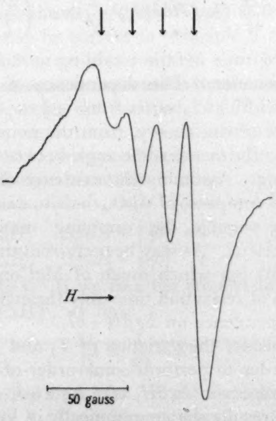

Fig. 3. Derivative of the Cu^{2+} spectrum, showing decrease in width, and consequent increase in amplitude, of the hyperfine components towards higher magnetic field.

Lorentzian lines having equal intensities but differing line-widths (in the ratio 1:1·26:1·57:1·91). The small discrepancies indicate a line shape which is slightly more Gaussian than the pure Lorentz shape chosen. The widths of the components are approximately equal to their separations (~ 20 gauss) so they are not completely resolved from one another.

Very similar observations have been reported for Cu^{2+} ions in solution (McGarvey 1956) and an explanation has been proposed by McConnell (1956). He takes as a model a $[Cu.6H_2O]$ complex which may be regarded as completely rigid but which undergoes a rapid tumbling motion in the liquid. He assumes the complex to possess an axis of symmetry and shows that the spin Hamiltonian may be written:

$$\mathscr{H} = \mathscr{H}_0 + \mathscr{H}_t, \qquad \ldots\ldots(4)$$

where

$$\mathscr{H}_0 = g\beta H S_z + a\mathbf{I}.\mathbf{S} \qquad \ldots\ldots(5)$$

with

$$g = \tfrac{1}{3}(g_{\parallel} + 2g_{\perp}) \quad \text{and} \quad a = \tfrac{1}{3}(A + 2B)$$

and

$$\mathscr{H}_t = (\Delta g\beta H + bI_z)(\cos^2\theta - \tfrac{1}{3})S_z + \tfrac{1}{2}(\Delta g\beta H + bI_z)\sin\theta\cos\theta(S_+e^{-i\phi} + Se^{i\phi}) + \ldots, \qquad \ldots\ldots(6)$$

with $b = A - B$ and $\Delta g = g_{\parallel} - g_{\perp}$. The angles θ and ϕ serve to define the direction of the complex axis relative to axes fixed in the laboratory. In consequence of the tumbling motion, θ and ϕ are functions of time. Assuming $\Delta g\beta H \gg b$, McConnell considers the first two terms in (6) and shows that Eqn (6) leads to values of spin–lattice (T_1) and transverse (T_2') relaxation times given by

$$\frac{1}{T_1} \sim \left(\frac{8\pi}{15}\right)^2 (\Delta g\beta H + bI_z)^2 \frac{1}{h^2}\left(\frac{\tau_c}{1 + 4\pi^2\nu^2\tau_c^2}\right) \qquad \ldots\ldots(7)$$

$$\frac{1}{T_2'^2} \sim \frac{32\pi}{45} (\Delta g\beta H + bI_z)^2 \frac{1}{h^2} \tan^{-1}\left(\frac{2\tau_c}{T_2'}\right), \qquad \ldots\ldots(8)$$

where τ_c is the correlation time for the tumbling motion and ν is the operating frequency of the spectrometer. The dependence of relaxation times on I_z implies a change of line-width as I_z varies from $-\frac{3}{2}$ to $+\frac{3}{2}$.

The important feature of this theory, from the point of view of the present work, is that it depends on the fact that the angle between H and the $[Cu.6H_2O]$ axis is constantly changing. Assuming the existence of oscillating Jahn–Teller distortions of the $[CuO_6]$ complex in MgO, the situation is similar except that, instead of all angles being possible, the 'tumbling' motion now occurs between a number of specific directions. As may be seen from the work of Bloembergen, Purcell and Pound (1948) (on which much of McConnell's theory is based), this will result in changes of relaxation time only through the correlation time τ_c and will not alter the dependence on $\Delta g\beta H + bI_z$.

It is of interest to consider the variation of T_1 and T_2' with τ_c, as given in Eqns (7) and (8). In order to perform some order-of-magnitude calculations we shall neglect b with respect to $\Delta g\beta H$, take $\Delta g \simeq 0{\cdot}3$, and $\nu \simeq 9 \times 10^9$ c/s. On this basis we arrive at the results shown graphically in Fig. 4. Except for values of τ_c of order 10^{-11} sec or less, $1/T_2'$ is considerably greater than $1/T_1$ and, for $\tau_c > 10^{-8}$ sec $1/T_2'$ is almost constant. Thus, for large values of τ_c, Eqns (7) and (8) predict that the line-widths will be determined by T_2' and should remain constant, independent of temperature. This is in accordance with observation for temperatures between 77°K and 20°K. Between 20°K and 4°K there are indications of some variation which may be associated with the transition to the 'low temperature' spectrum below 4°K. At 1·2°K when the anisotropic spectrum has replaced the isotropic one, there is no sign of a variation of line-width with I_z, which is consistent with the Jahn–Teller distortions having been 'frozen-in'.

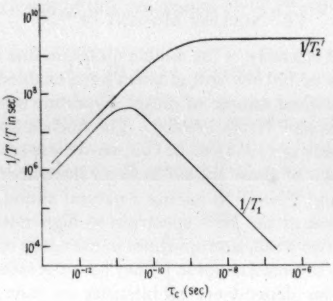

Fig. 4. Variation of $1/T_1$ and $1/T_2'$ with correlation time τ_c as predicted by McConnell's theory.

These conclusions should, of course, be accepted only with reserve, as we have neglected the other contributions to T_1 which may tend to reduce it considerably and the approximation $\Delta g\beta H \gg b$ is of doubtful validity. Also, it should be noted that the value 3×10^9 sec^{-1} for $1/T_2'$ corresponds to a line-width an order of magnitude larger than that observed. However, spin–lattice relaxation appears to determine the line-width only at temperatures about 77°K, so the above arguments may be correct in principle if not in detail. From the observed line-width at 1·2°K we may estimate $\tau_c > 10^{-7}$ sec, so values in the range 10^{-8}, 10^{-9} sec do not seem unreasonable for the higher temperature range.

Further evidence supporting the variation of $1/T_2'$ with a term of the type $\Delta g\beta H + bI_z$ is provided by measurements at a microwave frequency of 6·8 Gc/s. As $\Delta g\beta H$ is proportional to ν, we expect the line-width ΔH to be a function of ν also and this is confirmed experimentally.

We may write the ratio of the widths of first and fourth hyperfine lines as

$$\frac{\Delta H_1}{\Delta H_4} = \frac{\Delta g\beta H + \frac{3}{2}|b|}{\Delta g\beta H - \frac{3}{2}|b|} = \frac{x+c}{x-c} = R,$$

where x is proportional to ν. If we take the amplitude D of the line derivative to be proportional to $1/(\Delta H)^2$, we have

$$\frac{D_1}{D_4} = \frac{1}{R^2} = R'.$$

At 9·2 Gc/s, $R_1 = 1{\cdot}91$, giving $x/c = 3{\cdot}20$. At 6·8 Gc/s this leads to $x/c = 2{\cdot}36$ and, hence, to $R_2 = 2{\cdot}47$. Thus $R_2/R_1 = 1{\cdot}29$ and, therefore, $R_2'/R_1' = 1/(1{\cdot}29)^2 = 0{\cdot}60$, which agrees surprisingly well with our experimental value $R_2'/R_1' = 0{\cdot}68 \pm 0{\cdot}10$. In fact, it is not strictly correct to take $D \propto 1/(\Delta H)^2$ on account of the hyperfine lines being only partially resolved from one another. Allowing for this increases the theoretical ratio R_2'/R_1' slightly, making the agreement even better. This quantitative success may be somewhat fortuitous but the variation of line-width with microwave frequency appears to be established fairly satisfactorily.

The width of the single Ni^{1+} line below 77°K is approximately 2 gauss, which is the usual spin–spin width observed for many other ions in MgO. Why there should be this difference between Ni^{1+} and Cu^{2+} is not clear.

§ 6. NUCLEAR MOMENT OF ^{61}NI

The sharpness and intensity of the double quantum line in the Ni^{2+} spectrum (at microwave powers of 100 mw and greater) have enabled us to detect for the first time, in an unenriched sample of nickel, hyperfine structure from the ^{61}Ni isotope (Orton, Auzins and Wertz 1960 b). The nuclear spin of ^{61}Ni was found by Woodbury and Ludwig (1958) to be 3/2, so we expect four hyperfine lines from ^{61}Ni nuclei. Each of these should have an intensity 0·31% of that of the main line from ^{58}Ni and ^{60}Ni (^{61}Ni having a natural abundance of 1·25%).

Careful investigation of the Ni^{2+} spectrum at high microwave power levels shows the presence of two weak, isotropic lines in the wings of the double quantum line and symmetrically disposed about it. They have the same width as the central line and show a similar dependence of intensity on microwave power, i.e. it varies as the square of the power rather than linearly. We assume that these are the outermost components of the hyperfine quartet, the inner pair being lost under the main line. Confirmation is provided by measurement of the weak line intensity with respect to the main one, the ratio being $(0{\cdot}38 \pm 0{\cdot}10)\%$ in satisfactory agreement with the anticipated value of 0·31%.

As described in § 3, the Co^{1+} spectrum consists of eight hyperfine components of width of the order of 20 gauss spaced approximately 55 gauss apart. At large microwave powers a sharp double quantum line appears at the centre of each broad one.

The spin Hamiltonian for this system in cubic field may be written:

$$\mathscr{H} = g\beta\mathbf{H}\,.\,\mathbf{S} + A\mathbf{I}\,.\,\mathbf{S} \quad \text{with} \quad S=1 \text{ and } I=7/2,$$

where g and A are both isotropic. The corresponding energy eigenvalues of $\mathscr{H}$ are given by:

$$W_{M,m} = Mg\beta H + MmA + \frac{1}{4}\frac{A^2}{g\beta H}\{[S(S+1)-M(M-1)][I(I+1)-m(m+1)] - [S(S+1)-M(M+1)][I(I+1)-m(m-1)]\}, \qquad \ldots\ldots(9)$$

where $M=1$, 0 or -1 and $m=7/2, 5/2\ldots -7/2$. From (9) we may obtain an expression for the positions of the eight double quantum lines, as follows:

$$^2H_m = H_0 - m\frac{A}{g\beta} - \frac{A^2}{2g^2\beta^2H_0}[I(I+1)-m^2]$$

where $H_0 = h\nu/g\beta$.

Using this expression and the measured values of ^2H_m we can evaluate g and A. The positions of the $\Delta M=1$, $\Delta m=0$ transitions are given by

$$^1H_m = H_0 - m\frac{A}{g\beta} - \frac{A^2}{2g^2\beta^2H_0}[I(I+1)-m^2 \pm m]. \qquad \ldots\ldots(10)$$

This shows they are expected to lie on either side of the double quantum lines and separated from them by $\pm A^2m/2g^2\beta^2H_0$ gauss, which amounts to 3·3 gauss for $m = \pm 7/2$ (i.e. at the ends of the hyperfine pattern) and decreasing toward the centre. In our case, the separation is much less than the line-width of the $\Delta M = 1$ transitions and is not observable.

One important feature of the discovery of Co^{1+} is that it enables us to calculate a fairly reliable value for the nuclear moment of ^{61}Ni by comparison between the two hyperfine splitting constants $A(^{59}Co)$ and $A(^{61}Ni)$, making use of the relation $A = \gamma\beta\beta_N(\bar{I}/r^3)$. The result of this calculation gives $\mu^{61} = 0{\cdot}31R$ n.m., where R is the ratio

$$\left(\frac{\bar{I}}{r^3}\right)(\mathrm{Co}) \Big/ \left(\frac{\bar{I}}{r^3}\right)(\mathrm{Ni})$$

(Orton, Auzins and Wertz 1960 b). To gain some idea of the probable size of R, we calculated it for the parallel case of V^{2+} and Cr^{3+} in MgO and found $R \simeq 0{\cdot}98$. This led us to suggest a value of $\mu^{61} = 0{\cdot}30 \pm 0{\cdot}02$.

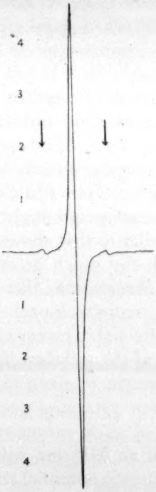

Fig. 5. Hyperfine structure from ^{57}Fe in the spectrum of Fe^{3+}. The lines shown result from the $M = -\frac{1}{2} \rightarrow \frac{1}{2}$ transition.

A further check on R may be obtained by comparing the hyperfine doublet from ^{57}Fe in the spectrum of Fe^{3+} in MgO with that from ^{55}Mn in the spectrum of Mn^{2+}. The nuclear spin of ^{57}Fe is $\frac{1}{2}$ (Ludwig, Woodbury and Carlson 1958) and the natural abundance 2·25%, so the hyperfine pattern associated with each fine structure line is expected to consist of two weak lines with intensity about 1% of that of the main one. This structure is clearly seen in Fig. 5 which shows a trace of the central ($M = -\frac{1}{2} \rightarrow \frac{1}{2}$) transition of the Fe^{3+} spectrum. The value of A^{57} is found to be $(11{\cdot}4 \pm 0{\cdot}1) \times 10^{-4}$ cm^{-1} and, comparing this with $A^{55} = 81{\cdot}0 \times 10^{-4}$ cm^{-1}, we find $\mu^{57} = 0{\cdot}092\,R$ n.m. A determination of μ^{57} by Ludwig and Woodbury (1960) from electron–nuclear double resonance of neutral iron atoms in silicon gave the value $0{\cdot}0903 \pm 0{\cdot}0007$ n.m. from which we again find $R \simeq 0{\cdot}98$, confirming the values used previously.

§ 7. PRODUCTION AND DECAY OF UNIVALENT IONS

A proper understanding of the production and decay of these univalent ions can only be obtained within the context of a complete study of all electronic changes taking place during different treatments. We have previously published an account of several of these (Wertz *et al.* 1958, 1959) and reference should be made to these papers for further details. Only one or two points will be touched on here.

On X-irradiation of MgO crystals, it is usually found that the intensity of the Fe^{3+} spectrum increases, indicating the liberation of electrons from Fe^{2+} ions. Another source of electrons in many cases is the production of hole centres at O^{2-} ions. These two processes may be represented by the equations:

$$Fe^{2+} \longrightarrow Fe^{3+} + \epsilon \qquad \ldots\ldots (11)$$

$$O^{2-} \longrightarrow O^{-} + \epsilon. \qquad \ldots\ldots (12)$$

The electrons may be trapped by other impurity ions such as (in this case) Fe^{2+}, Ni^{2+} and Co^{2+} to form the corresponding univalent ions or by Cr^{3+} to give Cr^{2+}.

The annealing behaviours of Fe^{1+}, Ni^{1+} and Co^{1+} are very similar. They are all fairly stable at room temperature in the dark but decay in a matter of a few days on exposure to daylight. Fe^{1+} and Co^{1+} decay very rapidly at 100°C (within $\frac{1}{2}$ hour) though Ni^{1+} decays surprisingly slowly at the same temperature. This behaviour is also very similar to that shown by the positive hole centre O^{-} and should be contrasted with the much greater stability of Fe^{3+}. It seems reasonable to infer from these observations that electrons released by the decay of Fe^{1+}, etc., are captured by O^{-} and this is probably the main reaction occurring, though some may be trapped by Fe^{3+}, reversing Eqn (11).

More detailed investigation of the stability of the univalent ions shows that it is dependent on the previous treatment given to the MgO crystals and suggests that the number of positive ion vacancies present in the crystal is of great importance. In the presence of such vacancies, which represent an effective negative charge, the stability of an M^{1+} ion will be less than in their absence, on account of the greater electrostatic potential energy. This suggestion is borne out by the following experiment.

Two MgO samples, containing iron, were cleaved from the same parent crystal and one of them, A, was heated *in vacuo* at 1200°C to reduce the number of positive ion vacancies present, while B was heated in oxygen to induce the opposite effect. They were then given identical doses of X-rays and examined at 20°K. A showed a much stronger Fe^{1+} spectrum than B and it proved to be considerably more stable. On exposure to daylight, the intensity in B was reduced by twenty times in two days, while that in A was reduced by only a factor of four after a week. Further evidence is provided by the fact that a sample which had been additively coloured, by heating in magnesium vapour, still showed an Fe^{1+} line some three years later, a remarkable increase in stability over untreated crystals.

The only impurity ions which have been detected in non-cubic crystal fields are Fe^{3+} and Cr^{3+} (Wertz and Auzins 1957, Griffiths and Orton 1959, Orton, unpublished) and these spectra have been interpreted as arising from ions associated with positive ion vacancies. Conversely, it is expected that univalent ions will be situated as far as possible from positive ion vacancies and this suggests that they will be likely always to occur in cubic field. This appears to be the case, experimentally.

Several papers (Weber 1951, Clarke 1957, Day 1953, Soshea, Dekker and Sturtz 1958, Peria 1958, Haxby 1957) have been published on studies of optical absorption, photoconductivity, and thermo-luminescence spectra of MgO crystals. The results have been interpreted in terms of a system of energy levels between the valency and conduction bands. Peria (1958) has criticized the interpretations suggested by earlier workers, finding that both positive and negative charge-carriers are involved. The recent work has been concentrated on interpreting the spectra in terms of iron-group impurity ions and points to the importance of iron. In particular, Peria postulated the existence of Fe^{1+} following x-irradiation.

The magnetic resonance results support these general conclusions and allow us to locate the different impurity levels in the MgO energy gap with rather more certainty. We have proposed an approximate order for several of them in an earlier paper (Wertz *et al.* 1958). It is of importance to try to put these results on a quantitative footing and we have made preliminary measurements on the univalent ions Fe^{1+}, Co^{1+} and Ni^{1+}. They decay under the influence of light from a tungsten filament lamp which appears to locate them all within 4 ev of the conduction band. By the use of suitable optical filters, we estimate the appropriate energies for Fe^{1+}, Co^{1+} and Ni^{1+} to be in the approximate region 2–3·5 ev. This is in agreement with the value for Fe^{1+} suggested by Peria from his photoconductivity results.

§ 8. CONCLUSIONS

(i) The ions Fe^{1+}, Co^{1+} and Ni^{1+} have been studied in irradiated MgO crystals containing the corresponding divalent ions. The stability of these centres is dependent on the concentration of positive ion vacancies in the crystal.

(ii) The electron spin resonance spectra of the univalent ions are very similar to their isoelectronic divalent analogues, Co^{2+}, Ni^{2+} and Cu^{2+}.

(iii) Evidence is presented that, in some cases, the crystal field shows small departures from exactly cubic symmetry.

(iv) The spectra of Cu^{2+} and Ni^{1+} indicate the existence of Jahn–Teller distortions which may be 'frozen-in' at low temperatures.

(v) The nuclear moment of ^{61}Ni is estimated as 0·30 nuclear magneton.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge helpful comments made by Dr. John Owen (Oxford). Dr. Richard Hansler of the General Electric Company, Cleveland, Ohio, and Dr. G. K. Finlay of the Norton Company, Chippawa, Ontario, have kindly supplied some of the magnesium oxide crystals used. We are particularly indebted to Mr. R. Pontinen who performed the measurements in the liquid helium range.

Electrical Breakdown of Gases: Ionization Growth in Air at High Pressures

By J. DUTTON, F. LLEWELLYN JONES and R. W. PALMER†

Department of Physics, University College of Swansea

MS. received 22nd *February* 1961

Abstract. The experimental conditions which have to be satisfied in order to measure ionization coefficients accurately at high values of the parameter pd (pressure × gap distance) are assessed. In an apparatus designed to fulfil these conditions, precision measurements were carried out for uniform electric fields E in air at values of the parameter pd up to 2300 mm Hg cm, which corresponds to a sparking potential of about 80 kv, thus extending the range so far investigated by Llewellyn Jones and Parker in 1950 and 1952. The results show that pre-breakdown ionization growth in air is due to the action of primary (α) and secondary (ω) ionization processes modified by the process of attachment a, and that significant space charge effects were absent. At a value of pd of 2300 mm Hg cm the sparking potential calculated ($81 \pm 1{\cdot}5$ kv) from the criterion (expressed in terms of the ionization and attachment coefficients) which gives the static sparking potential was in agreement, within the experimental error, with that ($79 \pm 0{\cdot}7$ kv) observed. It was also shown that the state of the cathode surface had a marked influence on the secondary ionization even at these higher values of pd.

For $35 \leqslant E/p \leqslant 40\,\mathrm{v\,cm^{-1}\,(mm\,Hg)^{-1}}$ and pressures between 400 and 1000 mm Hg, the apparent secondary ionization coefficient $\omega/(\alpha - a)$ was found to be a function of E/p alone, whereas the apparent primary ionization coefficient $(\alpha - a)/p$ showed a small, just detectable decrease with increasing pressure at a given value of E/p.

§ 1. Introduction

The use of increasingly higher voltages for the transmission of electrical power and in nuclear particle accelerators has stimulated considerable interest in recent years in the subject of the electrical breakdown of gases at pressures of an atmosphere and greater; the electrical properties of air are of particular interest because of its wide-spread use as an insulator. An understanding of the initiation, control or suppression of an electric spark can be achieved by a consideration of the basic physical processes leading to breakdown, and investigations of these fundamental processes are therefore of technological as well as of intrinsic interest. It is the purpose of this paper to describe and discuss accurate measurements of ionization coefficients in air for values of pd (pressure × electrode separation) up to those corresponding to breakdown in a 3 cm gap at atmospheric pressure for which the static sparking potential V_s is about 80 kv. This extends the range by a factor of about 3 above that previously investigated in this Department (Llewellyn Jones and Parker 1950, 1952; both to be referred to as I).

---

† Now at The English Electric Company, Chelmsford.

It has been shown in the earlier investigations that, provided the parameter E/p (E the electric field and p the gas pressure) is maintained constant to at least 0·1 %, the spatial growth of a pre-breakdown externally maintained ionization current for values of pd up to 760 mm Hg cm in a uniform field in air is in accord with the well-known equation

$$I = \frac{I_0 e^{\alpha d}}{1-(\omega/\alpha)(e^{\alpha d}-1)}. \qquad \ldots\ldots(1)$$

In this equation I_0 is a small ($\sim 10^{-13}$ A) externally maintained initial current from the cathode, α is the Townsend primary ionization coefficient and ω/α is a generalized secondary ionization coefficient which can be expressed as the linear sum of coefficients representing the action of many possible secondary ionization processes (Llewellyn Jones 1957, Chap. 4).

Equation (1) leads to the Townsend breakdown criterion expressed by equating the denominator of the right-hand side of (1) to zero. Using values of the coefficients α and ω valid over the whole range of current at the particular value of E/p, values of V_s calculated from this criterion for air have been found to agree with those experimentally observed, in that electrical breakdown could be produced for values of the applied potential exceeding V_s, but not when $V < V_s$ within the limits of experimental measurement.

Air having been considered, investigations were extended to other gases, nitrogen, (Dutton, Haydon and Llewellyn Jones 1952) and hydrogen (Crompton, Dutton and Haydon 1956, Davies, Dutton and Llewellyn Jones 1958), in which the detailed contribution of the various possible secondary ionization processes could be more readily assessed. In the course of these investigations the measuring techniques had been continuously improved, and in the present investigation these improved techniques were used both to repeat some of the early measurements (in order to obtain more accurate values of the ionization coefficients), as well as to extend measurements to higher gas pressures and sparking potentials.

As the value of the spark parameter pd_s (and therefore of V_s) increases, the value of the parameter E/p at sparking $= (E/p)_s$ decreases, so that the mean energy of the electrons also decreases (Llewellyn Jones 1957, Chap. 2). As a result of this decrease, the process of attachment of electrons to gas molecules can become important relative to the process of ionization of gas molecules by electron impact, and Eqn (1) is modified as shown by Penning (1938) and Geballe and Reeves (1953). If, as is likely to be the case in air, attachment occurs by one of the low energy processes such as three-bodied, collision stabilized or dissociative attachment (Massey 1950), the equation for ionization growth may be written

$$I = I_0\left[\frac{\alpha}{\alpha'}\exp(\alpha' d) - \frac{a}{\alpha'}\right] \Big/ \left[1 - \frac{\omega}{\alpha'}\{\exp(\alpha' d) - 1\}\right]. \qquad \ldots\ldots(2)$$

In this equation a is the coefficient of attachment defined, in exact analogy with the ionization coefficient α, such that the number of electrons attaching to neutral gas molecules when n electrons move a distance dx in the direction of the field is $nadx$; $\alpha' = \alpha - a$ is the apparent primary ionization coefficient and ω/α' is the apparent secondary ionization coefficient. It can be seen that this equation is analytically similar to Eqn (1), the only significant difference being the additive constant $-a/\alpha'$ in the numerator which gives rise to a downward curvature of the $(\log(I/I_0), d)$ graph at small values of d; moreover, the breakdown criterion, which becomes

$$1-\frac{\omega}{\alpha'}[\exp(\alpha' d)-1]=0, \qquad \ldots\ldots(3)$$

is analytically identical with the criterion valid in the absence of attachment, the apparent primary and secondary ionization coefficients α' and ω/α' replacing the coefficients α and ω/α in the Townsend criterion. The results of the present investigation are analysed in § 4 in terms of Eqns (2) and (3).

§ 2. CONSIDERATIONS UNDERLYING THE EXPERIMENTAL INVESTIGATION

2.1. *Physical Significance of the* $(\log(I/I_0), d)$ *Curves*

Measurements of the spatial growth of pre-breakdown ionization currents are conveniently expressed as graphs of $(\log(I/I_0), d)$, and the shape of such curves when determined accurately gives information concerning the mechanism by which ionization develops to set the criterion for determining the static breakdown potential.

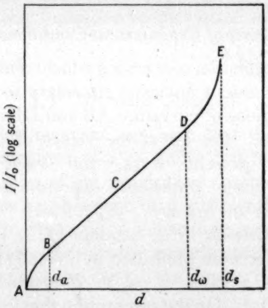

Fig. 1. The growth of ionization current represented by Eqn (2) when $a<\alpha$ and $\omega \ll \alpha$.

When the growth is due to the action in a uniform electric field of both primary and secondary ionization processes modified by attachment, the corresponding coefficients α', ω/α' and a are determined from the relation (2) which gives the form of the growth. When the coefficients a and ω are small compared with α', the main portion of the graph is nearly linear and the form of Eqn (2) is as given in Fig. 1. (The part BCD cannot, of course, be exactly linear when the coefficients a and ω are finite.) At values of $d<d_a$, $(\omega/\alpha')[\exp(\alpha' d)-1]\ll 1$, and the term a/α' becomes significant compared with $(a/\alpha')\exp(\alpha' d)$; the graph here shows a downward departure from linearity as indicated by AB. At large values of d, where $(\omega/\alpha')[\exp(\alpha' d)-1]$ increases to approach unity, the current increases more rapidly with distance and the graph curves up as shown by DE. The form of this increase gives a critical value d_s of d thus giving the static sparking potential $V_s=Ed_s$; the values of d_s, α' and ω then all satisfy the breakdown criterion (2) at the particular value of E/p.

On the other hand, if the criterion for the static sparking potential were set by a *kanal* or 'streamer' mechanism (Loeb and Meek 1941, Raether 1939, 1959) the form of the ($\log(I/I_0)$, d) graph would then be different at the larger values of d from that considered above. The criterion would be set by the sudden (in distance) attainment of a critical space charge field which would so enhance photo-ionization in the gas as to produce an extremely sharp increase of current. The ($\log(I/I_0)$, d) graph experimentally obtained should then be linear for gap distances d almost up to the critical sparking distance d_s, at which there would be almost a discontinuity, as I becomes larger extremely quickly.

As the gas pressure increases, in the usual experimental arrangements (see I), the ionization density increases due to a decrease in diffusion, so that any mechanism based on space charge distortion is more likely to be operative at high values of the gas pressure than at low values. It is clearly of interest, therefore, to extend measurements of ($\log(I/I_0)$, d) curves to still higher values of the parameter pd in order to investigate when and how any change occurs in the nature of the ($\log(I/I_0)$, d) curve up to the attainment of the sparking potential; such measurements would disclose any change in the basic mechanism by which the criterion giving the sparking potential is set as the parameter pd is increased.

2.2. *Choice of Experimental Conditions for Air*

In order to obtain information concerning attachment and secondary ionization processes in a particular case it is clearly necessary to choose the experimental conditions so that the regions of curvature AB and DE of the ($\log(I/I_0)$, d) curve can be fully investigated. For air at the values of the parameter pd_s under consideration in the present work, the value of $(E/p)_s$ is about 35 v cm^{-1} (mm Hg)$^{-1}$. Some published experimental data on ionization coefficients for this value of E/p are: $a/p \simeq 5 \times 10^{-3}$ (Harrison and Geballe 1953); $\alpha'/p \simeq 6{\cdot}0 \times 10^{-3}$ (Masch 1932, Sanders 1932), $\omega/\alpha' \sim 10^{-5}$ (I); values of α' and a of the same order were published by Prasad (1959). Insertion of these values in Eqn (3) gives a value of pd_s of 2000 mm Hg cm corresponding to $E_s/p = 35$ v cm^{-1}(mm Hg)$^{-1}$. On the assumption that ionization currents could be measured to within 5%, Eqn (2) shows that experimental detection and measurement of ω/α' is possible only for values of $pd > 1500$ mm Hg cm, and measurement of a only when $pd < 350$ mm Hg cm. If information concerning the secondary ionization is required, it is clear, therefore, that measurements have to be made within the range $1500 < pd < 2000$ mm Hg cm since 2000 is the upper limiting value of pd corresponding to spark breakdown. This range is indicated by the region d_ω to d_s in Fig. 1.

In the apparatus used in the present work the maximum gap distance d was 3 cm, so that a gas pressure of about 700 mm Hg cm was necessary to obtain values of pd up to 2000 mm Hg cm. Since a was only measurable when pd was less than 350 mm Hg cm, the detection and measurement of a was limited at a pressure of 700 mm Hg to gap distances less than 0·5 cm. However, no precise measurements could be made at distances below 0·3 cm because the error in setting these small distances in the large apparatus used would give a possible error in E/p larger than 0·1%, which was considered to be the largest permissible error in this parameter if accurate results were to be obtained. Hence, at the high gas pressures (700 mm Hg) which are essential to obtain the values of pd necessary for the determination of ω/α', only an extremely small section ($0{\cdot}3 < d < 0{\cdot}5$ cm) of the measured curve was available for the detection and measurement of a, and reliable evidence concerning this coefficient could not be obtained from such measurements alone. For these reasons, then, one single curve giving ($\log (I/I_0), d$) from small values right up to $d = d_s$ is not itself sufficient to obtain accurate values of α, ω and a. On the other hand, when the gas pressure is low, it is possible to choose the pressure so that the initial curved section AB of the ($\log (I/I_0), d$) graph together with a sufficient part BC of the linear section can be explored with the required accuracy as the gap distance d is increased up to 2 or 3 cm.

It was necessary in the present work, therefore, to study the current growths in two sets of conditions: first, at high pressures (400 mm Hg to 1000 mm Hg) to obtain the apparent primary ionization coefficient α' and the apparent secondary ionization coefficient ω/α', and then at low pressures (100 mm Hg to 300 mm Hg) at the same value of E/p to obtain the attachment coefficient a. Preliminary determinations of the coefficient a at low pressures have already been published (Dutton, Llewellyn Jones and Palmer 1959); work on the determination of the attachment coefficients in air and other gases is still in progress and will form the subject of a future paper. The present paper gives the detailed results of the determination of the apparent ionization coefficients α' and ω/α' carried out at high pressures.

2.3. *Method of Analysis*

It is perhaps advisable to point out here that the accurate experimental determination of coefficients such as α', ω and a depends not only on the use of cathode surfaces and samples of gas which have constant properties throughout the experiments and the employment of a sufficiently accurate technique of experimental measurement, but also on the soundness of the method of analysis used to deduce the coefficients from the experimental curves for ($\log (I/I_0), d$) obtained. The method of analysis used in the present investigation will therefore now be considered.

At values of $d > d_a$, when $a/\alpha' \ll (\alpha/\alpha') \exp(\alpha' d)$, Eqn (2) reduces to

$$I = I_0 \left(\frac{\alpha}{\alpha'}\right) \exp(\alpha' d) \Big/ \left[1 - \frac{\omega}{\alpha'} \{\exp(\alpha' d) - 1\}\right]. \qquad \ldots\ldots (4)$$

In theory it is possible to obtain the constants α' and ω/α' of this equation for any value of E/p from measurements of gas-amplified ionization currents at three suitable gap separations, provided I_0 remains constant throughout the measurements. As stated previously (Crompton, Dutton and Haydon 1956), the short-term stability of the ultra-violet light source used by them to produce the initial current I_0 was good (fluctuations $< 1\%$) over a period of minutes, but the long-term stability over a period of hours was not better than 10%. To take advantage of the accuracy now possible in the measurement of the ionization current (error $\sim 1\%$), it was therefore necessary to measure, in the present work, the initial externally maintained current as well as the gas-amplified current to which it gave rise, within a few minutes of one another. In practice it was found that in air, as in hydrogen, the (I, V) curve at a constant value of d did not attain a saturation value to give a constant value of I_0. It was therefore necessary to obtain a measure of I_0 by measuring the current I_c flowing at a low value of $E/p = (E/p)_c$. At this low value of $(E/p)_c$ no amplification took place in the gas and because of back scattering the magnitude of the current I_c was some fraction c of I_0. From measurements of the ratio I/I_c at three different electrode separations it is possible by means of a method of successive approximations to calculate accurate values of the coefficients α' and ω/α'.

§ 3. Apparatus and Experimental Procedure

Much of the apparatus used was the same as that used in previous investigations of current growth carried out in this Department; the voltage measuring system was, for example, that described in I, while the power supplies and current measuring system were those used by Crompton, Dutton and Haydon (1956). However, since the range of pressure investigated was increased to values somewhat above atmospheric, changes in the design of the ionization chamber and vacuum system were necessary and these will now be outlined.

3.1. *Ionization Chamber and Vacuum System*

The ionization chamber, which is shown diagrammatically in Fig. 2, was of the same general design as that described in I. The main differences from the earlier chamber were that the seals between the borosilicate glass chamber E and the anode support and base plate were such as to enable investigations to be made at gas pressures somewhat larger than atmospheric without leakage of the air from the chamber to the atmosphere. These seals were maintained by pulling the glass on to the metal, which was coated with Apiezon M grease, by means of steel flanges F_1 and F_2. The electrodes used were also different from those of I and were machined and polished to a profile suggested by Bruce (1947) to ensure that the field would be uniform and a maximum over the central section of the electrodes. The purpose of the metal strips L_1 and L_2 on the borosilicate glass chamber is discussed in § 3.2.

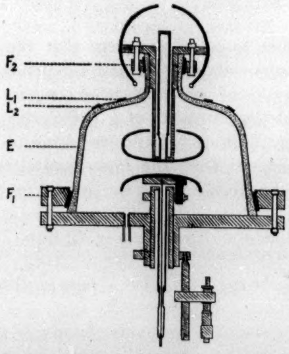

Fig. 2. Diagram of the ionization chamber for use at gas pressures greater than atmospheric.

The vacuum system was similar to that used previously, and as in I; the usual care was taken to avoid contamination due to mercury and other condensable vapours by placing a cold trap adjacent to the ionization chamber. This trap was always maintained at liquid air temperature when the ionization chamber was connected to the rest of the system. The main modification to the vacuum system was the use of special spring-loaded glass taps in all those parts of the system which were subjected to internal pressures greater than atmospheric.

The air, which was supplied by the British Oxygen Company as free from CO_2 ($<1{\cdot}0$ volumes per million), water vapour ($<0{\cdot}00056\,\mathrm{g\,m^{-3}}$) and SO_2 (nil), was admitted to the chamber very slowly, passing over P_2O_5 and through two cold traps maintained at the temperature of liquid air. The pressure was measured by a mercury manometer connected to the rest of the system through two cold traps maintained at liquid air temperatures. As a further precaution, the gauge was evacuated only through its own system and no flow of gas from gauge to ionization chamber took place.

3.2. *Experimental Procedure*

The ionization chamber was evacuated by an oil diffusion pump for several hours through cold traps maintained at the temperature of liquid air. The room temperature was stabilized with thermostats and electric heaters in order to specify accurately the density of the gas sample admitted.

The high resistances (10^7 to $10^{11}\,\Omega$) in the current measuring system were calibrated to within 1%.

The electrode separation was set at a predetermined value and the ratio I/I_c was measured in the following way. A voltage, chosen to make the value of $E/p=(E/p)_c$, was applied across the electrodes from a stable (fluctuations about 1 in 10^5) 6 kv supply, and the current I_c then measured. The actual values of I_0 which were obtained in the experiments are given in Fig. 4 in terms of I_c; the ratio I_0/I_c lay between about 1·6 and 4 depending on the value of $(E/p)_c$. The area of cathode irradiated was about $0{\cdot}25\,\mathrm{cm}^2$, so that the initial current densities J_0 were about $10I_c\,\mathrm{A\,cm^{-2}}$. I_c was of the order of 10^{-13} A. The effects of the very small residual fluctuations in the voltage supply were eliminated by means of a circuit similar to that previously described (Dutton, Haydon and Llewellyn Jones 1952). It was found necessary to maintain the metallic strip guard rings L_1 and L_2 on the outside of the chamber at earth potential during this measurement, otherwise movement of charge over the surface due to the application of a potential to the anode gave rise to induced currents in the measuring system. After measuring I_c, the voltage applied to the electrodes was then changed to give the required value of E/p, and the gas-amplified current I was then measured within about two minutes of the measurement of I_c. Since I (10^{-12} to 10^{-8} A) was larger than I_c it was possible to use a 100 kv supply (Crompton, Dutton and Haydon 1956) with a slightly lower stability (fluctuations 1 in 10^4) for this measurement. At these higher voltages it was not practicable to earth the metal strips L_1 and L_2 because of their proximity to the high tension terminal, but then any induced currents due to the movement of charge on the glass walls were negligible compared with the comparatively large gas-amplified current. After the measurements of the gas-amplified currents the strips L_1 and L_2 were again earthed and the whole procedure repeated. An experimental check was always made to make sure that the application of the high voltage required for the measurement of the gas-amplified current I did not affect the subsequent measurement of the much smaller I_c. It was usually found that it was necessary to wait for a period of about ten minutes after earthing L_1 and L_2 until induced currents became negligible compared with I_c. Having obtained several values for I/I_c at a particular gap separation, the gap distance d was then changed and the above procedure repeated.

It was considered that the employment of the above experimental technique was necessary and sufficient in order to obtain accurate and reproducible data.

§ 4. Results and Discussion

4.1. *Preliminary Results*

In order to ascertain whether the apparatus was working satisfactorily a preliminary set of measurements was carried out using a value of E/p of 45 v cm^{-1} (mm Hg)$^{-1}$ for a gas pressure of 200·3 mm Hg (all pressures are corrected to 20°c throughout this paper), and using an aluminium cathode. The curve obtained is shown in Fig. 3 where it is compared with the results given in I.

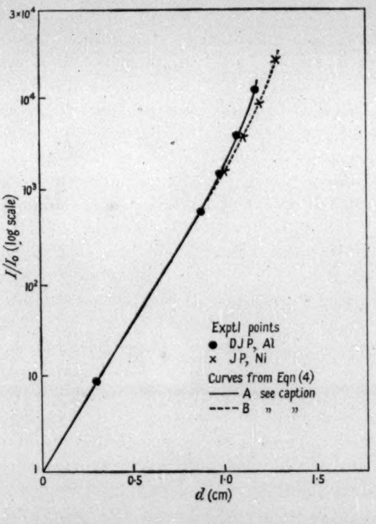

Fig. 3. Experimental and theoretical (log (I/I_0), d) curves for air at $E/p = 45$ v cm^{-1} (mm Hg)$^{-1}$ and $p = 200$ mm Hg using Ag and Ni cathodes. DJP, present work with Al cathode; JP, Llewellyn Jones and Parker (1952) with Ni cathode; A, $\alpha'/p = 3{\cdot}53 \times 10^{-2}$, $\omega/\alpha' = 160 \times 10^{-6}$; B, $\alpha'/p = 3{\cdot}45 \times 10^{-2}$, $\omega/\alpha' = 84 \times 10^{-6}$.

It can be seen that the growth was well represented by Eqn (4) with values of α'/p and ω/α' of $3{\cdot}53 \times 10^{-2}$ and $1{\cdot}6 \times 10^{-4}$ respectively. The value of α' is thus in agreement (within $2\frac{1}{2}$%) with that obtained in I, viz. $3{\cdot}45 \times 10^{-2}$, but the value of ω/α' is nearly double that ($0{\cdot}84 \times 10^{-4}$) obtained in I using a nickel cathode. The secondary ionization coefficient clearly depends on the nature of the cathode surface, and this indicates that secondary ionization processes acting at the cathode play an important role in breakdown at these values of pd ($\sim$250 mm Hg cm), a fact which was later confirmed at even higher values of pd (see § 4.3).

Although it was possible to make a significant analysis of the curve shown in Fig. 3, a certain effect was noted at the larger distances which was similar to that observed in the previous experiments in air (I) and nitrogen (Dutton, Haydon and Llewellyn Jones 1952); this effect was the gradual increase of the gas-amplified current with the time (some minutes) during which it was allowed to flow. In the present experiments with $E/p = 45$ v cm^{-1} (mm Hg)$^{-1}$ the effect, however, was very small, but in further experiments at $E/p = 40$ v cm^{-1} (mm Hg)$^{-1}$ and $p = 400$ mm Hg it was found that a gas-amplified current of 2×10^{-9} A increased by as much as 40% if allowed to flow for one minute. Measurement of the initial current before and after the passage of the gas-amplified current showed that the externally maintained current had increased by about 15%. The previous investigations in this laboratory of such effects had shown them to be due to the presence of oxide layers on the cathode surface, and in nitrogen it had been found possible to remove the effect altogether by a glow discharge treatment of the electrode in that gas. Clearly, in the present experiments in air, glow discharge treatment in the same gas would only thicken the oxide layer. Glow discharge treatment in another gas, e.g. H_2, which could remove the oxide layer, was also thought to be undesirable because of the adsorption of that gas on surfaces and its subsequent desorption as an impurity into the air being investigated.

Accordingly, the aluminium cathode was changed for one of silver on which any oxide layer so formed is much less tenacious. Experiment showed that this silver cathode was completely satisfactory, confirming the above view of the cause of the effect, and no increase of ionization current with time was observed even at currents of the order of 10^{-7} A. The apparatus was then considered to be in a state where reliable information about the ionization coefficients and mechanism of breakdown could be obtained.

4.2. *Detailed Results*

Measurements were made, using the silver cathode, for $35 \leqslant E/p \leqslant 40$ v cm^{-1} (mm Hg)$^{-1}$ for pressures between about 400 and 1000 mm Hg and values of pd up to 2300 mm Hg cm. About fifty ($\log(I/I_c), d$) curves were obtained and a selection of typical curves covering the range of values of pressure and E/p used is given in Fig. 4 (*a*)–(*d*). The form of all these curves is in agreement with Eqn (4), and this is consistent with the view that the growth was in all cases due to the action of primary and secondary ionization processes in the absence of any significant space charge effects. Accordingly, values of the appropriate coefficients α'/p and ω/α' can be found from the curves; these values are given in Fig. 4 for the respective graphs.

Numerical analysis of the experimental results on the growth of currents was carried out for the data obtained for a single sample of gas at a given pressure and also for the data for different samples at the various pressures. Typical results are given in Table 1. From this table it can be seen that the various values of α'/p relating to a given gas sample all agreed to within ± 2% but that the agreement between the values of α'/p from *different samples* was only to within ± 12%. These samples of gas were not all at the same pressure so that some of this variation may well be due to a pressure effect probably involving a (see § 4.3), but at a given pressure the variation is attributable to slight differences in the composition of the

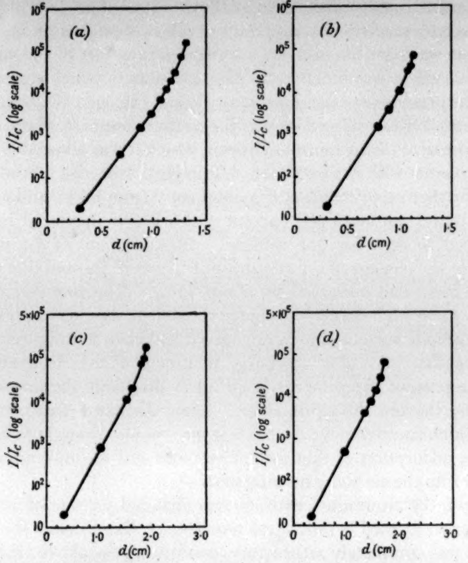

Fig. 4. Typical ($\log (I/I_c)$, d) curves in air using an Ag cathode: the points represent experimental values and the full line curve is calculated from Eqn (4) with the values of α'/p and ω/α' given below.

(*a*) $E/p = 40$ v cm^{-1} (mm Hg)$^{-1}$, $p = 402$ mm Hg, $\alpha'/p = 19 \times 10^{-3}$, $\omega/\alpha' = 33 \times 10^{-6}$, $I_c \sim 5 \times 10^{-13}$ A.

(*b*) $E/p = 38$ v cm^{-1} (mm Hg)$^{-1}$, $p = 700$ mm Hg, $\alpha'/p = 12{\cdot}6 \times 10^{-3}$, $\omega/\alpha' = 30 \times 10^{-6}$, $I_c \sim 3 \times 10^{-13}$ A.

(*c*) $E/p = 36$ v cm^{-1} (mm Hg)$^{-1}$, $p = 700$ mm Hg, $\alpha'/p = 7{\cdot}6 \times 10^{-3}$, $\omega/\alpha' = 26 \times 10^{-6}$, $I_c \sim 5 \times 10^{-13}$ A.

(*d*) $E/p = 35$ v cm^{-1} (mm Hg)$^{-1}$, $p = 1008$ mm Hg, $\alpha'/p = 5{\cdot}1 \times 10^{-3}$, $\omega/\alpha' = 65 \times 10^{-6}$, $I_c \sim 2 \times 10^{-13}$ A.

$J_0 \simeq 10 I_c$ A cm^{-2}. (The cathode in (*d*) had been affected by the passage of a high voltage spark.)

samples, which are shown up in this work. In former investigations on air (Paavola 1929, Masch 1932, Sanders 1932, Hochberg and Sandberg 1942, Llewellyn Jones and Parker 1950, 1952, Harrison and Geballe 1953, Prasad 1959) the error in determining α' was probably about 5 to 10% so that the degree of variation disclosed in the present work would not have been readily detectable in the previous work. However, it is interesting to note that the mean values of α'/p obtained from sample to sample in the present investigation are in general agreement with previous results, as is shown in Fig. 5 which gives all published results for comparison.

In order to make a significant comparison between the values of the secondary ionization coefficient ω/α' obtained at various values of E/p and at various gas pressures, it is clearly necessary not only to measure α'/p to a sufficient order of

accuracy to allow the determination of ω/α' to within the required limits of say 20%, but also to consider samples of gas for which the primary coefficient is as nearly as possible the same. A suitable set of results for this purpose is given in Table 2 which will now be discussed.

E in v cm^{-1}, p in mm Hg, α' in cm^{-1}, d_s in cm.

(Note: a spark occurred between run 9 and run 10—see text.)

4.3. *Ionization Coefficients and Gas Pressure*

It can be seen from Tables 1 and 2 that although the gas pressure was changed by more than a factor of 2 from 400 mm Hg to 1000 mm Hg there were only small changes in the values of either α'/p or ω/α' at a given value of E/p.

Thus at $E/p = 35$ v cm^{-1} (mm Hg)$^{-1}$ the mean value for the determinations of α'/p at pressures of about 700 mm Hg was $5{\cdot}3\times 10^{-3}$, while the mean for determinations at pressures of about 1000 mm Hg was $4{\cdot}8\times 10^{-3}$ (see Table 1). Again at $E/p = 36$ v cm^{-1} (mm Hg)$^{-1}$ the mean value of α'/p from measurements at about 700 mm Hg is $7{\cdot}6\times 10^{-3}$, while that from measurements at about 1000 mm Hg is $7{\cdot}2\times 10^{-3}$. These results are consistent with the view that there is a small, just detectable variation of α'/p with pressure, but that this variation is very nearly within the limits of the experimental error when different samples of gas are involved. Thus a dependence of a/p on pressure can not be eliminated, and as such a dependence is significant when considering the type of attachment process occurring in these conditions this effect will be considered in fuller detail elsewhere.

Considering now the secondary ionization coefficient, it can be seen from Table 2 that there is no significant variation of ω/α' with pressure. This result is in marked contrast to the case of hydrogen, in which gas it has been shown (Davies, Dutton and Llewellyn Jones 1958) that ω/α is strongly dependent on gas pressure as well as on E/p. The observed reduction of ω/α with increasing pressure in hydrogen has been shown to be due to the decrease in photoelectric emission as a result of the greater destruction of excited molecules in collision with neutral gas molecules at higher gas pressures. Since no such marked dependence of ω/α' on gas pressures occurs in air, it is concluded that *either* photoelectric effects in air at high values of pd are negligible, *or* that the cross section for the destruction of excited molecules in collisions of the second kind is very small.

These are some indications, however, from other investigations (Dutton, Haydon, Llewellyn Jones and Davidson 1953) that the photoelectric effect at the cathode plays an important role in ionization growth in air at pressures of about one atmosphere, so that it is reasonable to conclude that the cross section for collisions of the second kind in air is small.

4.4. *Secondary Ionization and the State of the Cathode Surface*

It has been shown in §4.1 that the nature of the cathode surface plays an important role in the growth of ionization in air at $pd_s \sim 250$ mm Hg cm. Since it has been established (Dutton, Haydon and Llewellyn Jones 1952, Davies, Dutton and Llewellyn Jones 1958) that the occurrence of a spark can have profound local effects in changing the properties of the cathode surface, care was taken in this work to try to avoid the production of a spark throughout the course of the investigation of current growth. On one occasion (at the end of run 9, Table 2), however, an inadvertent reduction of pressure established the conditions for sparking, and a short discharge occurred which, however, was quickly quenched by the voltage drop in the 5 MΩ limiting resistor. Use was made of this event to investigate the effects of the resulting change in the cathode at the highest values of pd_s used in this work.

It can be seen at once from Table 2 that there is a significant difference between the value of ω/α' obtained at the two different gas pressures at $E/p = 35$ v cm^{-1} (mm Hg)$^{-1}$, although there is no evidence from the other results of a dependence of ω/α' on gas pressure. It seemed likely, therefore, that this change in ω/α' was due to a change in the state of the cathode surface due to the spark between run 9 and run 10. That this was in fact the case was confirmed by two further experiments. First, using the cathode which had been sparked in air, measurements were carried out at $E/p = 35$ v cm^{-1} (mm Hg)$^{-1}$ at a pressure of 703·8 mm Hg; the results showed a high value of ω/α' (58×10^{-6}) characteristic of the sparked surface. The cathode was then removed and cleaned and another set of results obtained using the cleaned cathode at a pressure of 701·6 mm Hg; in this case the value of α'/p was found to be $4{\cdot}9 \times 10^{-3}$ and of ω/α' was 12×10^{-6}, i.e. the low value characteristic of the polished surface before sparking.

It has previously been pointed out (I) that investigation of ionization discharges in air involves complications due to the oxidation of the electrode in the process. This causes difficulty even in measuring extremely small pre-breakdown currents, as the electrical properties of the cathode are greatly influenced by the presence of thin oxide films (Llewellyn Jones and Morgan 1953). In the original work in air (I) two effects of the oxidation of the cathode were found. One was the change of secondary emission attributed to the presence of positive ions on an oxide layer, and the other effect (important in growth experiments) was due to the reduction of the photoelectric efficiency of the cathode and the consequent reduction of the magnitude of the current I_0 maintained by the external radiation. Even when care was taken to maintain and monitor the intensity of the radiation from the stabilized arc, the emission I_0 was considerably reduced during the course of the experiments by oxidation of the cathode surface; indeed, cases have been previously reported (I) in which the photoelectric effect had been practically eliminated. These effects were considerable at pressures less than atmospheric but on account of the occurrence of higher current densities at the higher pressures, the effects are likely to be greatly enhanced at the high gas pressures used in the present work. For these reasons, as has been previously mentioned, care was taken to avoid the production of an electric spark, and therefore the experimental determination of the sparking potential was not undertaken until the other work was completed, in order to preserve the consistency of the electrode properties during the growth experiments. On completion of the final ($\log(I/I_c)$, d) curve mentioned in § 4.4, the gap distance was gradually increased (adjusting the voltage to keep the ratio E/p constant at 35 v cm^{-1} (mm $\text{Hg})^{-1}$) until a spark occurred, as observed visually and also by the anode voltage collapse. The current, however, was not allowed to rise beyond a few μA and was quickly quenched by the presence of a 5 MΩ resistor in the anode circuit. The sparking potential obtained experimentally in this way was $79 \pm 0{\cdot}7$ kv. This value agreed well with the value of $81 \pm 1{\cdot}5$ kv at a $pd_s = 2300$ mm Hg cm calculated by inserting the measured values of the ionization coefficients in Eqn (3). A subsequent determination would have served little purpose in these circumstances because ω/α' would have changed significantly as shown in Table 2. Thus it can be seen that, even at the highest value of the parameter pd_s so far investigated, the growth of pre-breakdown ionization, and the subsequent setting of the criterion for the static sparking potential of air in uniform fields, is a consequence of the action of primary and secondary ionization processes, modified by the process of attachment, in accordance with the Townsend-type equations (3) and (4).

§ 5. CONCLUSIONS

Measurements of pre-breakdown ionization currents show that the spatial growth of pre-breakdown ionization at values of pd_s up to 2300 mm Hg cm is a consequence of the action of primary, α, and secondary ionization, ω, processes in the absence of significant space change, but modified by the process of attachment a. This extends the upper limit of the value of pd_s previously investigated in this way. Using the values of α' $(=\alpha - a)$ and ω/α' deduced from the observed growth of pre-breakdown ionization currents at a value of $E/p = 35$ v cm^{-1} (mm $\text{Hg})^{-1}$ in the theoretical sparking criterion (Eqn (3)), the sparking potential $(E/p)pd_s$ was calculated for uniform fields and was found to be equal to that measured within the limits of the experimental error. This is consistent with the view that the criterion which sets the static sparking potential is the consequence of the same ionization and attachment processes which led to the spatial growth, and there is no evidence from these results of the introduction of any new process (i.e. one not conforming to Eqn (4)) for setting the sparking potential in air within the full range of pd_s up to 2300 mm Hg cm.

It is also shown that while both the ionization coefficients α'/p and ω/α' are almost solely dependent on the parameter E/p alone in the range $400 < p < 1000$ mm Hg cm (in that within this range any pressure dependence is small), there appears to be a small decrease of α'/p with increasing pressure which is just greater than the experimental error. The dependence of ω/α' on E/p alone indicates that the destruction of excited molecules in collisions of the second kind does not appear to be an important process in ionization growth in air as it is in hydrogen.

Even at these high values of pd_s in air, the state and nature of the cathode surface have considerable influence on the apparent secondary ionization coefficient. This indicates that the production of secondary electrons at the cathode can play an important role in the mechanism setting the criterion for breakdown even at voltages up to about 80 kv.

ACKNOWLEDGMENTS

The authors acknowledge with gratitude the assistance which has been provided by the Electricity Supply Research Council in the provision of apparatus. We should also like to thank F. M. Harris for assistance with the experimental work in the later stages of the investigation. One of us (R.W.P.) is grateful to the University College of Swansea for the award of a Postgraduate Scholarship 1955–59 which enabled him to take part in the investigation.

On Resonant Charge Transfer in Ionized Dense Gases

BY IOVITZU POPESCU
Physics Institute of the RPR Academy, Bucharest

MS. received 22nd February 1961

Abstract. When a feebly ionized gas is compressed until the mean distance between atoms decreases down to approximately less than ten times an atomic radius, the positive charge is not carried by the ion in motion but rather jumps resonantly from atom to atom. This statement is arrived at by comparing the mean time of flight of the positive ion between two collisions with the resonant transfer time of the electron from the atom to the next positive ion.

THE simple hypothesis (Sena 1946) concerning the special role of the resonant charge transfer in the kinetics of positive ions through parent gases, seems to be sufficiently tested[†]. The relations derived from the corresponding model of ions moving in 'relays' generally hold true only for relatively small densities N of gas atoms, when the mean distance $N^{-1/3}$ is much larger than the radius of the effective collision region $(Q/\pi)^{1/2}$, Q being the transfer cross section.

The present paper briefly analyses the case $N^{-1/3} \simeq (Q/\pi)^{1/2}$; accordingly, a qualitatively different picture concerning the motion of positive charge in gases will occur.

Suppose a relatively small number of singly ionized atoms in the parent gas to be scattered. The positive charge will jump resonantly from one atom to the other with a frequency so high that the configuration of the atoms ought to be practically considered as frozen. If we use the simple model of the hydrogen molecule ion (Pauling and Wilson 1935) for the system consisting of two neighbouring ions and the electron interchanging between them, the corresponding lapse of time of the jump will be

$$\tau = h/|\Delta E| \qquad \ldots\ldots(1)$$

ΔE being the energy difference between the symmetric and antisymmetric combination of the wave functions localized on each ion; now, for our purpose, it will be sufficient to use the asymptotic expression $(R \gg a_0)$

$$\Delta E = -\frac{4}{3}\left(\frac{137^2}{mc^2}\right)^{1/2} \alpha^3 (2I)^{3/2} \frac{R}{a_0} \exp\left[-\alpha\left(\frac{137^2 \times 2I}{mc^2}\right)^{1/2} \frac{R}{a_0}\right] \ldots\ldots(2)$$

where R is the distance between the two ionic centres, I the first ionization energy, a_0 the radius of the first Bohr orbit, c the velocity of light in vacuum, m the rest mass of the electron, and α a correction factor of the hydrogen-like wave function, used in this computation, which is consistent with the different experimental data of the transfer cross section (Popescu and Ionescu 1960).

[†] For further literature about this problem see Badareu and Popescu (1959), Dalgarno (1958), Kagan (1958), Kushnir, Paliuh and Sena (1959), and Badareu, Popescu and Iova (1960).

The relations (1) and (2) lead to a practically exponential dependence of τ on R, such that the transition of the positive charge occurs with the greatest probability at the nearest atom. Once the starting point has been selected, the charge will travel a well-determined path, the mean distance between atoms being minimal and equal to $\beta N^{-1/3}$ all along the path. The empirical value of β, determined by means of models, in the three-dimensional case is approximately 0·56. A typical spatial model used consists of 400 'atoms' (plasticine balls a few millimetres in diameter, suspended by threads at a distance z from the x, y plane), arranged randomly in a volume of $90 \times 90 \times 90$ cm^3; the coordinates x, y, z were extracted from an urn containing 90 numbers. In the two-dimensional case the minimal mean distance between atoms is approximately $0{\cdot}75N^{-1/2}$ and in the one-dimensional case obviously it is N^{-1}.

Without entering into further details, we shall in the following approximate the real situation replacing R by $0{\cdot}56N^{-1/3}$.

In order to estimate the limit beyond which the movement of the positive charge in gases is better described by the model above than by that generally used (according to which the positive charge is accompanied all along by the atomic rest) we shall compare τ with the mean time

$$\tau_1 = 1/vQN, \qquad \ldots\ldots(3)$$

the latter being the time of flight of the positive ion between two successive collisions, where the transfer cross section decreases slowly with the increase of the relative ion–atom velocity v (Popescu and Ionescu 1960). Hence, an orientative quantitative picture is given in the Table, in which, for a series of gases at 300°K and vapours, are given the distances R_1, R_{10}, R_{50} and the corresponding pressures p_1, p_{10}, p_{50}, for which τ_1/τ has the values 1, 10, 50 respectively (R is given in units of the corresponding atomic radius a; this is defined as the radius of the sphere which contains 75% of the external electron cloud and is computed with the help of the hydrogen-like wave function corrected consistently by means of experimental charge transfer cross section data, as shown by Popescu and Ionescu (1960); the correcting factor α, used in the computation of both τ and a, is given in the third column of the Table).

The result is that, as a general feature, for a given $\tau_1/\tau \geqslant 1$, R/a has almost the same value for all the gases and vapours shown in the Table. At the same time, R/a may be compared with the corresponding radius of the transfer cross section $(Q/\pi a^2)^{1/2}$. Should the condition $\tau_1 \simeq \tau$ hold, then the quantitative description of the movement of the positive charge is hampered by its travelling along the path, partially carried by the ion and partially jumping; for $\tau_1 \gtrsim 10\tau$, however, the conduction of the positive charge is in many ways similar to that which seems to occur on semiconductor impurities at low temperatures.

Thus, for pressures of $p > p_{10}$ approximately, the diffusion coefficient $D = R^2/3\tau$ and the mobility, using Einstein's relation, increases practically exponentially with decrease of R:

$$\mu = 0{\cdot}1e/kTN^{2/3}\tau. \qquad \ldots\ldots(4)$$

Atom	I (ev)	α	$a \times 10^8$ (cm)	$(Q/\pi a^2)^{1/2}$	R_1/a	p_1 (atm)	R_{10}/a	p_{10} (atm)	R_{50}/a	p_{50} (atm)	
He	24·5	0·70	1·10	3·2	6·6	16·8	4·8	45·0	3·0	190·0	300°K
Ne	21·5	0·68	1·20	3·4	7·2	10·1	5·4	23·8	3·8	70·0	
A	15·7	0·71	1·36	3·8	7·1	7·2	5·4	16·4	3·8	46·4	
Kr	14·0	0·72	1·42	4·0	7·2	6·1	5·4	14·1	4·0	36·2	
Xe	12·1	0·69	1·59	4·1	7·1	4·5	5·4	10·3	4·0	25·5	
Hg	10·4	0·66	1·78	4·2(900°K)	7·0	10·0(790°K)	5·1	24·0(900°K)	3·5	100·0(1070°K)	
K	4·3	0·60	3·10	4·2(1100°K)	6·5	3·8(1190°K)	4·4	13·5(1380°K)	—	—	
Cs	3·9	0·42	4·60	3·2(1000°K)	6·7	0·8(960°K)	4·7	3·0(1130°K)	3·0	10·0(1420°K)	

The mobility μ_1 which the positive ion might have under these conditions is negligibly small:

$$\mu_1 = e/(2\pi MkT)^{1/2}QN, \qquad \ldots\ldots(5)$$

where M is the ion mass, k Boltzmann's constant and T the absolute temperature (Badareu and Popescu 1959).

Finally one may say that the customary treatment of the movement of positive ions in parent gases can no longer be applied to concentrations of gas atoms greater than approximately $(0{\cdot}56/R_{10})^3$. The crude model outlined above may, under these conditions, be considered as a first approximation.

Measurements of Rotational Energy Distributions in Ionic Collisions

By E. M. REEVES† and R. W. NICHOLLS
Department of Physics, University of Western Ontario, London, Canada

MS. received 28*th July* 1960, *in final form* 27*th April* 1961

Abstract. The measured rotational intensity distribution of N_2^+ First Negative bands excited by 1 MeV protons indicates that the rotation of the molecules is not greatly affected by the collisions. Measured rotational temperatures compare favourably with laboratory temperatures. Similar observations on N_2^+ bands excited by 1 to 3 kev Li^+ ions show that these collisions appear to cause a marked departure from Boltzmann distribution of rotational energies. Energy levels of high and of low quantum numbers are enhanced in population.

§ 1. INTRODUCTION

THE rotational energy distribution of molecules in a gas is determined by the environment to which they are subjected. In principle it is possible to learn something of the environment, and of the collision processes taking place in the gas, by measuring the rotational energy distribution of the molecules. One convenient means of doing this is through the measurement, in emission or absorption, of the intensity distribution in rotational lines in band spectra of the molecules concerned.

It is well known (Herzberg 1950) that if thermal equilibrium exists, and if there is no significant amount of self-absorption in the gas, that the intensity $I_{K'K''}$ of the $K'K''$ line of an emission band is given by

$$I_{K'K''} = \text{const.}\, S_{K'} \nu_{K'K''}^{4} \exp\left[-\frac{hcB_{v'}K'(K'+1)}{kT_{\text{rot}}}\right] \qquad \ldots\ldots(1)$$

and thus that a plot of $\log I_{K'K''}/S_{K'}$ against $K'(K'+1)$ will be linear and of slope $-hcB_{v'}/kT_{\text{rot}}$ from which the rotational temperature T_{rot} may be found. T_{rot} may also be inferred from the value of K' at the line of maximum intensity of the band (Johnson 1952). Should the plot be non-linear its shape will nevertheless be determined by the collision processes which cause a departure from the Boltzmann distribution.

Such simple ideas have been used extensively to study excitation processes in the aurora from intensity distributions in bands of N_2^+ (Vegard 1956, Vegard, Tönsberg and Kvifte 1951, Petrie 1953, Sheppard and Hunten 1955, Vallance-Jones and Harrison 1955, Vallance-Jones and Hunten 1960). A number of laboratory experiments have also been performed in recent years in which spectroscopic observations have been made upon 30 to 150 kev ion and electron beams in various gases (Vegard 1924, Branscomb, Shalek and Bonner 1954, Fan 1956, Carleton 1957, Roesler, Fan and Chamberlain 1958) in order to understand more of the collision processes which give rise to luminosity in the beams and in the aurora. In many of these experiments, temperatures have been inferred from the intensity distribution of rotational levels of N_2^+ bands.

---

† Now at Harvard College Observatory, Cambridge, Massachusetts.

In the present paper, intensity measurements upon N_2^+ bands excited by low energy (1–3 kev) lithium ions and high energy (0·5–1·5 Mev) protons and other hydrogenic ions (H_2^+, H_3^+) are discussed.

§ 2. EXPERIMENTAL

2.1. H^+, H_2^+, H_3^+ *Ion Beams*

Measurements of rotational temperatures of N_2^+ produced by the passage of ion beams of 0·5 to 1·5 Mev through N_2 were made in collaboration with Dr. D. A. Bromley using the facilities of the 3 Mev Van de Graaff accelerator at Atomic Energy of Canada Ltd., Chalk River. The ion beam was collimated by a series of 1/16 in. apertures which also acted as baffles in a differential pumping system. The experimental arrangements have been described elsewhere (Reeves, Nicholls and Bromley 1960). The nitrogen gas target pressure in the collision chamber was maintained at 58 μHg as previous work had shown that intensities of N_2^+ features varied linearly with pressure up to this pressure.

The luminous beam was focused upon the slit of a Bausch and Lomb 1·5 m grating spectrograph and the (0, 0) λ 3914 Å band of the N_2^+ First Negative system photographed on Kodak 103aF film at a reciprocal dispersion of 15 Å mm^{-1}. The emulsion response in 15 Å region of the band head was determined using the internal calibration available from the 2·1 intensity alternation between adjacent lines of the R branch.

2.2. Li^+ *Ion Beams*

Lithium ion beams of 1–3 kev were produced thermionically in an accelerator which has been described in greater detail elsewhere (Pleiter 1956, Nicholls and Pleiter 1956, Reeves 1960). Luminous beams in N_2 were focused upon the slit of an f/3·5 Applied Research Laboratories Raman 3 prism spectrograph, and the λ 4278 (0, 1) N_2^+ First Negative band photographed in each case on Kodak 103aF film at a reciprocal dispersion of 12 Å mm^{-1} in about 10 hours. The response of the emulsion was determined with the aid of a density wedge. Earlier experiments had shown that band intensities increased linearly with pressure up to the pressure of 25 μHg at which the collision chamber was maintained.

§ 3. RESULTS

3.1. 0·5 *to* 1·5 *MeV Beams of* H^+ *and* H_3^+ *in* N_2

A typical $\log I_{K'K''}/K'$ against $K'(K'+1)$ plot for R-branch lines of the (0, 0) N_2^+ First Negative band excited by 1·0 Mev protons in N_2 is shown in Fig. 1. Compensation has been made for intensity alternation between adjacent spectrum lines so as to obtain a single plot for the whole R branch rather than two parallel plots for even and odd K' respectively. The linearity of the plot in Fig. 1 suggests the existence of a Boltzmann distribution in the rotational energy levels of the upper ($B^2\Sigma_u^+$) state of the transition. The rotational temperature 276 ± 10°K derived from the slope agrees well with the laboratory temperature of 291°K.

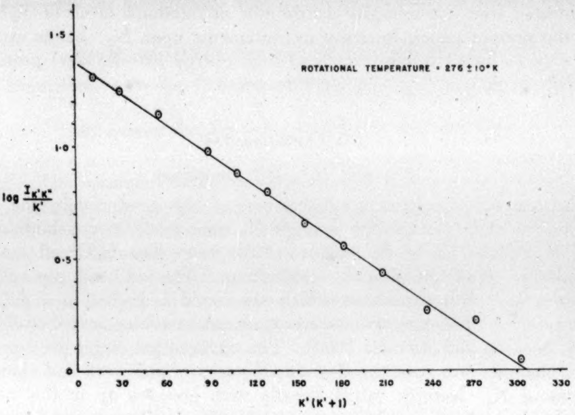

Fig. 1. Variation of log $I_{K'K''}/K'$ with $K'(K'+1)$ for lines of the (0, 0) N_2^+ First Negative band (λ 3914 Å) excited by a beam of 1 MeV protons in N_2 at a pressure of 50 μHg.

Temperatures of 301 ± 80°K were also inferred from the K' value of the line of maximum intensity, of the same band, excited by 0·5 MeV protons and 1·5 MeV H_3^+ ions. The uncertainty of ± 80°K was due to an uncertainty of ± 1 in K'.

The linearity of Fig. 1 together with the good agreement between laboratory and rotational temperatures indicate that hydrogenic ion excitation of N_2^+ at energies of about 1 MeV has little apparent effect upon the rotational energy distribution of the target molecules.

This does not necessarily appear to hold in less energetic ionization collisions by heavier ions as pointed out below.

3.2. 1–3 *keV Beams of* Li^+ *in* N_2

A microdensitometer trace of the rotational structure of the N_2^+ First Negative (0, 1) λ4278 band excited in a 2 kev Li^+ beam in N_2 is shown in Fig. 2. It is typical of results obtained in the 1–3 kev energy range. The first two rotational lines of the R branch are obscured by the Li I line at 42 723 Å. Marked differences in profile are observed between traces such as Fig. 2 and those of bands excited by protons. The R branch rises steeply to a maximum at R(6) and falls to zero at R(16) for proton excitation. It is greatly extended in lithium ion excitation and overlaps the (1, 2) band at 4236·5 Å. (A similar effect in unresolved bands has been discussed by Smyth and Arnot (1930) in their comparison between electron and canal-ray excitation of N_2^+.) The perturbation at $K' = 39$ (Childs 1939) caused by the $A^2\Pi$ state of N_2^+ is also seen in Fig. 2 by the displacement of the P(38) line near R(14).

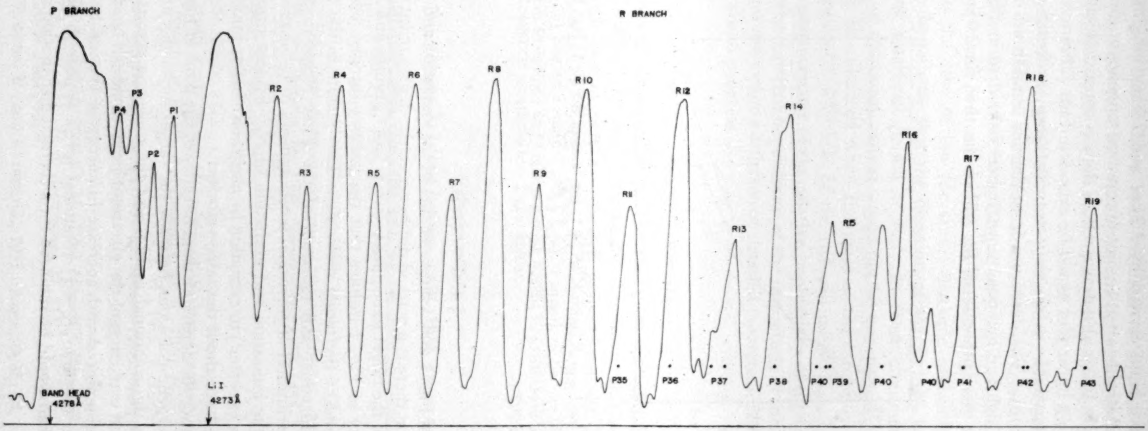

Fig. 2. Microphotometer trace of the (0, 1) N_2^+ first negative band (λ 4278 Å) excited by a beam of 2 kev lithium ions in N_2 at a pressure of 24 μHg.

Comparative plots are shown in Fig. 3 of $\log I/K'$ against $K'(K'+1)$ for the (0, 1) First Negative band excited by 3·2 kev and 2·0 kev lithium ions. The curves have been arbitrarily set at a point of common tangency at $K'=7$, through which point a straight line is also drawn whose slope is consistent with laboratory temperature. Such a linear plot would be expected if the lithium ion excitation collisions were comparable in all respects with those involving protons and other hydrogenic ions. The departure from thermal equilibrium in a manner which emphasizes high and low quantum numbers is evident in Fig. 3 and the effect appears to be more pronounced for 3·2 kev ions than for 2·0 kev ions.

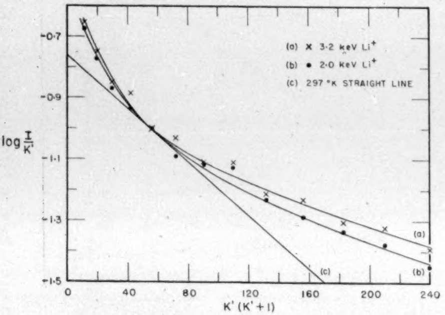

Fig. 3. Variation of $\log I_{K'K''}/K'$ with $K'(K'+1)$ for lines of the (0, 1) N_2^+ First Negative band (λ 4278 Å) excited by beams of (*a*) 3·2 kev lithium ions and (*b*) 2 kev lithium ions, in N_2 at a pressure of 24 μHg. (*c*) is a straight line equivalent to the laboratory temperature of 297°K.

§ 4. Discussion

A comparison of Figs 1 and 3 indicates that in the ionization and excitation of N_2 by ionic collision there is a marked difference in the degree of interaction with rotational motion of the target molecules between 1 Mev protons and 2 kev lithium ions. The linearity of Fig. 1 implies that the protons interact solely with the electron charge cloud of the target molecule. This results in the formation of $N_2^+(B^2\Sigma_u^+)$ by ionization, and radiation of the First Negative bands. The thermal energy distribution of rotational levels appears to be unaffected in such collisions. Thus the ionization and excitation of N_2^+ by Mev protons is quite similar (as might be expected) to excitation by electrons of a few hundred electron volts energy which have about the same velocity.

On the other hand, the departure from linearity of the plots of Fig. 3 indicates that in the less energetic collisions between the target molecules and Li^+ ions, a severe change in the rotational motion and the molecule results in addition to the ionization and excitation of the electron charge cloud. The effect appears to become more pronounced with increase in energy of the ion beam, and the high ($K'\sim 10$) and the low ($K'\sim 1$) rotational levels appear to become more highly populated than would be required for a thermal distribution at laboratory temperature.

Similar qualitative observations of Smyth and Arnot (1930) in canal-ray excitation of N_2^+ bands have been referred to above. Oldenberg (1934) specifically cites excitation by ions as one case in which the internal motion of a target molecule may be significantly changed by collisions. He also points out (Oldenberg 1957) that in eccentric atomic collisions, the collision duration may be significantly longer than that predicted by elementary considerations as a result of the effect of the molecular rotation on molecular potentials. The collision duration may in fact be as long as one rotational period of the diatomic molecule temporarily formed during the atomic collision. Extension of his arguments to the case of ion (or atom)–diatomic molecule collisions makes plausible the hypothesis that the duration of the Li^+–N_2 collisions may also extend to one rotational period of N_2. In these circumstances, the severe perturbation of rotational motion would not be unexpected. This effect would also probably be enhanced when the mass of the ion beam projectile ($Li = 6$, $H = 1$) is comparable with that of the reduced mass ($N_2 = 7$) of the molecular target. The enhancement of the relative populations of high and low rotational energies and the apparent dependence of the magnitude of the effect upon energy of the ion beam still awaits a satisfactory detailed theoretical explanation. Further experiments are in progress.

On the Extra Reflections in Electron Diffraction Patterns from Thin Evaporated Films of Some of the Face-centred Cubic Metals

BY KANWAR BAHADUR AND P. V. SASTRY
National Physical Laboratory of India, New Delhi

Communicated by D. W. Pashley; MS. received 13*th February* 1961

Abstract. Polycrystalline thin films of a number of face-centred cubic metals have been prepared by evaporation on to rock-salt, followed by annealing. In a number of cases, transmission electron diffraction patterns show, in addition to the normal face-centred cubic rings, some extra rings which fit well with those which would be expected from a hexagonal close-packed form of the metals. No hexagonal close-packed rings are observed with aluminium films, and this is correlated with the absence of stacking faults on transmission electron microscope images of aluminium films.

MANY workers have reported the presence of extra rings and spots in the transmission diffraction patterns from thin films of some face-centred cubic metals like gold and silver. The earliest observation of these extra reflections in polycrystalline films was made by Finch, Quarrell and Wilman (1935), see also Quarrell (1937). They explained these rings on the hypothesis of 'basal plane pseudomorphism'. Recent electron diffraction studies have proved beyond doubt that the 'basal plane pseudomorphism' hypothesis is not valid (Pashley 1956). Many of the abnormal streaks and spots observed in the diffraction patterns obtained from single crystalline films of these metals have been attributed to twinning of the lattice and these results have been confirmed by a number of workers (Lassen 1934, Kirchner and Lassen 1935, Bruck 1936, Goche and Wilman 1939, Ogawa, Watanabe and Fujita 1955). However, some spots in these patterns also still remain unidentified (Ogawa, Watanabe and Fujita 1955).

We have examined in detail the transmission diffraction patterns from polycrystalline films of some of the face-centred cubic metals and alloys. The films, about 250 Å in thickness, were obtained by evaporating the pure metals (Au, Ag, Cu and Al of 99·99% and Cd of 99·95% purity) in a vacuum of approximately 10^{-4} mm on freshly cleaved rock-salt substrates maintained at temperatures between 150–250°c. These films on rock-salt substrates were subsequently heat treated at the same temperature for one to two hours, without breaking the vacuum. The transmission diffraction patterns in all cases were recorded at room temperature. A typical transmission diffraction pattern from a gold film is shown in the Plate (Fig. 1 (*a*)). All the extra lines in this pattern fit perfectly into the scheme of closest packed hexagonal structure with its lattice spacing value $a = a^*/\sqrt{2}$ (where a^* is the normal lattice spacing of the face-centred cubic structure) and $c/a = 1{\cdot}63$. The d values of these extra reflections are listed in the Table given below. These results are in agreement with the results of Hirsch, Kelly and Menter (1955) obtained from experiments on beaten gold foil.

Extra Diffraction Rings due to Hexagonal Close-packed Lattice in Thin Evaporated Films of Gold

hkil	*d* (obs.) (Å)	*d* (calc.) (Å)
$10\bar{1}0$	2·50	2·52
$10\bar{1}2$	1·70	1·72
$10\bar{1}3$	1·32	1·33
$20\bar{2}2$	1·02	1·10

We have obtained similar results in the case of thin films of silver, copper, α-solid solution of silver–cadmium and the complete solid solution of silver–gold.

It is well known that stacking faults and dislocations can occur in metals of face-centred cubic structure by a slip occurring in the (111) family of planes. These dislocations can be split up into two partials separated by a faulted region which can be regarded as a thin sheet of lattice of closest-packed hexagonal type (Heidenreich and Shockley 1948). Such stacking faults have been observed in electron microscope examination of thin films of gold (Pashley 1959). In view of the above evidence we attribute the extra reflections observed in our diffraction patterns to reflections from those faulted regions having the closest-packed hexagonal structure. We have failed to observe these extra lines in transmission diffraction patterns from polycrystalline films of pure aluminium (Plate, Fig. 1 (*b*)). This is again in conformity with the electron microscope evidence of the failure to observe the above type of stacking faults in thin films of aluminium (Whelan, Hirsch, Horne and Bollman 1957, Pashley 1959).

ACKNOWLEDGMENTS

We are thankful to Dr. D. W. Pashley, Tube Investments Research Laboratories, England, for his helpful comments and The Director, National Physical Laboratory of India, for permission to publish this note.

The Michelson Stellar Interferometer : A Phase Sensitive Variation of the Optical Instrument

By R. C. JENNISON
Nuffield Radio Astronomy Laboratories, Jodrell Bank, University of Manchester

*Communicated by A. C. B. Lovell; MS. received 10th June 1960,
in revised form 7th April 1961*

Abstract. A short summary is given of a variation of the Michelson stellar interferometer. This is an adaptation of part of the principle of the radio-frequency phase-sensitive interferometer developed by the author in 1958 and it enables the phase component associated with the structure of the source to be determined. The technique may also be used to determine the correct relative amplitude of the visibility function of the star at two spacings even when phase and amplitude errors are present.

§ 1. INTRODUCTION

IN an original paper on the stellar interferometer Michelson (1890) predicted that the fringes should reverse in the second maximum of the visibility function from a typical symmetrical source. This reversal is not easy to observe in practice, especially when scintillations are present, and it is even more difficult to determine the smaller changes of phase associated with asymmetry in a stellar object. If both the phase and amplitude of the fringes can be measured in all position angles it is possible to obtain a unique solution for the distribution of brightness over the object and hence to determine its structure. This has been achieved in a radio-frequency system where it was necessary to nullify the errors due to variations in attenuation and phase of the limbs of the interferometer (Jennison 1958). The full realization of the radio-frequency technique in an optical instrument would require the incorporation of a phase switching device and an arrangement to continuously rotate the phase of the fringes. These refinements are omitted from the present design in which the main feature of the radio-frequency system, the use of three slit apertures, is applied to an optical telescope.

§ 2. THE OPTICAL ARRANGEMENT

The optical arrangement is shown in Fig. 1 (*a*) and (*b*). The objective of the telescope is preceded by a slotted mask as shown in Fig. 1 (*a*). For higher resolution it may be fitted with a beam and extending mirrors comprising three parallel slits, one in the centre of the system and the other two spaced equally to either side (Fig. 1 (*b*)). The length of the slits is arranged so that the slits form three independent pairs as shown in the end elevation (Fig. 2 (*a*)). The eyepiece of the instrument is a cylindrical lens whose axis is aligned with the length of the objective slits.

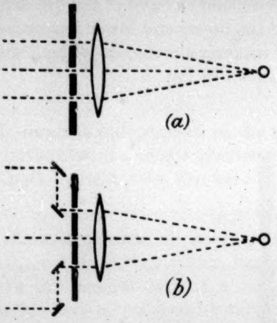

Fig. 1. (*a*) The ray paths along the axis of the system. The spacing of the slits may be varied by rotating the slit system about an axis through the central slit. (*b*) The extension of the system by mirrors to form an instrument of wider aperture. The circle on the right represents a cylindrical eyepiece.

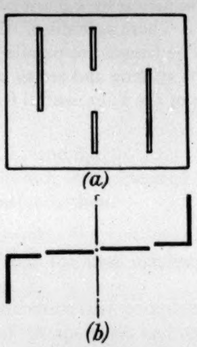

Fig. 2. (*a*) The arrangement of the slits in the plane of the telescope objective. (*b*) The arrangement of the slits in echelon to compensate for the foreshortening of the individual slits.

§ 3. PRINCIPLE OF OPERATION

The visibility of the fringe system formed by any pair of slits is in general a complex function given by the component of the Fourier transform of the brightness distribution across the source at the spacing concerned. Thus, if the angular distribution of the source is $F(\theta)$, the Fourier transform $f(x)$ of the distribution may be expressed as

$$f(x) = \int_{-\infty}^{\infty} F(\theta) \exp(2\pi i x\theta)\, d\theta,$$

where $f(x)$ is in general complex; having a modulus at any value of x corresponding to the visibility criterion given by Michelson,

$$|f(x)| = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}$$

and a *phase angle* $\xi(x)$ corresponding to the rotation of $f(x)$ in the complex plane as a result of the partial resolution of certain features of the source (Jennison 1961). Thus a source consisting of two eccentric components, one of which is broad and the other small but bright, would result in a rotation of the phase angle $\xi(x)$ and a corresponding shift in the position of the fringes as x is extended. Viewed with a conventional Michelson stellar interferometer, the effect is to cause the fringe pattern to become centred on the small source at the value of x where the larger source is resolved. The phase information may therefore be determined in principle by observing the position of the fringes relative to the source at all values of the slit spacing but this operation is neither easy nor accurate. The system of three slits described above enables the phase components to be determined without reference to the absolute position of the source.

Illumination by a point source produces three systems of fringes in the field of view. These systems of fringes are separated along the axis of the cylindrical lens. The fringes are parallel to this axis, and the upper and lower sets occur at twice the spacing and are so phased that their maxima are aligned with alternate maxima of the finer central fringes. This is shown in Fig. 3.

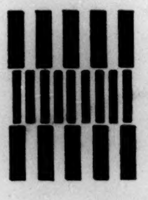

Fig. 3. The appearance in the field of view of the fringe patterns from a point source.

In the general case of an arbitrary distribution of brightness across the star the phase of the fringes will be such that they are not aligned and the phase difference may be determined at the larger spacing relative to the shorter spacings. The expression for the intensity distribution of the image along the x axis, perpendicular to the fringes, when monochromatic light passing through one slit interferes with that through another will be of the form

$$I(x)\{1+|f(x)|\cos[\omega(x)+\xi(x)+\Delta]\} \qquad \ldots\ldots(1)$$

where $I(x)$ is the intensity in the diffraction pattern of the slits and is only slowly varying with x, $\omega(x)$ is the spatial frequency of the fringe system, Δ is the resultant phase difference of phase errors associated with the two slits and $|f(x)|$ and $\xi(x)$ are, as before, the amplitude and phase components of the Fourier transform of the brightness distribution across the source.

We shall refer to the expression within the square brackets as the argument of the fringe system. Thus, if the three slits A, B and C have associated phase errors δ_A, δ_B and δ_C the argument of the fringes when light from slit A interferes with that from slit B will be

$$\omega(\mathrm{AB})+\xi_{\mathrm{AB}}+\delta_A-\delta_B. \qquad \ldots\ldots(2)$$

The argument of the fringes when C interferes with B will be

$$\omega(\mathrm{BC})+\xi_{\mathrm{BC}}+\delta_B-\delta_C. \qquad \ldots\ldots(3)$$

The argument of the fringes formed between A and C will be

$$\omega(\mathrm{AC})+\xi_{\mathrm{AC}}+\delta_A-\delta_C. \qquad \ldots\ldots(4)$$

Adding expressions (2) and (3), the arguments of the fringe systems AB and BC, we obtain

$$\omega(\mathrm{AB})+\omega(\mathrm{BC})+\xi_{\mathrm{AB}}+\xi_{\mathrm{BC}}+\delta_A-\delta_C=\omega(\mathrm{AC})+\xi_{\mathrm{AB}}+\xi_{\mathrm{CB}}+\delta_A-\delta_C. \quad \ldots\ldots(5)$$

Comparing expressions (4) and (5) it will be seen that they represent the arguments of two fringe systems of identical frequency and relative phase

$$\phi = \xi_{AC} - (\xi_{AB} + \xi_{BC}) \qquad \ldots\ldots(6)$$

and if AB = BC

$$\phi = \xi_{AC} - 2\xi_{AB}. \qquad \ldots\ldots(7)$$

This result is independent of the phase errors δ_A, δ_B and δ_C.

In the case of a simple symmetrical source distribution, if the spacings AB and BC both lie before the first zero of the Fourier transform, then

$$\xi_{AB} = \xi_{BC} = 0.$$

In these circumstances $\phi = \xi_{AC} = 0$ if AC lies within the first maximum and $\phi = \xi_{AC} = \pi$ if AC lies within the second maximum.

In the general case of a complex source distribution the complete phase function may be mapped by varying the spacings of the apertures and recording the relative phases of the fringe systems. It should be noted that it is not necessary for the spacing AB to equal spacing BC in order to measure the phase, provided that, if AB $\neq$ BC, both the fringe systems AB and BC are displayed and this sum is recorded.

The amplitude of the Fourier transform of the source distribution may be obtained in the usual way from the visibility of the fringes and it has been shown (Jennison 1958) that if errors exist in the amplitude function as a result of scintillation or other defects these may be removed in principle by a comparison of the visibilities of the three fringe systems and the simultaneous recording of the intensity from any one of the slits.

The brightness distribution across the source may be reconstructed from the Fourier transform of the amplitude (visibility) function and the associated phase function derived in the manner indicated above.

In a small laboratory instrument the spacing of the apertures is varied by rotating the objective mask about an axis through the central slit. The slits are arranged in echelon to reduce the foreshortening of the individual slits at very small angles of incidence, Fig. 2 (*b*). This arrangement enables the instrument to be used with very short projected slit spacings and hence large angular features may be examined.

Provided that the fringes can be distinguished, the technique enables a unique solution of the source structure to be computed subject only to the limitation of detail imposed by the restriction of maximum spacing. It also provides an analytical method for the removal of the effect of scintillation upon the computed visibility.

Extension of Series in the First Spectrum of Indium (In I)

By W. R. S. GARTON and K. CODLING
Department of Physics, Imperial College, London

MS. received 27th March 1961

Abstract. The ultra-violet absorption spectrum of indium vapour has been photographed by means of a 3-metre grating spectrograph. Lines of the series $5^2P_{1/2}{}^0$–$n^2S_{1/2}$ ($n=9$ to 27), $n^2D_{3/2}$ ($n=7$ to 33), $5^2P_{3/2}{}^0$–$n^2S_{1/2}$ ($n=10$ to 29), $n^2D_{3/2}$ ($n=8$ to 19), $n^2D_{5/2}$ ($n=8$ to 34), have been measured against good wavelength standards. A short sixth series is identified as $5^2P_{1/2}{}^0$–$n^2P_{1/2}{}^0$. The accepted value for the ionization potential has been confirmed. From a consideration of the character of the perturbations in the n^2D series we conclude that the $sp^2\,{}^2D$ term lies above the ionization limit, instead of, as formerly supposed, below.

---

§ 1. Introduction

An earlier paper by one of us (Garton 1954) has dealt with the absorption spectrum of indium vapour, observed by means of 1 metre vacuum-grating and medium-quartz spectrographs, combined with a small carbon-tube furnace as absorption vessel. That paper was concerned mainly with the portion of the absorption spectrum, in the Schumann ultra-violet, due to transitions from the ground doublet $5s^25p\,{}^2P^0$ to levels of configurations sp^2, sp*nl*, and with the effects of autoionization. In addition, the paper reported measurements, made at the modest resolution of the medium-quartz spectrograph, on a total of thirty-two lines of the series $5^2P_{1/2}{}^0$–$n^2S_{1/2}$ ($n=13$ to 24) and $5^2P_{1/2}{}^0$–$n^2D_{3/2}$ ($n=11$ to 30).

Since 1954 the instrumental equipment available for studies of ultra-violet absorption spectra has been considerably supplemented in this laboratory, in particular by a very good 3 metre normal incidence vacuum spectrograph and a large King furnace. Aside from extension of such studies to other elements (cf. Garton and Codling 1960, Codling 1961), it has proved profitable to make fresh observations on some of the spectra previously examined at low dispersion, and the present paper concerns one such case. The new photographs show good development of the five strong series $5^2P_{1/2}{}^0$–$n^2S_{1/2}$, $n^2D_{3/2}$, $5^2P_{3/2}{}^0$–$n^2S_{1/2}$, ${}^2D_{3/2,\,5/2}$ and traces of a sixth—presumably $5^2P_{1/2}{}^0$–$n^2P_{1/2}{}^0$—series. Though the two series, which locate the $n^2S_{1/2}$, $n^2D_{3/2}$ levels, reported on previously have been extended by only a few further members, the new measurements have been made against better wavelength standards at higher dispersion, and are much more reliable. Also, it has been possible to resolve the ${}^2D_{3/2,\,5/2}$ terms up to $n=33$, as compared with the previous limitation to $n=15$. The series measurements confirm the accepted value for the ionization potential of In I (Paschen 1938). It is believed that the unidentified $sp^2\,{}^2D$ term lies above the series limit, instead of below as hitherto supposed, and gives a curious course to the photo-ionization cross section of the atom.

§ 2. Experimental

The main experimental details are to be found in other papers (Garton and Codling 1960, Codling 1961). In the present case the King furnace was held at a succession of temperatures between 950 and 1300°c, and the absorption spectra were photographed on the background continuum provided by a flash-tube (Garton 1953). Wavelength standards were obtained by means of a copper hollow cathode placed in line with furnace and flash-tube. Though the spectral region of interest lay entirely above 2000 Å, the 3-metre spectrograph was nevertheless evacuated, with the advantages of avoidance of air tremor and of the need for reduction of air wavelengths to vacuum wavenumbers. Measurements of lines on several plates were made on a Zeiss Abbe comparator and our wavelengths are believed good to 0·004 Å.

§ 3. Results and Interpretation

The results of the measurements on the sharp and diffuse series of In I are listed in Tables 1 to 5. The term values T have been calculated on Paschen's (1938) limit, 46669·93 cm^{-1}, quoted by Moore (1958), and originally derived from the 5^2D–n^2F^0 series. The Figure shows quantum defect plotted against T.

The $n^2S_{1/2}$ series is very regular, and practically Rydbergian from $n=9$ onward; this provides additional support for the value of Paschen's limit. The members of this term series below $n=9$ not shown in the Figure, exhibit a progressive drop in the Rydberg denominator to the value 2·2185 for $n=5$.

A check on the accuracy of the measurements is provided by the notably good agreement in Tables 1 and 2 between the two values of $n^2S_{1/2}$, and of $n^2D_{3/2}$ in Tables 3 and 4, based respectively on combinations with $5^2P_{1/2}{}^0$, $5^2P_{3/2}{}^0$. Our estimate of measurement error is thus confirmed, viz. 0·004 Å, or about 0·1 cm^{-1}.

Indium sharp and diffuse series: quantum defect plot.

The course of the quantum defect plots for the diffuse series, in the Figure, is interesting. The rapid fall for higher members of the $^2D_{3/2}$ and $^2D_{5/2}$ series strongly suggests the presence of a perturbing term beyond the series limit (Shenstone and Russell 1932). Of the terms of the $5s5p^2$ configuration, ^4P lies deep (Paschen 1938, Sawyer and Lang 1929, Lansing 1929) ^2S and ^2P lie well above the ionization limit (Garton 1954); the remaining term ^2D, has hitherto been presumed to be deep, but has not been certainly identified. Paschen (1938) argued that the term accepted as 4^2F^0 was actually $5s5p^2\,^2D$, as follows. In In II and Al II, it is well established that $p^2\,^1D_2$ has been absorbed into the low members of the s*n*d series, either of the first two members of which can indifferently be thus assigned. By analogy, and because of a large splitting anomaly in the ^2D terms between $n = 5$ and $n = 7$, it might be thought that $5s5p^2\,^2D$ lay deep amongst $5s^2nd$, except that the quantum defects of the latter series would then acquire unlikely values. Paschen therefore looked elsewhere for $5s5p^2\,^2D$, and suggested that previous identification of an emission line pair λλ2518, 2666, as $5^2P_{1/2}{}^0{}_{,3/2}$–4^2F^0 was incorrect, and rewrote 4^2F^0 as $5s5p^2\,^2D$. This placing has, however, been questioned by Edlén (Moore 1958), who has stated that the original identification of 4^2F^0 was correct. Confirmation that Paschen indeed wrongly identified $5s5p^2\,^2D$ is found in the fact that the line pair mentioned is not obtainable in absorption, even at high vapour densities in the furnace. Moreover, a quantum defect plot of the whole ^2D series, i.e. an extension of the curves of the Figure to the right (to $n = 5$), shows no large perturbation in term position amongst the low series members, though the strong splitting anomaly exists amongst the first few members ($n = 5, 6, 7$).

The following seems a likely answer to these difficulties. From the course of the n^2D plots of the Figure we place $5s5p^2\,^2D$ above the ionization potential, but lying closer to it than do $5s5p^2\,^2S$, ^2P. Support for this is to be found in the rather curious intensity distribution of the photoionization continuum $5^2P_{1/2}{}^0$–E(s, d) which we have photographed in the region between the series limit and the very diffuse group 5^2P^0–$5s5p^2\,^2S$, ^2P. This absorption continuum can be seen on two of the spectra in the plate accompanying the earlier paper (Garton 1954). What is perhaps not so clear on that plate is the fact that the absorption continuum does not set in strongly at or close to the series limit, but increases in strength from there towards shorter wavelengths, to a flat maximum at about 2026 Å, that is, some 2700 cm^{-1} beyond the limit. It seems probable that we have here a case of local enhancement of the photoionization cross section, similar to cases observed in Ca, Sr, Ba (cf. Garton and Codling 1960, Garton, Pery-Thorne and Codling 1960), arising from presence of an extremely diffuse term, in the present instance, $5s5p^2\,{}^2D$.

We have yet, however, to explain the splitting anomaly in the diffuse series, already mentioned. The details of this are: $\Delta 5^2D = 23{\cdot}3\ \mathrm{cm}^{-1}$, $\Delta 6^2D = 49{\cdot}89$, $\Delta 7^2D = 25{\cdot}34$. Apparently either $\Delta 5^2D$ is smaller or $\Delta 6^2D$ larger than it would be in absence of a perturbation. It is tempting to try to explain this anomaly in the following way.

In the theory of configuration mixing we distinguish electrostatic and magnetic (spin–orbit) interaction affecting levels of similar parity and identical J-value (Condon and Shortley 1951). For magnetic interaction to occur it is necessary that at least one electron in the two configurations concerned shall have the same value of n, in which case a perturbation can take place between widely separated terms (Shortley 1932)†. On this basis $5s5p^2\,{}^2D$ can interact magnetically with $5s^2\,5d\,{}^2D$, but not with 6d, 7d ${}^2D$ etc., it being remembered that the closed subshell $5s^2$, with $j = 0$, has no magnetic moment.

We may be thus inclined to interpret the splitting anomaly in In I in the sense that it is $\Delta 5^2D$ that is reduced, as a result of magnetic interaction with $5s5p^2\,{}^2D$, below the value it would have in the unperturbed series. The general fall in the quantum defect plots of the Figure, for higher members of the diffuse series is, on the other hand, to be ascribed to electrostatic interaction with $5s5p^2\,{}^2D$.

Similar splitting anomalies to that discussed exist in the Al I and Ga I spectra, and may be similarly explicable. However, the above qualitative argument concerning spin–orbit configuration interaction is revealed as too naïve when we proceed to Tl I, in which 6^2D shows no fine-structure anomaly, although $6s6p^2\,{}^2D$ has been located as a very diffuse term at $12740\ \mathrm{cm}^{-1}$ above the series limit (Beutler and Demeter 1934). Another distinction between Tl I and the earlier spectra of the same group concerns the relative position of $sp^2\,{}^4P$. In Al, Ga and In this term lies deep, and close to the first diffuse term. In Tl I, $6s6p^2$ has ${}^4P_{1/2}$ below and the other two quartet levels slightly above the ionization limit, whereas the term value of 6^2D is about $13000\ \mathrm{cm}^{-1}$. Another, possibly relevant, peculiarity is that in Pb II 6^2D is inverted, for no obvious reason. It is possible that our qualitative argument concerning magnetic interaction of the sp^2 and s^2d configurations has some validity, but should be given proper expression in a more complex form which would involve the $sp^2\,{}^4P$ term. On balance, the evidence seems to point to $sp^2\,{}^2D$ in In I having a position above the series limit, though we are then left with the necessity for proper explanation of the course of the $s^2d\,{}^2D$ intervals.

Other perturbations, of less striking nature, for which we cannot offer explanation, are noticeable in the intensities of the 5^2P^0–n^2D absorption lines. As shown in Table 4, the $5^2P^0_{3/2}$–$10^2D_{3/2}$ line is missing altogether. Also, in the series $5^2P_{1/2}{}^0$–$n^2D_{3/2}$ the members $n = 8$ and 9 are considerably weaker than the members $n = 10$, 11.

The sole remaining feature of the absorption spectra needing explanation is the presence of the short sixth series (Table 6), which we have observed at high

---

† An example of this sort of disturbance is supposed found in the inversion of many of the doublet terms of the alkali arc spectra (Phillips 1933).

Table 6. $5s^25p\,^2P_{1/2}{}^0$–$5s^2np\,^2P_{1/2}{}^0$? Series

vapour densities. The lines of this series appear as, slightly diffuse, satellites to the short wavelength side of members of $5^2P_{1/2}{}^0$–$n^2D_{3/2}$; starting as quite weak absorption lines in the low members, they increase rapidly in strength and eventually merge with, and supplement the intensities of, the higher members of the $^2D_{3/2}$ series. The values of the Rydberg denominator in Table 6 suggest that the lines belong to the forbidden series $5^2P_{1/2}{}^0$–$n^2P_{1/2}{}^0$. We can tentatively attribute the presence of such lines to the occurrence of forced dipole transitions, at the high vapour densities used. Under the same conditions we have seen traces of higher members of yet a seventh series, consisting of lines too feeble for measurement, but having the correct locations for $5^2P_{1/2}{}^0$–$n^2P_{3/2}{}^0$.

ACKNOWLEDGMENTS

The considerable help of several bodies has once again to be acknowledged. We express thanks to the Royal Society for funds towards erection of the 3m spectrograph, and to the University of London for provision, from the Central Research Fund, of King furnace and associated apparatus.

The experiments reported have been made possible by a supporting contract with the Atomic Energy Research Establishment (CTR Division), including provision of a research assistantship for one of us (K.C.).

Van der Waals Forces for Hydrogen and the Inert Gases

By A. DALGARNO and A. E. KINGSTON

Department of Applied Mathematics, The Queen's University of Belfast

MS. received 6th February 1961

Abstract. Experimental data and theoretical calculations on neon and argon are analysed to yield consistent sets of electric dipole oscillator strengths. The derived oscillator strengths are used with known values for hydrogen and helium to calculate the van der Waals energies between all pairs of atoms selected from hydrogen, helium, neon and argon. The results are summarized in the Table. The probable error is less than 10%.

§ 1. Introduction

The magnitudes of the long range forces between pairs of atoms are important parameters in such diverse fields as low energy elastic scattering, transport phenomena, the structure of crystals, the formation of radicals at low temperatures and the collision broadening of spectral lines.

§ 2. Theory

The leading term in the series representation of the long range interaction energy for a pair of atoms A and B separated by a distance R has the form $-C_{\mathrm{ab}}/R^6$ provided the atoms are in states of zero orbital angular momentum. If $\epsilon_m{}^{\mathrm{a}}$ denotes the binding energy of atom A in the mth excited state and $\epsilon_n{}^{\mathrm{b}}$ the binding energy of atom B in the nth excited state, measured in atomic units, the coefficient C_{ab} appropriate to A and B in the ground states may be written

$$C_{\mathrm{ab}} = \frac{3}{2} \underset{\substack{m \ \ n \\ m,n\neq 0}}{\mathbf{S}'\,\mathbf{S}'} \frac{f_m{}^{\mathrm{a}} f_n{}^{\mathrm{b}}}{(\epsilon_0{}^{\mathrm{a}}-\epsilon_m{}^{\mathrm{a}})(\epsilon_0{}^{\mathrm{b}}-\epsilon_n{}^{\mathrm{b}})(\epsilon_0{}^{\mathrm{a}}+\epsilon_0{}^{\mathrm{b}}-\epsilon_m{}^{\mathrm{a}}-\epsilon_n{}^{\mathrm{b}})} \quad \ldots\ldots(1)$$

where $f_m{}^{\mathrm{a}}$ is the oscillator strength of the electric dipole transition from the ground state of A to the mth excited state and $f_n{}^{\mathrm{b}}$ is the oscillator strength of the electric dipole transition from the ground state of B to the nth excited state (cf. Margenau 1939).

The problem of evaluating C_{ab} therefore reduces to the determination of the oscillator strengths of the individual atoms. Experimental data on oscillator strengths are scarce and in general theoretical calculations yield values of uncertain accuracy. However, oscillator strengths satisfy various sum rules of the form

$$S(k) = \underset{t}{\mathbf{S}'} f_t(\epsilon_0-\epsilon_t)^k \quad \ldots\ldots(2)$$

(Dalgarno and Lynn 1957) and it is often possible to determine $S(k)$ accurately by theoretical calculation or by analysis of experimental data. In particular, Dalgarno and Kingston (1960) have analysed the measurements of refractive indices and of Verdet constants of neon and argon incidentally obtaining $S(k)$ for negative even values of k and they also estimate $S(-1)$ Further $S(0)$ is known for it is equal to the total number of atomic electrons. These sum rules are similar in form to (1) and our procedure consists of selecting oscillator strengths which satisfy the known values of $S(k)$ and substituting them into (1) (cf. Dalgarno and Kingston 1959). Although the accuracy of the oscillator strengths of any individual transition is not high, the control exerted by $S(k)$ prevents serious error entering into the evaluation of (1).

The possible error can be more closely limited in the cases of neon and argon because there exist experimental values of the oscillator strengths of transitions into the continua (Lee and Weissler 1953, 1955, Ditchburn 1960) and theoretical Hartree–Fock calculations of the oscillator strengths of the resonance transitions (Knox 1958, Gold and Knox 1959).

§ 3. RESULTS AND DISCUSSION

We have computed C_{ab} for all pairs selected from hydrogen, helium, neon and argon, using for hydrogen the exact theoretical oscillator strengths and for helium the values derived by Dalgarno and Stewart (1960). The results are shown in the Table. The value for H–H was derived earlier by Pauling and Beach (1935) and the value for He–He supersedes the estimate of Dalgarno and Lynn (1957).

Values of C_{ab} in Atomic Units†

	H	He	Ne	A
H	6·50	2·82	5·67	20·15
He	2·82	1·46	3·07	9·88
Ne	5·67	3·07	6·63	20·63
A	20·15	9·88	20·63	68·08

† The leading term in the interaction energy between A and B is $\dfrac{-C_{ab}}{(R/a_0)^6}\dfrac{e^2}{a_0}$.

We believe that the absolute error in C_{ab} is certainly less than 10% and may be much smaller. The limits claimed are consistent with the available experimental data. For example, Guggenheim and McGlashan (1960) are able to reproduce a wide range of data for two argon atoms by adopting the value of C_{ab} equal to 67·7 recommended by Margenau (1939), which differs from our computed value of 68·08 by less than 0·5%. This close agreement is partly fortuitous since the experimental data do not lead to a unique value of C_{ab}, the derived value depending to some extent on the form adopted for the complete interaction.

We shall not present the detailed oscillator strengths that we have derived, but it is worth noting that our analysis provides no evidence for attaching large oscillator strengths to transitions into the auto-ionizing levels which lie between the neon and argon $^2P_{1/2}$ and $^2P_{3/2}$ series limits. A previous discussion of refractive index data for argon (Koch 1949, Garton 1957) had suggested anomalously large oscillator strengths, but it appears that it did not take proper account of the contribution from transitions into the continuum. This is in harmony with the conclusions of Garton, Pery and Codling (1960) but there remains the problem of explaining the apparently large intensities of lines terminating at auto-ionizing levels that have been observed in absorption studies of the inert gases (Beutler (1935).

ACKNOWLEDGMENT

This work has been partially supported by the United Kingdom Atomic Energy Research Establishment.

The Absorption Spectrum of the BiF Molecule in the Ultra-violet Region

By K. C. JOSHI†

Physics Department, Allahabad University, India

MS. received 15*th February* 1961

Abstract. One system of bands comprising thirty-two bands of the BiF molecule has been obtained in absorption in the region λλ2400–2180. Three of these bands were previously observed in emission by Rochester. The bands have been analysed and can be represented by the following formula:

$$\nu_{v'v''} = 44222{\cdot}0 + 615{\cdot}0(v'+\tfrac{1}{2}) - 2{\cdot}50(v'+\tfrac{1}{2})^2 \\ - 512{\cdot}0(v''+\tfrac{1}{2}) + 2{\cdot}25(v''+\tfrac{1}{2})^2.$$

A discussion regarding the electronic states involved in the transition shows that the ground state is a triplet state, whereas the upper one a single state and not otherwise as suggested by Rochester.

§ 1. Introduction

The spectrum of bismuth fluoride has been the subject of numerous investigations. Howell and Rochester (1934) were the first to observe the spectrum of BiF and BiBr in a high-frequency electric discharge. Later, Howell (1936) made a detailed study and analysed about forty bands occurring in the region λλ5100–4200. He ascribed the two electronic states involved in the production of these bands to A and X states having the following constants (in cm^{-1}):

	ν_e	ω_e	$\omega_e x_e$	$\omega_e y_e$
A	22959·7	381·0	3·00	0·10
X	0	510·0	2·05	—

Morgan (1936), using a long column of BiF_3 vapour heated to 1200°C in an electric furnace and using a 500 watt incandescent lamp as the source of continuum, obtained the same system in absorption. He confirmed the analysis of Howell and identified the X state as the ground state of the molecule. In addition, he also mentioned the occurrence of bands in the near ultra-violet region.

Rochester (1937) made further investigations on the spectrum of BiF in emission and obtained in addition to the known A–X system, fifteen bands, degraded to violet, in the region λλ3250–2250. He classified them into three systems arising from an upper triplet electronic state to the ground state of the molecule. Due to insufficient data and the low dispersion of the instrument used by him, he could mention only the order for the vibrational frequency of the upper state.

No study has, however, been made for this molecule in absorption in the ultra-violet region, though other bismuth halides are known to possess several bands in this region. It was with the object of obtaining more complete information regarding this molecule that the present investigation was undertaken. The spectrum was studied in absorption and thirty-two bands degraded to violet were observed in the region λλ2400–2180. The bands have been analysed into one system and the vibrational constants determined.

† Now at Air Force Cambridge Research Laboratories, Bedford, Massachusetts.

§ 2. EXPERIMENTAL

Pure bismuth fluoride was put inside the graphite tube of the vacuum graphite furnace. The furnace tube was 18 cm long and had an internal diameter of 1 cm. In order to prevent the rapid effusion of the vapours from the tube ends, the furnace chamber was filled with nitrogen gas at a pressure of about 35 cm Hg. A hydrogen discharge lamp manufactured by Thermal Syndicate Ltd., England, was used as the source of ultra-violet continuum. Observations were taken at temperatures ranging from 800°c to 1800°c.

§ 3. RESULTS

Well-defined bands developed at about 1600°c. A few strong bands of Bi_2 along with a couple of atomic lines of bismuth also appeared on the spectrum plate. The spectrum was photographed with a medium quartz spectrograph of Messrs. Carl Zeiss, having an average reciprocal dispersion of about 6 Å mm^{-1} in the region λλ 2392–2193. Ilford N.40 thin plates were used to record the spectrum. A copper arc was employed for the comparison spectrum.

† Also observed in emission by Rochester.

Table 3. Condon Distribution of the Band Intensity for the c–x_1 System of BiF

v'' / v'	0	1	2	3	4	5	6	7	8
0	6	6	5	4	2	1			
1	4	3	4	5	4	2	1		
2	2	2	6	1	4	3	2	1	
3		2	4	6	1	2	2	2	1
4					2	1	2		

The wavelengths, the relative visual intensities of the bands, and the respective wave-numbers are given in Table 1. The last column of the table gives the vibrational analysis and the preceding one the wave-numbers of the band heads calculated on the basis of the proposed formula:

$$\begin{aligned}\nu_{v'v''} = 44222{\cdot}0 + 615{\cdot}0(v'+\tfrac{1}{2}) - 2{\cdot}50(v'+\tfrac{1}{2})^2 \\ - 512{\cdot}0(v''+\tfrac{1}{2}) + 2{\cdot}25(v''+\tfrac{1}{2})^2.\end{aligned}$$

In Table 2 all the bands observed have been arranged according to the Deslandres scheme. Table 3 shows the Condon distribution of the intensity of the bands. In Fig. 1 (Plate) the spectrogram showing the bands has been given.

§ 4. DISCUSSION

Altogether thirty-two bands have been observed in this investigation. These include four of the bands obtained in emission by Rochester (1937). The fifteen bands obtained by Rochester have been clasified by him into a triplet system, with wide multiplet separations (4780 cm^{-1} and 7330 cm^{-1}). He attributes these bands as due to transitions between an upper triplet electronic state comprising three components, c_1, c_2 and c_3 and a lower singlet ground state x. The three bands mentioned above, according to him, are due to the transition c_3–x (Fig. 2(*a*)).

In the present investigation all the thirty-two bands fit in a single Deslandres scheme, showing that all of them belong to the same system. None of the bands of the c_2–x and c_3–x component systems of Rochester have been observed in absorption, though they are expected to be present. The absence of these two component systems in absorption shows that the ground state is not involved in the transitions. Thus there appears to be some doubt about the nature of the electronic states involved in the above transitions. This doubt may be removed if it is assumed that the ground state is a triplet state, $x_1 x_2$ and x_3, and the upper state a single level c, as represented in Fig. 2(*b*). The ground state of BiF is

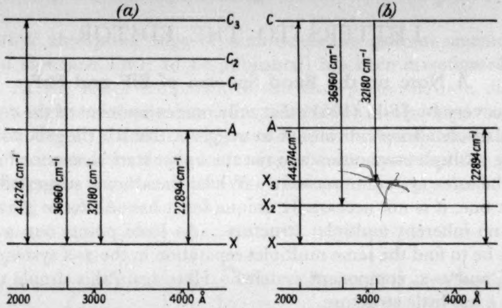

Fig. 2. Energy level diagram of the BiF molecule giving the (0, 0) bands of different systems: (*a*) observed by Rochester, (*b*) present investigation.

expected to be a multiplet state, as $\mathrm{Bi}(^4\mathrm{S}) + \mathrm{F}(^2\mathrm{P})$ cannot give rise to a singlet state. If we take the values $4780\,\mathrm{cm}^{-1}$ and $7330\,\mathrm{cm}^{-1}$ as the multiplet separations of the three components of the ground state, the experimental facts can be accounted for. The absence of the other two component systems in absorption is due to the fact that the states X_2 and X_3 are much too high up and the possibility of transition from them, by absorption of energy, is very small at the temperature of the experiment.

Now the system A–X is known both in emission and absorption with the 0, 0 band at $22\,894\,\mathrm{cm}^{-1}$. If the ground state X is assumed to be a triplet state, transition between the upper two component levels X_2 and X_3 and the level A may also occur in emission though not in absorption. In the case of A–X_2, the 0, 0 band would lie at $15\,564\,\mathrm{cm}^{-1}$ ($\lambda 6423{\cdot}3$) and for A–X_3, the 0, 0 band would lie at $10\,784\,\mathrm{cm}^{-1}$ ($\lambda 9027{\cdot}0$). Investigations of the emission spectra in these regions under high dispersion are likely to throw more light regarding the electronic states of the molecule.

LETTERS TO THE EDITOR

A Note on the Band Spectra of BiF and SbF

The discovery by Joshi (1961) that only one component of the C–X system of BiF is found in *absorption* indicates, as he suggests, that it is the ground state which has the wide multiplet separation and not the upper state as assumed earlier from a study of the same system in *emission*. Whilst the scheme suggested by Joshi is the simplest one, it is not necessarily unique for it has still to be proved that the state C has no inherent multiplet structure. As Joshi points out, a test of his scheme will be to find the same multiplet separation in the A–X system by looking for the A–X_2 and A–X_3 component systems. Here again this simple test will fail unless state A has little structure.

It is of interest to examine whether the same scheme can be applied to the related molecule SbF, the data for which are in some respects more complete than BiF.

Two groups of triplet systems, one occurring in the visible region and another in the ultra-violet, have been observed in emission (Rochester 1937, Howell and Rochester 1939). These band systems occur in the same regions of the spectrum as the systems A–X and C–X of BiF and the SbF bands degrade in the same directions as the BiF bands in the corresponding systems. Moreover, the vibrational constants are such as might be expected for a related molecule like SbF. The following assumptions are therefore made:

(i) The observed SbF systems correspond to the A–X and C–X systems of BiF.

(ii) The lowest observed state of SbF, common to all the systems, is the ground state, and, by analogy with BiF, is a triplet.

(iii) The multiplet structure of state C is small.

With these assumptions it appears that the spectrum of SbF can be explained if state A is also a triplet. Details are as follows:

Ground State $X_3 - X_1 = 6820\ \mathrm{cm}^{-1}$

$X_2 - X_1 = 1244\ \mathrm{cm}^{-1}$

where X_1 is the lowest level.

State A $A_3 - A_1 = 3471\ \mathrm{cm}^{-1}$

$A_2 - A_1 = 2675\ \mathrm{cm}^{-1}$.

The overall separation of the ground state of SbF, that is, 6820 cm^{-1}, may be compared with the corresponding value for BiF, which is approximately 12 100 cm^{-1}. The analysis shows that the relative spacings of the multiplet levels of the ground states of BiF and SbF are very different. It also shows that if state A in SbF has been correctly identified, state A in BiF will be a multiplet.

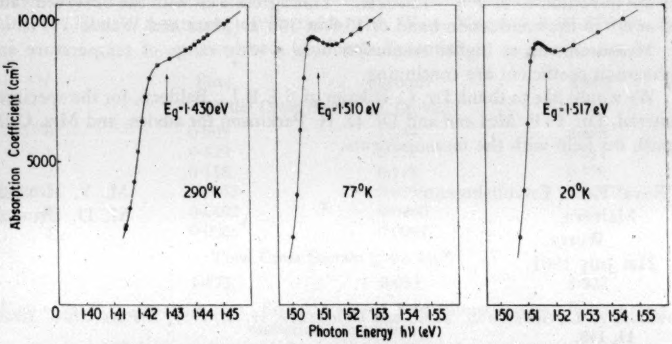
The Optical Absorption Edge of Gallium Arsenide

The optical absorption edge of semi-insulating gallium arsenide (Gooch, Hilsum and Holeman 1961, to be published) has been investigated at 290, 77 and 20°K. At the lower temperatures the absorption shows a distinct peak followed by a region of slowly increasing absorption. The peak is interpreted as absorption due to direct transitions to bound exciton states at the centre of the Brillouin zone and the slowly increasing absorption as that due to unbound electron–hole pairs. In this respect the absorption is very similar to that of germanium (Macfarlane *et al.* 1958).



By fitting the theoretical absorption curve of Elliott (1957) to the experimental data the band gap and exciton binding energy have been obtained. The band gap is found to be 1·430 ($\pm$0·002) ev at 290°K, 1·510 ($\pm$0·001) ev at 77°K and 1·517 ($\pm$0·001) ev at 20°K.

The measured exciton binding energy is 0·0025 ($\pm$0·0005) ev at 290°K, 0·0027 ($\pm$0·0003) ev at 77°K, and 0·0033 ($\pm$0·0002) ev at 20°K. These values are to be compared with the theoretical exciton binding energy $m^*e^4/2\hbar^2\epsilon^2$, where m^* is the reduced mass and ϵ is the dielectric constant. Using a reduced mass of 0·055m (Moss and Walton 1959) and dielectric constant of 12·5 (Hambleton, Hilsum and Holeman 1961), this gives an exciton binding energy of 0·0039 ev. Due to the slight non-uniformity of thickness of this specimen ($\sim 6\,\mu$ thick) the absolute value of the absorption coefficient at the band edge could only be estimated to be of the order of 9000 cm^{-1}.

During the experiment the specimen, prepared by hand grinding and polishing, was freely suspended in an optical cryostat, helium gas being used to ensure thermal equilibrium with the refrigerant. Due to the low transmission with this specimen slits 0·003 ev wide were used. Using slits less than 0·001 ev wide, a slightly more pronounced peak at 77°K was observed but with the same exciton binding energy.

A measurement has also been made on a specimen 4·7 μ thick glued to a glass backing. The temperature was 53°K and the resolution $2{\cdot}5 \times 10^{-4}$ ev. The exciton binding energy is 0·0027 ($\pm$0·0002) ev, the mean band gap 1·524 ($\pm$0·001) ev, and the exciton line is split into two main components 0·0040

($\pm 0{\cdot}0002$) ev apart. The compressive strain in the specimen is calculated from the relative expansion coefficients to be approximately $0{\cdot}6 \times 10^{-3}$. Inserting the data in the formulae of Kleiner and Roth (1959) we find $|D_{\mathrm{u}}'| \simeq 4$ ev and $D_{\mathrm{d}}^{\mathrm{c}} - D_{\mathrm{d}}^{\mathrm{v}} \simeq -10$ ev, the latter in fair agreement with the value -7 ev deduced from the variation of band gap with hydrostatic pressure (Edwards, Slykhouse and Drickamer 1959, Ehrenreich 1960). Here $2D_{\mathrm{u}}'$ is the splitting of the valence band edge due to unit shear in the [111] direction, and $\mathrm{D}_{\mathrm{d}}^{\mathrm{c}}$ and $D_{\mathrm{d}}^{\mathrm{v}}$ are the shifts in the band edges due to unit dilatation.

The absorption coefficient at the band edge in this specimen is 8000 (± 500) cm^{-1}. From Elliott's formulae we can calculate the oscillator strength for the transition to be $F = -13\hbar^2/2m$. This agrees well with the observed value for m/m^* in the conduction band of 13·8 at 300°K (Moss and Walton 1959).

Measurements at higher resolution over a wide range of temperature and absorption coefficient are continuing.

We would like to thank Dr. C. Hilsum of S.E.R.L., Baldock, for the specimen material, Dr. T. P. McLean and Dr. D. H. Parkinson for advice, and Mrs. C. A. Smith for help with the measurements.

Scattering by the Screened Coulomb Potential

The purpose of this Letter is to investigate the accuracy of the second Born approximation to the cross sections for the scattering of particles by a central potential.

We consider the case of the screened Coulomb potential given by

$$V(r) = -Ar^{-1}\exp(-\lambda r)$$

with $A = 2{\cdot}365$ and $\lambda = 1$, treated in a previous paper by Gerjuoy and Saxon (1954). The values of the partial cross sections Q_l and the total cross section Q for incident particles with wave number $k = 1{\cdot}816$ obtained by exact numerical integration, by the first Born approximation and by the second Born approximation, are displayed in Table 1.

In the investigation of Gerjuoy and Saxon all terms of the second Born scattering amplitude were retained in calculating Q. This is an inconsistent procedure (Dalitz 1951, Kingston, Moiseiwitsch and Skinner 1960); only terms up to the third order in A should be retained.

In the particular case under consideration we see that though the first Born approximation gives the zero-order partial cross section Q_0 quite accurately, the second Born approximation seriously overestimates it, indicating that the Born expansion is here unsatisfactory. For the higher order partial cross sections, however, the Born expansion converges rapidly towards the correct value.

Table 1. Elastic Scattering of Particles with Wave Number $k = 1{\cdot}816$ by the Screened Coulomb Potential

l	First	Second†	Exact
	Partial Cross Section Q_l (in πa_0^2)		
0	0·905	1·244	0·848
1	0·429	0·522	0·511
2	0·158	0·178	0·179
3	0·0555	0·0596	0·0597
4	0·0192	0·0200	—
5	0·0066	0·0067	—
	Total Cross Section Q (in πa_0^2)		
	1·577	2·033	1·627

First = first Born approximation; Second = second Born approximation; Exact = exact numerical integration.

† Only terms up to the third order in A have been retained.

Table 2. Elastic Scattering of Particles with Wave Number $k = 1{\cdot}816$ by the Screened Coulomb Potential

θ	First	Second†	Exact
	Differential Cross Section $I(\theta)$ (in a_0^2)		
0	5·59	6·53	5·30
$\pi/2$	0·097	0·145	0·127
π	0·028	0·044	0·048
	Real Part of Scattering Amplitude $f(\theta)$ (in a_0)		
0	2·36	2·56	2·18
$\pi/2$	0·31	0·39	0·078
π	0·17	0·21	−0·053

θ = scattering angle (rad); First = first Born approximation; Second = second Born approximation; Exact = exact numerical integration.

† Only terms up to the third order in A have been retained.

By chance the first Born approximation gives a value $1{\cdot}577\pi a_0^2$ for the total cross section which is only 3% less than the exact value $1{\cdot}627\pi a_0^2$, whereas the second Born approximation overestimates the total cross section Q by 25%. However, if the relevant Born zero-order partial cross section is replaced by the exact value, the first Born approximation yields $1{\cdot}520\pi a_0^2$ for Q which is in error by about 7%, whereas the second Born approximation yields $1{\cdot}637\pi a_0^2$ for Q which is in error by less than 1%.

It would appear from Table 2 that the second Born approximation gives rise to a fairly satisfactory set of values for the differential cross section $I(\theta)$. This is accidental as can be readily seen by comparing the exact values of the real part of the scattering amplitude $f(\theta)$ with those given by the second Born approximation also displayed in Table 2. Considerable cancellation occurs between the contributions arising from the various partial waves for large angles of scattering θ. Consequently, unless the exact values of the contributions to $f(\theta)$ from the partial waves with l small are used, it is not possible to obtain reliable values for $I(\theta)$.

We conclude, therefore, that a satisfactory method for obtaining cross sections is to carry out an exact numerical integration for the partial waves associated with small values of l and to use the second Born approximation for the remaining partial waves. At sufficiently high impact energies it is, of course, permissible to use the second Born approximation for all the partial waves.

Plasma Drift Velocity Across a Confining Magnetic Field

The steady drift velocity of fully ionized plasma across a confining magnetic field is usually given as

$$v = -\frac{\eta}{B^2}\nabla p, \qquad \ldots\ldots(1)$$

where η is the electrical resistivity and B a steady magnetic field normal to the plasma pressure gradient ∇p (Spitzer 1956).

The above equation is derived from the equation of plasma motion by neglecting the inertia term $(v\,.\nabla)v$. It is shown, in this note, that the $(v\,.\nabla)v$ term cannot be neglected if the plasma is bounded by a material wall. However, this does not imply that a plasma cannot be confined by a magnetic field as Slepian (1960) has suggested.

Consider a plasma in a steady state which drifts normal to a magnetic field directed along the z axis of rectangular coordinates. If a plane surface $(0, y, z)$ is drawn in the plasma sufficiently close to and parallel to the material wall on which the charges are recombining, the flow can be considered as one dimensional and the rate of charge generation between this surface and the wall neglected in comparison with the flux of entering charges. The plasma is assumed uniform in the y direction and drifts across the magnetic field with a velocity v in the x direction.

The equations of motion of the plasma fluid are

$$m_i n v \frac{\partial v}{\partial x} = j_y B - \frac{\partial p}{\partial x}, \qquad \ldots\ldots (2)$$

$$\eta j_y = -vB, \qquad \ldots\ldots (3)$$

$$E_x + \frac{1}{ne}\left(\frac{\partial p_e}{\partial x} - j_y B\right) = 0, \qquad \ldots\ldots (4)$$

and

$$nv = n_0 v_0 = \text{constant}, \qquad \ldots\ldots (5)$$

where η is the electrical resistivity, p the plasma pressure, p_e the electron partial pressure, j_y the current density in the y direction, E_x the electric field in the x direction and $n_0 v_0$ the flux of electrons or of ions passing through the surface towards the wall. The electron and ion temperatures T_e and T_i are assumed constant.

It is easily shown from the above equations that

$$(c^2 - v^2)\frac{\partial v^2}{\partial x} = Av^4, \qquad \ldots\ldots (6)$$

where $A = \frac{2B^2}{\eta m_i n_0 v_0}$ and $c^2 = \frac{k(T_e + T_i)}{m_i}$.

The solution of Eqn (6), using the condition $v = v_0$ at $x = 0$ is

$$\frac{c^2}{v_0{}^2}\left(1 - \frac{v_0{}^2}{v^2}\right) - 2\ \ln\frac{v}{v_0} = Ax. \qquad \ldots\ldots (7)$$

The presence of a j_y current implies that the B_z field has a gradient in the x direction. This gradient can be neglected provided $\mu_0 cx/\eta \ll 1$. When this condition is violated Eqn (7) takes a different form but the conclusions are unchanged. For simplicity the gradient of B_z is neglected.

The curve v^2 as a function x is sketched in Fig. 1 and it is seen that x has a maximum value when $v = c$.

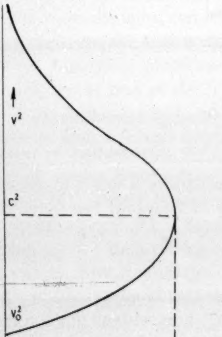

Fig. 1. The plasma velocity v as a function of x.

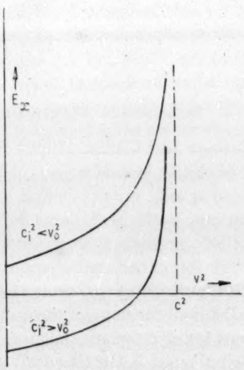

Fig. 2. The electric field E_x as a function of v.

The distribution of E_x is given by

$$E_x = \frac{m_i}{2e}\left(1 - \frac{c_i^2}{v^2}\right)\frac{\partial v^2}{\partial x} \qquad \ldots\ldots(8)$$

where $c_i^2 = kT_i/m_i$. E_x as a function of v^2 is shown in Fig. 2. Now $E_x \to \infty$ as $v \to c$ since $\partial v^2/\partial x \to \infty$ as $v \to c$. The appearance of the infinities is due to the assumption that $n_i = n_e$. If the electrostatic force $e(n_i - n_e)E_x$ is taken into account the infinities are removed. It has been shown by Tonks and Langmuir (1929) that the plane at which $E = \infty$, following the assumption $n_e = n_i$, marks the formation of a space charge sheath at the plasma boundary. If the sheath thickness is small compared to the plasma dimensions, as is usually the case, the plasma may be assumed to terminate when $v = c$ at the boundary wall.

It is concluded that the velocity of plasma drift transverse to a magnetic field is correctly given by Eqn (1) for an unbounded plasma provided $v^2 \ll c^2$ whereas for a bounded plasma the upper limit to the drift velocity is close to $[k(T_e + T_i)m_i]^{1/2}$ independent of the magnetic field strength. Therefore the $(v.\nabla)v$ term should be taken into account when the drift of a bounded plasma across a confining magnetic field is under consideration.

Two of the authors (S. M. and S. I.) wish to acknowledge their gratitude to Professor Yamamoto for his interest and help in this investigation.

Sub-lattice Magnetic Moments in Manganese Ferrite

Hastings and Corliss (1956) found that the ionic distribution in manganese ferrite $MnFe_2O_4$ was $Mn_xFe_{1-x}\,[Mn_{1-x}Fe_{1+x}]O_4$ with $x \simeq 0{\cdot}8$, where the brackets enclose the ions on octahedral (B) sites in the spinel lattice. Whatever the distribution, with Mn^{2+} and Fe^{3+} ions only (both $3d^5$), ferrimagnetic theory (Néel 1948) predicts a net magnetic moment per molecule of 5 Bohr magnetons (β). Yet the experimental moment was 4·6, in agreement with earlier results (e.g. Guillaud 1951). Gorter (1957) showed that this result would be expected for $x = 0{\cdot}8$ if all the manganese on B sites were Mn^{3+} ions with an equal number of Fe^{2+} ions for electrostatic balance, but that this did not explain the fact that both B (octahedral) and A (tetrahedral) sub-lattice moments had to be reduced (to 9·2 and 4·6 β respectively) to satisfy the neutron diffraction intensities. At the same time the suggestion was made (Osmond 1957) that these reductions might be caused by the turning of oxygen **p** orbitals away from the cube diagonals towards the Mn^{3+} ions in order to make square d^2sp bonds with these $3d^4$ cations, as suggested by Goodenough and Loeb (1955). This interpretation is unsatisfactory since it involves the virtual annulment of some moments of both B and A ions. The existence of some canted spins in both sub-lattices now seems to be a more likely cause of the reduced moments. This note suggests a mechanism by which such canted spins could arise.

A more comprehensive explanation than the square bond theory for the distorting effect of the Mn^{3+} ion is given by ligand field theory (Dunitz and Orgel 1957). The four oxygens at the extremities of the axes of the empty $d_{x^2-y^2}$ cation orbital are drawn closer to this cation than are the two oxygens at the ends of the half-filled d_{z^2} orbital. This gives a tetragonal distortion ($c/a > 1$) to this octahedron of surrounding oxygens from which arises the tetragonal spinel structure observed when 60% or more of the B sites are occupied by Mn^{3+} ions (Wickham and Croft 1958, Irani, Sinha and Biswas 1960). Thus for an isolated Mn^{3+} B ion in $MnFe_2O_4$ the empty $d_{x^2-y^2}$ orbital is directed at four of the six nearest oxygen neighbours, and each lobe of this orbital can temporarily receive a **p** electron from its own oxygen neighbour if one orbital of the latter is directed at the cation. This orbital is then turned away from the cube diagonal along which, in other circumstances, it might be expected to lie in order to overlap the empty hybrid sp^3 orbital of the A ion. Then in the new arrangement there is less screening by oxygen electrons between the Mn^{3+} ion and two of its nearest B neighbours, so that direct B–B interactions are more possible between each of these neighbours and the Mn ion, as proposed by Wickham and Goodenough (1959). The mechanism suggested is the overlapping of the half-filled d_{xy} cation orbitals. Since the acceptance by such an orbital of an electron from the other cation must entail opposite spins for the two cations there is an impulsion for the Mn^{3+} spin to be reversed relative to that of each of these two B neighbours. Moreover, the second half of each turned **p** orbital will overlap a half-filled d_{xz} or d_{yz} orbital of the A ion (as pointed out by Wollan 1960). Thus if one **p** electron goes into the empty $d_{x^2-y^2}$ orbital of the Mn^{3+} ion, with the same spin as that of this ion, the other, with opposite spin, can only go into the half-filled orbital of the A ion if the latter has the opposite spin to that of the electron, i.e. the same spin as the Mn^{3+} ion. This possibility provides a further impulsion for the Mn^{3+} ion to reverse its spin relative to that of the B sub-lattice as a whole (considered to be opposite to that of the A sub-lattice). Alternatively it provides an impulsion for the A ion to reverse *its* spin. These impulsions may lead to canted spins rather than actual reversals.

With $x = 0{\cdot}8$ the B sub-lattice should consist of $Mn_{0\cdot2}{}^{3+}Fe_{0\cdot2}{}^{2+}Fe_{1\cdot6}{}^{3+}$ with a Néel moment per molecule of $9{\cdot}6\beta$. The observed reduction of 0·4 could arise from 0·05 Mn^{3+} ion with reversed spin offset by 0·05 Mn^{3+} ion with normal spin. These values are together well within the maximum possible concentration of isolated B ions of one type which is four per unit cell or 0·5 per molecule. However, it is quite possible that there are no reversed spins, but that for a higher proportion of the Mn^{3+} ions the combination of usual antiparallel A–B interactions with opposed B–B interactions and some reversed A–B interactions leads to canted spins among the Mn^{3+} ions and some or all of their nearest B neighbours. As an extreme case, if all Mn^{3+} ions, supposed isolated, together with all six nearest B neighbours per ion (2/3 of the total Fe^{2+} and Fe^{3+} content) have such canted spins the net reduction of the moment of these 1·4 ions per molecule is from 6·67 to 6·27. The average angle made by each canted spin with the general spin direction of the B sub-lattice is then $\cos^{-1} 0{\cdot}94 \simeq 20°$. Other spin arrangements, leading to a larger average angle, are of course possible.

Since the A sub-lattice consists of $0{\cdot}8\,\mathrm{Mn}^{2+} + 0{\cdot}2\,\mathrm{Fe}^{3+}$ the Néel moment per molecule is 5β. Here the observed reduction of 0·4 is equivalent to the presence of 0·1 Mn^{2+} ion in the low spin state with one unpaired electron, giving a moment of 1β per ion. However, although theoretical reasons and experimental evidence have been given (Sinha 1958, Sinha and Sinha 1957) for the occurrence of such an A ion in $\mathrm{Mn_3O_4}$, it is unlikely that any would be present with the scattered distribution of Mn^{3+} B ions expected in $\mathrm{MnFe_2O_4}$. More probably, the presence of some parallel instead of antiparallel A–B interactions, aided by canted B spins, leads to local groups of canted A spins. In the very special case that all four A neighbours of each Mn^{3+} ion linked to it by the oxygens at the ends of its $d_{x^2-y^2}$ orbital have canted spins, and that all these sets of four A ions are independent of each other, the observed reduction in the moment of this total of 0·8 ion per molecule is from 4·0 to 3·6. The average angle made by each canted spin with the general spin direction of the A sub-lattice is then $\cos^{-1} 0{\cdot}90 \simeq 26°$. Other, less ordered canted spin arrangements are of course possible.

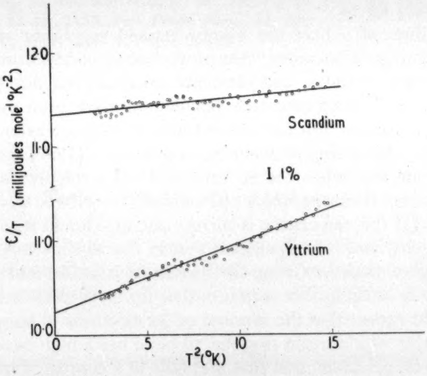
The Low Temperature Specific Heat of Scandium and Yttrium

The electronic structures of scandium, yttrium and lanthanum are of special interest, as each metal is the first member of its respective transition series. Hitherto specific heat measurements below 4°K have been made only on lanthanum (Berman, Zemansky and Boorse 1958), and the purpose of this note is to report similar measurements on the other two metals.

The specimens were obtained from Messrs. Johnson Matthey, in the form of cast cylinders 2·3 cm diameter by 3 cm long. Spectroscopic analysis of the scandium indicated that the chief impurities were about 100 parts per million by weight of Cu, 70 of Fe, 50 of Pb, and 100 of lanthanides. On metallographic examination the scandium showed a grain size of about 2 mm: there were very few inclusions, although a light precipitate was to be seen at the grain boundaries. However, the yttrium specimen was found to be considerably less pure and according to spectrographic analysis the chief impurity was about 1000 parts per million of Ta. Metallographic examination revealed a grain size of 2–4 mm and there were considerable areas of inclusions of four different types. With an electron probe micro-analyser the major inclusion was shown to be yttrium oxide and the tantalum was found to be associated with one of the minor inclusions.

Specific heat measurements were made between 1·7 and 4·2°K in a calorimeter which will be described in detail elsewhere. The specimen was cooled by a mechanical heat switch similar to that used by Rayne (1956) and exchange gas was used only for the thermometer calibration at the end of the run. The measurements on the scandium were repeated using a different heater and carbon thermometer, and at all temperatures the two determinations agreed to 1%.



C/T–T² plot for Sc and Y.

The figure shows the experimental data for the two specimens, the curves being displaced to avoid confusion. Scandium has a relatively small cubic term, and measurements at hydrogen temperatures would be needed to obtain a precise value for the Debye temperature. Both metals show large linear components in their specific heats, which rules out the possibility of either being superconductive above 1·7°K. The question arises as to whether these linear terms are a property of the pure elements, or whether they are merely due to impurities. Magnetic impurities such as manganese and iron frequently cause a specific heat curve to turn upwards at the lowest temperatures, but concentrations of the order of 0·5% are required before they can produce a linear specific heat in copper (Zimmerman and Hoare 1960). The present results show no tendency to turn up at low temperatures, and it will be assumed that the linear term is at least predominantly the electronic specific heat of the pure metal.

Values of the electronic coefficients γ and the Debye temperatures are tabulated below, together with overall estimates of random and systematic error. The data for lanthanum derive from the paper by Berman, Zemansky and Boorse (1958).

Element	γ (millijoules mole^{-1}°K^{-2})	θ(°K)
Sc	$11{\cdot}3 \pm 0{\cdot}1$	470 ± 80
Y	$10{\cdot}2 \pm 0{\cdot}1$	300 ± 10
La	$10{\cdot}1 \pm 0{\cdot}2$	142 ± 3

The variation of θ between the elements is typical of transition metal groups (Parkinson 1958), and is due partly to the variation of atomic mass, and partly to the fact that in the earlier members of a group the ionic repulsions are stiffer and hence give rise to higher elastic constants. It is interesting to note that the Debye temperatures of all these metals are much higher than those of the neighbouring elements Ca, Sr, Ba (Parkinson 1958); this is connected with the fact that the latter group of metals have larger atomic volumes than the scandium group. Thus, even a small number of d electrons has a considerable effect upon the atomic binding forces.

The high values of γ bear out a very marked regularity among the early members of each transition series: elements with an odd number of electrons have a high density of states, and elements with an even number have a low density of states. No band structure calculations have been made specifically upon the scandium group, but one can extrapolate to some extent from calculations on calcium. According to Manning and Krutter (1937) the bottom of the 3d band in calcium lies below the 4p band and has a steeply rising n(e) curve: this ensures that any electrons which spill out of the 4s band enter the 3d band and not the 4p. (If this calculation is correct calcium should strictly be regarded as a transition metal, and it is significant that in the alkaline earths n(e)f is four or five times higher than in Group 2b metals such as Zn and Cd (Parkinson 1958).) Now it is unlikely that scandium has fewer 4s electrons than calcium, so that one would expect that the number of 3d electrons in scandium is of the order of unity: this would mean that the 3d band has a high peak in n(e) in the region of 1 electron per atom, and that n(e) falls to a comparatively low value in the neighbourhood of 2 d electrons per atom, corresponding to the case of titanium. The experimental evidence suggests that similar conclusions hold for the 4d and 5d bands.

This general picture predicts that scandium and its analogues should have a high magnetic susceptibility with a negative temperature dependence. The susceptibilities of these metals have been measured by Bommer (1939), whose data on lanthanum have been well confirmed by Lock (1957). In the case of scandium and yttrium the room temperature susceptibility is considerably higher than the Pauli value calculated from the electronic specific heat, as is usually the case in transition metals: in the lanthanum, however, the observed susceptibility is slightly lower than the specific heat value, a fact which is difficult to explain at present. In all three metals the susceptibility has a marked negative temperature dependence, and the susceptibility of scandium falls by 20% between 90°K and 300°K. However, this temperature dependence is much larger than that commonly found among transition metals (Kreissman 1953), and it is possible that it arises not from band curvature but from other causes such as an antiferromagnetic transition at low temperatures. Measurements are being planned on the magnetic properties of the present samples of scandium and yttrium in order to study this problem further.

Many thanks are due to Mr. A. D. Le Claire and Dr. W. E. Gardner for very useful discussions.

The Skeletal Modes of Long-chain Molecules

The torsional oscillations of long-chain paraffin molecules have recently been investigated theoretically by Szigeti (1961). In an infinitely long hydrocarbon chain, torsional waves have a dispersion curve of the form shown in Fig. 1, in

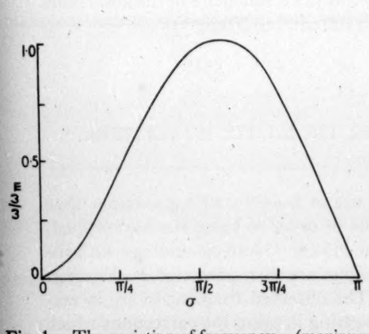

Fig. 1. The variation of frequency ω (maximum value ω_m) with wave-number σ for torsional waves in an infinite, straight, hydrocarbon chain.

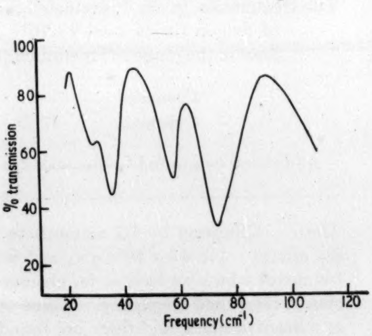

Fig. 2. Spectral transmission through a sample of $(C_{11}H_{23})_2CO$ approximately 0·1 mm thick.

which the frequency reaches a maximum value ω_m near the centre of the zone. The application of the correct boundary conditions for a finite molecule leads to the conclusion that each of the $(L-3)$ torsional modes of a paraffin molecule containing L carbon atoms is a combination of two sinusoidal waves having the same frequency, one having a wave-number greater than that corresponding to ω_m in Fig. 1, and the other with a wave-number smaller than that at ω_m. The corresponding frequencies thus range up to a maximum value close to ω_m. A torsional mode is made up of rotational displacements around each carbon–carbon bond and the characteristic frequencies are, for this reason, directly proportional to the torsional constant, k, of a C–C bond. No entirely satisfactory theoretical account of the resistance to rotation about such a bond is known. If use is made of the value for k determined experimentally for the C–C bond in ethane, i.e. $k = 4{\cdot}1 \times 10^3$ c.g.s., the value for ω_m is about 5×10^{12} c/s.

These torsional oscillations of a paraffin molecule are not infra-red active, but Dr. Szigeti pointed out to us that the substitution of a C=O group for a CH_2 group, to form the related ketone molecule, would leave the C=O dipole to librate as part of the *skeletal* torsional modes. Associated spectra would then be expected in the range of wavelengths which can be studied using our techniques for the extreme infra-red (Bloor *et al.* 1961) because the value above for the maximum frequency ω_m corresponds to 167 cm^{-1}.

The purpose of this note is to report the observation of absorption spectra, with several solid ketones, which are in accord with the general predictions of Szigeti. Fig. 2 shows the extreme infra-red spectrum of $C_{11}H_{23}.CO.C_{11}H_{23}$, obtained at 100°K where the lines are more clearly revealed than at room temperature. This is a symmetrical ketone and the central C=O dipole can reveal only the symmetrical modes. Corresponding frequencies for a *paraffin* molecule have been evaluated by Szigeti and his results, increased by a factor 1·2, are recorded in the table together with the observed frequencies for the ketone.

The frequencies, in cm^{-1}, evaluated for $CH_3(CH_2)_{21}CH_3$ from the computations of Szigeti (using $k = 4{\cdot}9 \times 10^3$ c.g.s.) and the frequencies of the absorption lines in the range so far studied (from 100 cm^{-1} to 20 cm^{-1})

Computed	37	60	83	115
Observed	37, 28	58	73	115

Additional computed frequencies are at 7·2, 136, 161, 178, 192 and 198 cm^{-1}.

The multiplication by 1·2 amounts to the use of $k = 4{\cdot}9 \times 10^3$ c.g.s. rather than the ethane value $4{\cdot}1 \times 10^3$ c.g.s., and is made in order to bring the highest line-frequency which we have so far observed (at 115 cm^{-1}) into coincidence with the closest computed frequency. Three other lines are then predicted in the range at present studied, and three are found. The observed frequencies are in reasonable agreement with the computations, bearing in mind the corrections which may be necessary to allow for the loading of the paraffin chain by the oxygen atom, as discussed by Szigeti. The doublet splitting at 37 cm^{-1} in Fig. 2 might be produced by the dipolar interaction between neighbouring molecules which

Szigeti estimates should lie between 1 and 10 cm^{-1}. Similar spectra have been obtained with several other ketones, kindly lent to us by Dr. V. Daniel.

A systematic study of a wide series of ketones is now being made, and the range covered is being extended to reach the maximum frequency expected at about 200 cm^{-1}. Such observations will give a measure of the long-chain torsional constant, of the extent of torsional and rotational motion in the solids and of intermolecular dipole interactions.

REVIEWS OF BOOKS

Plasma Physics, a course given by S. CHANDRESEKHAR at the University of Chicago. Notes compiled by S. K. TREHAN. Pp. 217. (Chicago: University Press; London: Cambridge University Press, 1960.) 14*s*.

There is serious need for a comprehensive monograph describing recent developments in the study of plasma dynamics, which are scattered throughout the scientific literature, or more often buried in laboratory or conference reports. Professor Chandrasekhar's lecture notes, while not quite that, do contain a full account of one of the most interesting of these developments. This is the quasi hydrodynamic treatment of a diffuse plasma in a strong magnetic field, which shows how such a plasma may exhibit cohesive hydrodynamic-like behaviour even though the mean free path be extremely large, the localizing feature being the small Larmor radius of particle orbits. In the first few chapters the perturbation theory of particle orbits in slowly varying fields is developed, particular attention being paid to the extremely useful adiabatic invariants of the motion. This theory is then applied to the study of the equilibrium and stability of plasmas confined by magnetic fields, problems in which fields and orbits must be made consistent. The stability of the pinch, a cylinder of plasma confined by a surface current, merits an entire chapter, in which in addition to magneto-hydrodynamic instabilities those produced by anisotropy in the pressure tensor are described. A section on plasma oscillations gives much space to dispersion relations for a non-magnetic plasma and a rather cursory glance at the effect of a magnetic field. A final chapter considers the effect of collisions and the origin of transport processes; of particular interest is the rather spectacular effect on transport processes produced by consideration of a small admixture of neutral gas.

Within a single course of lectures one cannot expect to cover the subject completely, but it is unfortunate that in spite of the space devoted to pinch stability the work of Suydam and Rosenbluth which exposed the artificiality of a stabilized pinch is not mentioned. More serious is the absence of any reference to experiment with which the theory here presented is not always in complete agreement; the flute instabilities which are described and were predicted as diseases of the magnetic mirror have not appeared, although those arising from anisotropy in the pressure tensor have been demonstrated. On the other hand some configurations, especially the ' hard-core ' pinch, predicted to be stable have failed to be so. In spite of these limitations, this is the most complete study of the diffuse magnetized plasma yet to have appeared and as such demands the study of all those seriously interested in the field. W. B. THOMPSON.

Relativity : The General Theory, by J. L. SYNGE. Pp. xv + 505. (Amsterdam: North Holland, 1960.) 110*s*.

This is a beautiful book. Wherever one turns in it one finds some subject treated in a novel, clear and lucid way, surveyed in a detached and cool fashion. The stress of the whole approach is on the geometrical aspect of general relativity, as might be expected. What is surprising, however, is the success Professor Synge has had in helping one to visualize highly abstruse geometrical concepts, and part of the joy of reading the book lies in this.

A novel method is employed in dealing with Riemannian geometry, the ' world function ' first introduced by Ruse. This is of great help in getting an intuitive feeling for the theory, because this function is essentially simply the square of the distance between two events. The geometrical aspects of general relativity are firmly in control, guiding, shaping and illustrating the book, but there are also clear and precise references to the observational tests of the theory, right up to the present.

No book of such beauty could possibly have been written had Professor Synge not adopted a well-defined point of view, putting in the forefront the clear and precise notions of geometry, of which he is such an unrivalled master. This has necessarily ruled out detailed attention to the various links between the theory and the rest of physics. It is hard to find beauty (though easy to see fascination) in that odd mixture of compelling argument, half-baked suspicion and wide-open mystery that is characteristic of many of these connections.

The book ranges far and wide. Chapters like those on integral conservation laws and on gravitational waves take one deep into active fields of research. The bibliography of 60 pages forms an extremely valuable part.

The book can be heartily recommended to all who are interested in general relativity. However, the knowledgeable reader will find much that is new to him. For the novice his taste must decide whether this should be his first book on general relativity or whether he prefers to start with the physics, in which case this is an ideal second book for him.

The book is beautifully produced and is a pleasure to own. H. BONDI.

Solid State Physics, Vol. 11, *Advances in Research and Applications*, Supplement 2, *Paramagnetic Resonance in Solids*, by W. LOW. Edited by F. SEITZ and D. TURNBULL. Pp. viii + 212. (New York: Academic Press; London: Academic Books, 1960.) 60*s*.

As its title and membership of the excellent 'Solid State Physics' series might suggest, this book sets out to point the importance of paramagnetic resonance techniques in the armoury of the solid state physicist. It cannot be claimed that there is great originality of presentation or context. However, the book is to be welcomed as it synthesizes many ideas scattered in the literature in such a way that the basic features of paramagnetic resonance in solids may be understood. The theory of the crystalline field is first developed and followed by a detailed exposition of its application to the iron, rare-earth and uranium groups. A section on relaxation times and line width leads to a short discussion of solid state devices. There are also brief notes on paramagnetic resonance studies of colour centres and defects in crystals. The short final section is concerned with the experimental side of paramagnetic resonance spectrometry. Throughout the whole text many useful references to original articles are given as footnotes. R. STREET.

Quantum Theory of Atomic Structure, Vol. 1, by J. C. SLATER. Pp. xii + 502. (New York, Toronto, London: McGraw-Hill, 1960.) 85*s*. 6*d*.

This is the first of a two-volume text on atomic structure, which is itself the first of a series that the author hopes to write on the application of quantum mechanics to the structure of atoms, molecules, solids and the physical and chemical properties of matter.

The approach is very elementary. The book starts with a fifty-page historical introduction to quantum theory, leading in a purely heuristic way to the Schrödinger equation, for a single particle in a potential. Rules of thumb are then given for writing down the Schrödinger equation in more general circumstances. Matrices are introduced as expectation values in the Schrödinger representation.

The book then gets down to the restricted field implied by the title including a discussion of the hydrogen atom, the Hartree self-consistent field, the determinantal method and the theory of multiplet structure. Angular momentum including spin is treated rather superficially.

Professor Slater has built up for himself a great reputation as a pedagogue, and, as one would expect, everything in this book is explained with his usual clarity. The latter half of the book which starts to deal with atomic structure is excellent, but the first half is disappointing and rather old fashioned. It is perhaps significant that Dirac is not mentioned along with Heisenberg and Schrödinger among the great pioneers of the subject.

The two-volume text will no doubt become a standard work for those primarily interested in atomic structure, but this first volume by itself is not, as the author hopes, suitable as an introductory text in quantum mechanics for those with wider interests in quantum physics, or a desire to gain in physical terms an understanding of the general structure of quantum theory as we now understand it. P. T. MATTHEWS.

Progress in Nuclear Physics, Vol. 8, edited by O. R. Frisch. Pp. vii + 304. (Oxford: Pergamon Press, 1960.) 90*s*.

The articles in the eighth volume of this well-known series, with one exception, have a strong inclination towards high energy physics. The exception is the chapter ' Collective motion in nuclei ' by D. M. Brink, which provides firstly a brief review of the whole subject and then a more detailed treatment of recent work on pairing correlations and coupling schemes. The collective model is clearly becoming more intelligible theoretically, although it has hardly gained in simplicity.

The volume opens with an interesting account of ' The composition of the primary cosmic radiation ' by C. J. Waddington. This is a subject of perpetual interest because the energies involved reach out beyond the applicability of present theories. The article is primarily experimental and deals in detail with the charge spectrum of the heavy incoming particles. One of the techniques which, like the nuclear emulsion method, has found a place both in cosmic ray studies and in high energy physics in the laboratory is Cherenkov counting. In a stimulating and informative article on ' Cherenkov detectors ' G. W. Hutchinson continues from existing reviews of the subject into the design and application of new forms of counter, many of which have interesting possibilities so far largely unexploited. Instrumentation for cosmic ray research in satellites will clearly be much aided by these devices.

Laboratory studies in medium and high energy nuclear physics receive attention in the articles by E. J. Squires on ' The interaction of polarized nucleons with nuclei ' and by E. H. Bellamy on ' The photoproduction of pions '. The former is a valuable account of a subject in which interest is rapidly increasing following the development of polarized ion sources and targets. A full account of the available experimental material and a clear presentation of the relevant theory are given. The latter article is a readable account of the main experimental techniques and results in photo-pion physics, with emphasis on high energy photon interactions with nucleons. The theoretical treatment of these results is outlined and the reader cannot fail to notice the frequency with which reference is made to calculations of excitation functions and angular distributions based on dispersion relations. It is therefore fortunate that this volume provides what is perhaps the first attempt to describe the present status of this subject to a general audience, in the chapter ' Dispersion relations for elementary particles ' by J. Hamilton. The relation between absorption and scattering processes is a very general one and embraces many physical phenomena; in the present article the somewhat complicated field-theoretic results are approached via several interesting and immediately tangible classical examples.

The volume under review makes perhaps more demands of the reader than some of its predecessors because of its high theoretical content, but this is inevitable if the subjects presented are to be treated adequately. The material discussed is that which was available at about the middle of 1959, and most of the references are dated within the decade 1950–60. The standard of production is high, although rather more misprints and errors in spelling than usual have crept through the proof-reading. W. E. BURCHAM.

Studies in Theoretical Physics : The Proceedings of the Summer School of Theoretical Physics held at Mussoorie, India on 22nd May–18th June 1959, Part 3. Pp. 341 + 535. (New Delhi: Government of India Ministry of Scientific Research and Cultural Affairs, 1959.) Rs. 5.

The papers contained in this part of the *Proceedings* are listed in three sections: Chemical physics, Astrophysics and magneto-hydrodynamics, and Selected topics, which include papers on the exact solution of the equations of charged particles in a plane electromagnetic radiation field and the Compton scattering, the theory of distributions and its applications to field physics, fundamentals of function algebra, relativistic cosmology and Einstein's field equations.

Proceedings of the 1960 *Annual International Conference on High Energy Physics at Rochester*, edited by E. C. G. SUDARSHAN, J. H. TINLOT and A. C. MELISSINOS. Pp. xxv + 890. (Rochester, N.Y.: The University of Rochester; New York: Interscience, 1960.) $13.50.

The Conference consisted of sessions of three different types—four main sessions on Strong interactions of pions and nucleons (experimental), Strong interactions of pions and nucleons (theoretical), Strong interactions of strange particles, and Weak interactions, at which invited papers were presented; four sessions on the same group of subjects, in which summarized reports of associated work were given; and three sessions devoted to subjects of general interest, Structure of elementary particles, New results at superhigh energies, and Theories of elementary particles.

Annual Review of Nuclear Science, Vol. 10, edited by E. SEGRÈ, G. FRIEDLANDER and W. E. MEYERHOF. Pp. vii + 617. (California: Annual Reviews Inc., 1960.) $7.50.

This volume, the tenth of a series of Annual Reviews of Nuclear Science, contains chapters on the following subjects: Neutrino interactions, Nuclear interactions of heavy ions, Cosmic ray showers, Bubble chambers, Optics of high-energy beams, Nuclear structure effects in internal conversion, Recoil techniques in nuclear reaction and fission studies, Labelling of organic compounds by recoil methods, Nucleon–nucleon scattering experiments and their phenomenological analysis, Theoretical interpretation of the energy levels of light nuclei, Nuclear methods for sub-surface prospecting, Experiments on cosmic rays and related subjects during the International Geophysical Year, and Cellular and vertebrate radiobiology.

Some Ionospheric Results obtained during the International Geophysical Year, Proceedings of a Symposium organized by the URSI/AGI Committee, Brussels, 1959, edited by W. J. G. BEYNON. Pp. xi + 399. (London, Amsterdam, New York, Princeton: Elsevier, 1960.) 72*s*.

During the International Geophysical Year scientific observation was coordinated throughout many countries and outstanding advances resulted in many fields.

One of the fields in which the most intensive research was carried out was that of the ionosphere. The results of this research were discussed at a symposium organized by the International Scientific Radio Union, more usually known as U.R.S.I.

During the course of the International Geophysical Year many millions of radio observations were made. These have been scrutinized for interpretation but more information will no doubt be obtained in future scrutinies of the same material. As the Editor and Chairman of the International Geophysical Year Special Commission say in their Preface to the volume, a comment of the late Lord Rutherford is relevant, " This is a grand subject because there is so much in it we do not know ".

A large number of articles on various aspects of the ionosphere will encourage workers to seek further explanation of the material available. The book is divided into eight sections: F2 layer phenomena, High altitude studies, Disturbance phenomena, Ionospheric irregularities, $N(h)$ profiles, Absorption, Drifts, Noise: whistlers, rockets, satellites.

Elektronenbeugung, by ERNST BAUER. Pp. 233. (Munich: Verlag Moderne Industrie, 1960.) DM. 32.

There are few books on the subject of electron diffraction. The principal texts are still those of Thomson and Cochrane (1939), von Laue (1944) and Pinsker (1949). Since the publication of these books there has been a massive growth of the subject of electron microscopy. The application of the methods of this new technology has transformed the subject of electron diffraction, and the appearance of a book which takes account of these developments is therefore timely.

About a quarter of the present book is devoted to the basic theory of the subject. The presentation of this is competent but not outstanding. Much more satisfactory is the section of 84 pages dealing with the constructional details and theoretical limitations of electron diffraction apparatus and the preparation of specimens. A general description of some half dozen commercial instruments from different countries serves to illustrate the discussion of the desirable electron optical and mechanical features of the diffraction camera. The author has given a good general description of the methods available for the preparation of specimens, and the numerous references to published papers enable the reader to obtain readily any further details he may need.

A section on the interpretation of electron diffraction patterns leads naturally to a discussion of the applications of electron diffraction in the metallurgical, chemical and optical industries. The only fault I have to find with an admirably comprehensive treatment is that no indication is given of the difficulty of some of the techniques, so that a reader without prior knowledge of the subject can hardly judge which details of the structure of a specimen are immediately evident in an electron diffraction pattern, and which are brought to light only after prolonged study.

A few pages near the end deal briefly with the diffraction of low energy electrons, and the combination of electron diffraction with electron microscopy. The book concludes with a valuable bibliography of 589 references and—an unusual feature—the addresses of a number of firms in eight countries which manufacture complete instruments or component parts.

The text is marred by numerous errors in references to figures and page numbers; it is to be hoped that these blemishes in an otherwise admirable book will be remedied in later editions. T. B. RYMER.

Theoretical Physics in the Twentieth Century : *A Memorial Volume to Wolfgang Pauli*, edited by M. FIERZ and W. F. WEISSKOPF. Pp. x + 328. (New York: Interscience, 1960.) 72*s*.

This volume of articles was originally intended to celebrate the sixtieth birthday of Pauli. His death converted it into a memorial volume instead. As the editors say themselves, no collection of articles could do justice to the memory of Pauli's work and his impact on modern physics, for only further progress in physics carried out in his spirit can ever serve as a true memorial. Nevertheless, this volume is a fitting tribute that leads the reader again and again to marvel at the influence that Pauli had throughout his active life. One tends to think of Pauli as the conscience of theoretical physics, expressing in unmistakable terms his profound abhorrence of any argument not founded upon the strictest mathematical rigour. Indeed he was that; but he was also a physicist of deep intuitive insight who could see through the complexities of atomic spectra to the need for the exclusion principle long before his restless demand for rigour eventually enabled him to set it upon an adequate mathematical framework, and who predicted the existence of the neutrino long before that most elusive of particles was prepared to vindicate him.

There are two different kinds of article in this memorial volume. The first kind concentrates on the exciting days of the discovery of quantum mechanics, filling in the background without which it would be impossible to understand Pauli's own contributions at that time. The other kind traces the development of subjects up to the present day in which Pauli had at some stage a special interest. Quite apart from its other many virtues, this is one of the best accounts I have ever read of the early days of quantum mechanics, giving a vivid description of the many profound difficulties which arose and the part that each of the great physicists of those days played in their eventual resolution. It would have been so easy, and so understandable, to overdo the part of Pauli in all this; but then the result would have been a lesser, not a greater, tribute to one to whom exactness and simplicity of expression were always paramount.

B. H. FLOWERS.

An Introduction to Astro-Dynamics, by R. M. L. Baker Jr. and M. W. Makeson. Pp. xiv + 358. (New York: Academic Press, 1960.) $7.50.

The advent of space science has demanded a greatly increased activity in those branches of theoretical astronomy that are concerned with the motions of planets, satellites and interplanetary particles, whether these be artificial or natural. The celestial mechanical principles on which such theory is based are well known, having been developed since the time of Newton. However, methods of applying them to the extensive high speed requirements of space science are now being devised and improved. To cope with these advances special study courses are needed supported by suitable textbooks. This new science of celestial mechanics applied to contemporary problems of space vehicles is called ' Astro-dynamics '.

The book under review provides a very effective introduction to this subject. Its essential aim is to provide the mathematical basis for the practical calculations of space motion. The text is therefore designed for engineers and space scientists rather than astronomers. The reader does not require a knowledge of classical celestial mechanics but will use calculus, vectors and rectangular coordinates. Hamiltonian mechanics is avoided, and spherical and polar coordinates are used only to a restricted extent. The mathematical developments are rather concise. The Table XV is very useful in providing a summary of the combinations of observational data that are likely to be available and indicating those theoretical sections developed elsewhere in the book that should be applied in the various cases. Much attention is given to the application of orbital perturbations to terrestrial and atmospheric problems.

Although the main part of the book is devoted to mathematical utility, there is much that will be useful to the general reader. The early chapters give readable discussions on relevant background subjects such as coordinate systems, general laws, minor planets, comets, and their relations to space science. The value of the book as a reference handbook is enhanced by introducing a chapter in which astrodynamic quantitative concepts are clearly described and the latest numerical values given. There is a very extensive glossary of both terms and symbols.

The book is well printed and has clear efficient notations. It deserves a wide distribution among all who are connected with or interested in space science.

C. W. ALLEN.

Principles of Optics, by M. Born and E. Wolf. Pp. xvi + 803. (London, New York, Paris, Los Angeles: Pergamon Press, 1959.) £6.

The preface to this book explains that it is restricted to " those optical phenomena which may be treated in terms of Maxwell's phenomenological theory ". Material media are regarded as continua for which quantities like the dielectric constant are given and the classical molecular optics which occupied about half the space of Born's *Optik* is excluded. Applications of relativity and quantum theory to optics are omitted. This involves the omission of the experiments on moving media, the theory of radiation detectors (including the eye) and the application of information theory to optics. The topics treated include the detailed theory of interference, with special reference to coherence, the theory of diffraction (with an extended treatment of diffraction by ultrasonic waves) and the theory of optical instruments discussed both in terms of geometrical optics and of wave theory. There is an interesting historical introduction.

One can see that difficult decisions were needed to prevent this book extending to well over 1000 pages and that it was not possible to be strictly logical in deciding what to omit. I wish that moving media had been included and I feel that, since photo-elasticity was included, the electro-optical and magneto-optical effects might also have been treated. The treatment of the diffraction theory of optical instruments is inevitably a little unsatisfactory because discussion of the properties of the receptor and of the ultimate limits of measurement set by noise is excluded. It is thus impossible to show that a loss of transmission in higher spatial frequencies, due to aberration, results in an irretrievable loss of information.

A very large part of this book is concerned with a systematic account of the wave theory of light, including the most recent developments. The treatment is logical and authoritative. To those who are prepared to give concentrated attention to a subject which is not always simple, it is clear and straightforward. All who are concered with optical theory—and in view of the many applications of wave theory this means all theoretical physicists—are indebted to the authors. The account of optical instruments and of experimental methods is uneven in coverage and in quality. Many topics of interest, such as the sheared-wave interferometer, are very adequately treated. On the other hand, the account of experiments on the velocity of light is inadequate and completely out of date. The choice of material in this part is not very satisfactory; the Lummer–Gehrcke Plate (now mainly of historical interest) is treated at length (6 pages), while there is very little discussion of interference spectroscopy or of optical standards of length.

Let us accept the excellence of the main part of this book and consider the general question of the function of a book of this type in the dissemination of scientific information. If any considerable scientific topic is to be fully discussed in a book, the treatment may become nearly as lengthy as the original papers from which it is derived. Unless the presentation is an advance on the original papers in clarity of exposition, so that the reader obtains a deeper insight, then most people will prefer to have a general introduction together with references to the papers. At a certain point the book must give way to the *Handbuch* or the *Progress Report* containing a series of articles by people who are most expert in restricted fields.

The treatment of coherence in this book is very lengthy, yet I feel that the length is justified because the subject can be seen as a unity (apart from the quantum theory aspects). An endeavour has been made to obtain some of the advantages of the *Handbuch* by calling in a panel of consultant experts (to whom acknowledgment is made in the preface) while retaining the unity which is available when there are one or two authors. Although I would have preferred from these authors a book which omitted much of the experimental and instrumental side and gave a little less space to some theoretical topics which seem to me unimportant, I hope and believe that this book will be very successful. I also hope that its success will not encourage other authors to write at equal length. Every rule may have an exception. Let us regard this as an exception to the rule that a good book should not be too heavy to hold in one's hand.

R. W. DITCHBURN.

Kybernetik, Band 1, Heft. 1—Journal dealing with the transmission and processing of information and with control processes in organisms and automata. Pp. 56. (Berlin, Göttingen, Heidelberg: Springer-Verlag, 1961.) DM. 12.80.

This new journal intends to become a forum on the subjects of information theory, theory of automata, theory of control systems, mathematical foundations of communication theory, sensory processes and micro- and macrophysiology of the central nervous system in relation to information handling, information handling by organisms (including man) and task-oriented groups, and mathematical models for communication and control processes in organisms. This covers to an appreciable degree the scope of the *Journal of Electronics and Control* and the journal *Information and Control*. Judging from the first number we can expect that it will complement them in a happy way because it shows a strong bias towards neurophysiology and biology. Küpfmüller and Jenik contribute a clear and simple article on information processing by neurons. Reichardt sums up his well-known, remarkable investigations on the fungus *Phycomyces*, probably the best explored organism from the point of view of sensory dynamics. Trincker, Sieber and Bartual describe their investigations of eye movements. Vossius gives a mathematical analysis of the efferent–afferent sensory–muscular control circuit. Wenzel gives a most interesting numerical analysis of the reaction times of piano players who read their music. Steinbuch contributes a remarkable article on the learning matrix, with an electro-chemical model. Carson's article on 'Letter constraints within words in printed English' is a further elaboration of one of the classical fields of information theory. Ivo Kohler comes back to Pavlov's equally classical dog.

As always with a new journal, one wonders whether it will be possible to maintain this high level, but this is fairly guaranteed by the distinguished international list of editors. From now on the new journal will have to be followed with attention by everybody working in the various fields which have branched out from information theory. D. GABOR.

Selected Scientific Papers, by B. VAN DER POL, edited by H. BREMMER and C. J. BOUWKAMP. Vol. I, pp. xiii + 660. Vol. II, pp. 661–1339. (Amsterdam: North-Holland, 1960.) £6 13*s*. per volume.

We hear frequently these days about scientific radio, but radio has not always been very scientific, and this aspect of physical science has been almost more than any beset by empiricism. Few men have done more than Van der Pol to put radio on a sound scientific basis. Together with his life-long friend Sir Edward Appleton he did much to found and foster the Union Radio Scientifique Internationale. Van der Pol was essentially a theoretician but with a very practical turn of mind. His interests were wide and he made notable contributions to the theory of radio wave propagation, theory of oscillations and the development and applications of operational calculus, to quote only a few of the more important fields in which his researches lay. He was a man of great industry and insight and wrote a great deal that is important in his long and busy life, working right up to the end. The two substantial volumes under review represent only a fraction of his work. We have here, however, a representative selection covering most of the fields in which he made notable contributions and including his most famous papers.

The papers are scattered over a large number of journals and the present collection will make reference much easier for many of those who will, undoubtedly, consult them for a long time to come.

The individual reader may feel that the two volumes are somewhat costly but those who came to know Van der Pol and his work will surely wish to have them as a fitting memorial to one who did so much to give dignity to his subject. Libraries associated in any way with radio research should, of course, have a copy.

The volumes are beautifully produced and the editors, Dr. H. Bremmer and Dr. C. J. Bouwkamp, both of whom were closely associated in his work with Van der Pol, are to be congratulated on the clear presentation and arrangement of the papers. These are introduced by a fitting biographical note by Dr. H. B. G. Casimir. R. A. SMITH.

The Rotation of the Earth, Cambridge Monograph on Mechanics and Applied Mathematics, by W. H. MUNK and G. J. F. MACDONALD, edited by G. K. BATCHELOR and S. GOLDSTEIN. Pp. xix + 323. (Cambridge: University Press, 1960.) 70*s*.

This is a delightful book. When one opens a book on an imposing subject, full of uncertainties requiring a tremendous amount of detailed discussion of theories as well as of observations, one expects to find that the authors have undertaken this formidable task in a spirit of duty or as a penance for having added to the confusion of the subject. This expectation is often fulfilled and leads one to anticipate that such a monograph might make heavy reading, but Munk and MacDondald are writers of an entirely different class. They not only love their subject, they positively enjoy writing about it. They convey their pleasure and interest so vividly and in such expressive language that few readers, however little interest the subject may have possessed for them, will be able to resist its fascination.

Phrases like " problems becoming unsolved " and " excursions into the jungle of theory " deserve to become part of the scientific vocabulary.

The range of subjects covered by the authors is tremendous and their mastery is complete at every point. It is most refreshing to find such a degree of healthy scepticism and thorough appreciation of both observational and theoretical difficulties amongst people so deeply immersed in their subject. The full discussion of the various aspects, such as the wobble of the earth's axis and the variations in the length of day, naturally lead the authors deeply into the subject of the evaluation of the observations of the earth's rotation for theories of the structure of the planet. Thus, to use a phrase of theirs, they " make a geophysical asset out of an astronomical nuisance ". The treatment is everywhere clear and intelligible to anybody willing to make the effort, and with such fascinating guidance it would require considerable power of will not to make the effort.

The diagrams are particularly intriguing and greatly aid the understanding. Though in some places three-dimensional models might have been more helpful, one can understand the aversion of the publisher to these. My only complaint, if complaint it be, is that glancing through the pages one becomes so attracted by some of the diagrams that, on finding the legend insufficiently informative, one turns to the text to discover just what they refer to, but making a reader read is not really a crime on the part of an author. To anybody interested in the subject, one of the limited number of possible approaches to a theory of the constitution of the earth, this is an essential book. Few authors, whose work brings them in contact with related disciplines, such as rigid body dynamics, elasticity, plasticity or astronomy, will not benefit from a study of the book and, in addition, will enjoy reading it. The book has been beautifully produced by Cambridge University Press. H. BONDI.

Complex Variables and the Laplace Transforms for Engineers, by W. R. LE PAGE. Pp. xvii + 475. (London: McGraw-Hill, 1961.) 97*s*.

Books on the Laplace transform generally fall into two groups: (i) those intended for mathematicians where mathematical concepts and rigour are the matters of primary interest, and (ii) those intended for engineers which are in the main concerned with applications to technical problems, and where only sufficient mathematical analysis is presented to give a reasonable understanding. However, in the more advanced applications a thorough knowledge of the complex variable becomes necessary, and some authors have been content to refer to standard texts. This approach can be wasteful and it is one of the claims of this book that the complex variable theory is presented with applications to engineering problems in mind.

The first seven chapters deal with the development of the appropriate complex variable theory, the subjects including the following: system analysis, analytic functions, conformal mapping, complex integration, Cauchy's integral theorems, infinite series, singularities, residues multivalued functions and a collection of useful theorems.

In Chapter 8 the author presents the theory of convergence of real integrals. Then follows a short chapter on the Fourier integral where its properties are presented. The next four chapters present the definitions, properties and applications of the Laplace transform, one chapter being on the convolution integral and its implications. Here again strict attention is paid to the question of convergence. The next chapter presents in detail the impulse function and the amount of space is justified on the grounds that engineers find it difficult to believe in this function. The last two chapters are concerned with periodic functions and the *Z*-transform and its application to sampled data.

All sixteen chapters are followed with a selection of problems designed to augment the text (no answers).

The book has been written by an engineer for engineers and has been developed out of a series of lectures, and the level is set at the final year and first year postgraduate stage. C. C. RITCHIE.

Proceedings of the International Conference on Nuclear Structure, edited by D. A. BROMLEY and E. W. VOGT. Pp. 990. (Toronto: University Press; Amsterdam: North-Holland, 1960.) 125*s*.

This book is an account of the International Conference on Nuclear Structure held at Kingston, Ontario, from August 29th to September 3rd, 1960. To all research workers in this field the value of the publication has been greatly enhanced by the exemplary speed with which the editors managed to get this enormous mass of material into print and circulation, there being an interval of only several weeks between the close of the conference and the availability of the *Proceedings*. The material is presented with great clarity and in a form which makes it easy to use for reference.

The rapporteur system was used at the conference and in the *Proceedings* the main talks are reproduced in full. The topics discussed were the physical foundations of nuclear models, the gross properties of nuclear matter, nuclear reaction mechanisms, the properties of individual levels, statistics of nuclear levels, giant dipole resonances and finally fission phenomena as related to nuclear structure. There were also two stimulating talks given by R. E. Peierls and D. H. Wilkinson on open problems in nuclear structure.

In addition to the talks given by the main speakers and the resulting discussions a number of selected research contributions are also printed and abstracts of all other contributed papers are presented as an Appendix.

The editors have been successful in achieving in this volume a balance between the large quantity of experimental data of impressive precision and the astonishingly good theoretical description of these data in terms of nuclear models. As Professor Weisskopf points out in his conference summary, which is a gem of elegant simplicity, that this description is so good is an indication of how little we know about the nucleus. J. E. BOWCOCK.

Physique Nucléaire, par M. BAYET. Pp. 404. (Paris: Masson, 1960.) 65n fr.

This French undergraduate textbook of nuclear physics follows the traditional syllabus at a fairly elementary level. The first hundred pages are devoted to the ideas of wave mechanics, classical and quantum statistics, scattering theory, spin, and relativity. Next comes a brief survey of elementary particles and the characteristics of stable nuclei, enough being said about nuclear forces to provide a framework on which to attach the various models of nuclear structure. The treatment of natural radioactivity which follows makes room for some relatively modern developments (such as the regularities in the lifetimes of M4 gamma transitions) but is notably out of date in failing to make any reference to parity non-conservation. There is a long section on the interaction of nuclear particles with matter, leading up to a brief description of particle detectors. The book ends with a short account of neutron physics and of fission and fusion processes.

The book is much less ambitious in scope than the textbooks of R. D. Evans, D. Halliday, and I. Kaplan, on which it is avowedly based. This pruning down to essentials might well prove an advantage to some students, and the writer would certainly recommend it to those who can surmount the language barrier but are appalled at the acres of reading often expected of them by all but the most tolerant of lecturers. H. R. ALLAN.

Physics of the Atom, by M. RUSSELL WEHR and JAMES A. RICHARDS JR. Pp. xi + 420. (Reading, Massachusetts; London: Addison-Wesley, 1960.) 49*s*.

This textbook is written at about the level of a first-year university course in this country. It begins with chapters on the atomic view of matter, of electricity, and of radiation; it ends with chapters on nuclear energy, cosmic rays and the fundamental particles. Between these extremes, and making up about two-thirds of the book, is an admirably clear account of elementary atomic structure, relativity, X-rays, matter waves, the solid state, radioactivity, and nuclear physics.

With such a vast syllabus, the treatment is inevitably brief. But it is not scrappy. Some formulae are derived, others simply quoted, but their significance is always made clear and there are plenty of numerical problems to drive home what has been learned. Each chapter ends with a list of useful references for further reading.

As an indication of the degree of detail attempted we observe that the simple Bohr theory of the hydrogen atom is developed fully, whereas electron spin is mentioned only briefly as a cause of fine structure. The exclusion principle is applied to illustrate the building up of the chemical elements, but we are not taken beyond the first two short periods of the Periodic Table.

Special relativity is given a comparatively full treatment: the Lorentz transformation and mass–energy equivalence are both derived and illustrated numerically. Matter waves are discussed without the use of Schrödinger's equation. Solid state physics, too, has an almost wholly qualitative treatment, directed towards an understanding of transistors. The section on nuclear physics, on the other hand, begins with radioactivity and the equations of radioactive growth and decay; and in the survey of nuclear transmutations there is a detailed presentation of Chadwick's evidence for the existence of the neutron. There is no discussion at all of nuclear models, but reactor physics is dealt with at length.

All in all, a very reasonable balance has been struck between rigour with the fundamentals and concessions to the student's interests with qualitative treatments of practical applications and the more glamorous recent discoveries. This is a very good textbook indeed. H. R. ALLAN.

Frozen Free Radicals, by G. J. MINKOFF. Pp. ix + 148. (New York and London: Interscience Publishers, 1960.) 36*s*.

There are few branches of physics and chemistry whose 'early history' can be stated to have ended a mere five years before the present. The rapidly growing field of the stabilization of free radicals at low temperatures is one of these. Admittedly, as is the case for many other low temperature phenomena, Dewar's work in the 1890's provides the first examples, but a systematic study and use of frozen free radicals is less than a decade old.

Such a rapidly growing field, which relies on a careful blending of a variety of techniques, demands a book which can serve both as a guide to the newcomer, and as a quick reference book for the specialist. Dr. Minkoff has aimed high but the result is disappointing. It is true that the table of contents makes impressive reading: experimental methods for the production and trapping of radicals, cryogenic techniques, theoretical work on trapping, and finally, the properties of active atoms and of a large variety of free radicals, are all included. But alas, the treatment is patchy, uneven, and there are some misleading, or trivial, or naïve or useless statements, especially in the chapter on experimental methods. Thus for instance, one wonders whether in describing a method for delivering a gas at a predetermined rate (p. 32), the author refers to the 'recent' discovery of Charles' law, or Poiseuille's law, or of the temperature dependence of viscosity, or of the thermal expansion of solids. Again, to give another example, a sentence on p. 53 might well convey to the uninitiated the idea that the numerical value of the ratio Boltzmann constant/Bohr magneton was not established until 1957. The most charitable explanation for passages like these is that they are the result of hasty and careless composition. One can only hope that the novelty of a subject and the urge to publish a book quickly will not be allowed to become an excuse for such regrettable practices. N. KURTI.

Direct Interaction with Strong Coupling in Nuclear Collisions II. E2 Excitations

By C. B. O. MOHR
Physics Department, University of Melbourne

MS. received 14*th April* 1961

Abstract. The work of a previous paper on the effect of coupling between elastically and inelastically scattered waves for the case of E0 excitations of the nucleus throughout its volume has been extended to E2 excitations. The inclusion of coupling causes inelastic cross sections to deviate even more from the distorted wave values for E2 excitations than for E0 excitations. The effect is greater for a volume interaction than for a surface interaction of equivalent strength.

---

§ 1. Introduction

Since direct interaction is the main mechanism in nuclear collisions at the higher energies of impact, many calculations of total cross sections and angular distributions have been carried out with the distorted wave approximation. Unfortunately, various complicating effects such as exchange and spin–orbit forces can cause as much change in calculated angular distributions as permissible adjustments in the nuclear potential, and have therefore to be taken into account.

The further complication of coupling between elastically and inelastically scattered waves also seems to be of importance whenever the inelastic cross section is comparable with the geometric cross section. Solution of the coupled equations for light nuclei has been carried out for a surface interaction (Yoshida 1956), also for a volume interaction by using a perturbation approximation to a standing wave solution (Yoshida 1958).

In this paper the coupled equations are solved for a light nucleus, for a volume interaction with a simplified model neglecting spin, in an attempt to gain physical insight into the problem, the work of a previous paper on E0 excitations (Mohr 1959, to be referred to as I) being extended to E2 excitations. The extent of the difference in the value of partial cross sections obtained with and without strong coupling is systematically followed as the coupling is increased to give the maximum cross section. The results are compared with those for the simpler case of a surface interaction.

§ 2. Theory

We shall adopt and extend the notation of I. The ingoing and elastically scattered particles have wave number $k/2\pi$, energy $E=k^2h^2/8\pi^2M$, wave function $F_0(\mathbf{r})$, and move in a potential $-V_{00}(r)$. For the inelastically scattered particles the corresponding quantities are $k_1/2\pi$, $E_1=k_1{}^2h^2/8\pi^2M$, $F_1(\mathbf{r})$ and $-V_{11}(r)$. Then, putting $\gamma=8\pi^2M/h^2$, the coupled equations take the form

$$(\nabla^2+\gamma E+\gamma V_{00})F_0(\mathbf{r})=-\gamma V_{01}(\mathbf{r})F_1(\mathbf{r}), \qquad \ldots\ldots(1\,a)$$

$$(\nabla^2+\gamma E_1+\gamma V_{11})F_1(\mathbf{r})=-\gamma V_{10}(\mathbf{r})F_0(\mathbf{r}), \qquad \ldots\ldots(1\,b)$$

where $-V_{01}(\mathbf{r})$ is the transition potential, or potential energy of the direct interaction between the incident particle and the nuclear particle excited in the collision averaged over the transition density of the nuclear particle. If this interaction is taken to be of short range, $V_{01}(\mathbf{r})$ has approximately the form of $\psi_0^*(\mathbf{r})\psi_1(\mathbf{r})$.

We consider the frequently occurring case of the nucleus being raised from a 0^+ ground state to a 2^+ excited state by the collision, in which case $\psi_0(\mathbf{r})$ is spherically symmetrical and $\psi_1(\mathbf{r})$ depends on angle as $Y_{2,M}(\theta,\phi)$. We may then write

$$V_{01}(\mathbf{r}) = V_{01}(r) Y_{2,M}(\theta,\phi). \qquad \ldots\ldots(2)$$

Taking the z axis along the incident beam, and putting

$$F_0(\mathbf{r}) = r^{-1}\sum_l F_0^l(r) Y_{l,0}(\theta,\phi), \qquad \ldots\ldots(3\,a)$$

$$F_1(\mathbf{r}) = r^{-1}\sum_l F_1^l(r) Y_{l,m}(\theta,\phi), \qquad \ldots\ldots(3\,b)$$

the coupled equations (1) become

$$\sum_l \left(\frac{d^2}{dr^2} + \gamma E + \gamma V_{00} - l(l+1)r^{-2}\right) F_0^l Y_{l,0} = \sum_{l'} \gamma V_{01}(r) F_1^{l'} Y_{2,M} Y_{l',m'}, \qquad \ldots\ldots(4\,a)$$

$$\sum_l \left(\frac{d^2}{dr^2} + \gamma E_1 + \gamma V_{11} - l(l+1)r^{-2}\right) F_1^l Y_{l,m} = \sum_{l'} \gamma V_{01}(r) F_0^{l'} Y_{2,-M} Y_{l',0}. \qquad \ldots\ldots(4\,b)$$

Since the equations hold for all ϕ, we have $m = -M = m'$. On the right-hand side of (4 *a*) we expand $Y_{2,M} Y_{l',-M}$ as a series of $Y_{L,0}$'s with different values of L, and for (4 *b*) likewise we have a series of $Y_{L,M}$'s with particular M (Rose 1957). From the properties of the Clebsch–Gordan coefficients occurring in the expansion, there are only three terms in the series, with $L = l'+2,\ l',\ l'-2$. Equating coefficients of corresponding Y's we obtain

$$\left(\frac{d^2}{dr^2} + \gamma E + \gamma V_{00} - l(l+1)r^{-2}\right) F_0^l$$
$$= -\gamma V_{01}(r)\left(a_{l+2,M} F_1^{l+2} + a_{l,M} F_1^l + a_{l-2,M} F_1^{l-2}\right), \qquad \ldots\ldots(5\,a)$$

$$\left(\frac{d^2}{dr^2} + \gamma E_1 + \gamma V_{11} - l(l+1)r^{-2}\right) F_1^l$$
$$= -\gamma V_{01}(r)\left(b_{l+2,M} F_0^{l+2} + b_{l,M} F_0^l + b_{l-2,M} F_0^{l-2}\right), \qquad \ldots\ldots(5\,b)$$

the a's and b's denoting numerical coefficients. We have to solve the complete set of equations for a particular value of M and different values of l, noting that all the even order waves are coupled together, similarly all the odd order waves.

At a given energy E the waves $F_0^l(r)$ and $F_1^l(r)$ have appreciable values inside the nuclear radius for only a limited number of orders l, so that the set of equations (5) is limited in number. Suppose there are $2n$ equations in the even (or odd) set, n of type (5 *a*) and n of type (5 *b*). A single differential equation for a given F_0^l or F_1^l may be obtained by eliminating all the other F's, this equation having $2n$ regular solutions which may be denoted by $F_{0,\nu}^{\ l}$ or $F_{1,\nu}^{\ l}$, with $\nu = 1, 2, \ldots 2n$.

The most general set of solutions of (5) consists of linear combinations of the $F_{0,\nu}^{\ l}$ or $F_{1,\nu}^{\ l}$, and may be written

$$F_0^l = \sum_{\nu=1}^{2n} c_\nu F_{0,\nu}^{\ l}, \qquad F_1^l = \sum_{\nu=1}^{2n} c_\nu F_{1,\nu}^{\ l}, \qquad \ldots\ldots(6)$$

the c's being arbitrary (complex) coefficients. They must join smoothly on to the exterior solutions, which for neutrons have the form

$$F_0{}^l = (2l+1)^{1/2}(4\pi)^{-1/2} i^l (kr\mathrm{j}_l(kr) + i\alpha_{l,M} kr\mathrm{h}_l{}^{(1)}(kr), \qquad \ldots\ldots(7\,a)$$

$$F_1{}^l = (2l+1)^{1/2}(4\pi)^{-1/2} i^{l+1} \beta_{l,M} k_1 r\mathrm{h}_l{}^{(1)}(k_1 r), \qquad \ldots\ldots(7\,b)$$

where j_l is a spherical Bessel function and $\mathrm{h}_l{}^{(1)}$ a spherical Hankel function of the first kind. For charged particles the corresponding Coulomb wave functions are of course used. The c's, α's and β's form a set of $4n$ undetermined quantities, which may be found by fitting the $2n$ interior solutions on to the corresponding exterior solutions so that both the functions and their derivatives are continuous across the boundary. The α's and β's are thus obtained for a particular value of M, and the whole process is repeated for all of the M values 0, ± 1, ± 2. $|\alpha_{l,M}|^2$ and $|\beta_{l,M}|^2$ are the probability of elastic and inelastic scattering respectively for particles with a given l and M and, after averaging over all M values, have the maximum values of 1 and $k_1/4k$ given by the conservation theorem.

The differential cross sections for elastic and inelastic scattering are given by

$$\sigma_{\mathrm{el}}(\Theta) = (4\pi/5)k^{-2} \sum_{M=-2}^{2} |\sum_l (2l+1)^{1/2} \alpha_{l,M} Y_{l,M}(\Theta, 0)|^2, \qquad \ldots\ldots(8\,a)$$

$$\sigma_{\mathrm{in}}(\Theta) = (4\pi/5)k_1 k^{-3} \sum_{M=-2}^{2} |\sum_l (2l+1)^{1/2} \beta_{l,M} Y_{l,M}(\Theta, 0)|^2, \qquad \ldots\ldots(8\,b)$$

and the corresponding total cross sections by

$$\sigma_{\mathrm{el}} = (4\pi/5)k^{-2} \sum_{M=-2}^{2} \sum_l (2l+1)|\alpha_{l,M}|^2, \qquad \ldots\ldots(9\,a)$$

$$\sigma_{\mathrm{in}} = (4\pi/5)k_1 k^{-3} \sum_{M=-2}^{2} \sum_l (2l+1)|\beta_{l,M}|^2. \qquad \ldots\ldots(9\,b)$$

The factor 1/5 comes from averaging over the five values of M, i.e. from averaging over all orientations of the quadrupole moment in $V_{01}(\mathbf{r})$.

The effect of coupling in E1 excitations may in principle be considered in a similar way, but odd and even order waves are now all coupled together, so that at a given energy the labour of the calculation is greatly increased.

§ 3. CALCULATIONS

For simplicity a square well was taken for $V_{00} = V_{11}$, with depth 47 MeV and radius $R = 2{\cdot}9$ fermi, as in I, corresponding to a carbon nucleus for which the principal energy loss of 4·4 MeV corresponds to an E2 excitation from the 0^+ ground state. The incident neutron energy was taken to be 18 MeV, for which energy the $l = 4$ and higher order waves are small inside the nuclear radius. Then there are only two equations of type (5 *a*) and two of type (5 *b*) for the even order waves, similarly for the odd order waves. The energy loss in the collision was neglected in comparison with the incident energy, so that $k_1 = k$, an approximation which greatly reduces the work without affecting the general conclusions.

3.1. *Solution of the Coupled Equations*

For $M = 0$ each b in (5 *b*) is equal to the corresponding a in (5 *a*)—a considerable simplification. Then, taking $E_1 + V_{11}$ to be equal to $E + V_{00}$, Eqns (5) clearly have two types of solution, viz.

$$F_{1,\nu}{}^l = \pm F_{0,\nu}{}^l. \qquad \ldots\ldots(10)$$

Then the equations to be solved for $F_{0,\nu}{}^{l}$ are of the form

$$F_{0,\nu}{}^{1\prime\prime}+(K^2-2r^{-2})F_{0,\nu}{}^{1}=\mp(p_1F_{0,\nu}{}^{1}+p_3F_{0,}{}^{3}), \qquad \ldots\ldots(11\,a)$$

$$F_{0,\nu}{}^{3\prime\prime}+(K^2-12r^{-2})F_{0,\nu}{}^{3}=\mp(q_1F_{0,\nu}{}^{1}+q_3F_{0,\nu}{}^{3}), \qquad \ldots\ldots(11\,b)$$

for the odd order waves, all upper signs being taken together or all lower signs. The modifications in the equations for the even order waves $F_{0,\nu}{}^{0}$ and $F_{0,\nu}{}^{2}$ are obvious. K is 2π times the interior wave number. The p's and q's contain the factor $V_{01}(r)$ and so are functions of r.

The equations (11) may be rewritten in the form

$$F_{0,\nu}{}^{1\prime\prime}+(s_1-2r^{-2})F_{0,\nu}{}^{1}=pF_{0,\nu}{}^{3}, \qquad \ldots\ldots(12\,a)$$

$$F_{0,\nu}{}^{3\prime\prime}+(s_3-12r^{-2})F_{0,\nu}{}^{3}=qF_{0,\nu}{}^{1}. \qquad \ldots\ldots(12\,b)$$

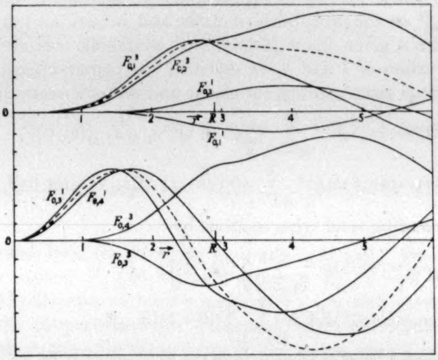

Fig. 1. Graphs of the wave functions $F_{0\nu}{}^{l}$ ($\nu=1, 2, 3, 4$) for ingoing and elastically scattered neutron waves of order l which are solutions of the coupled equations (11). The distance r is in fermis. The neutrons have energy $E=18$ MEV, and are scattered by a square well of radius $R=2{\cdot}9$ fermi and depth $V_{00}=47$ MEV. The transition potential $V_{01}(\mathbf{r})=0{\cdot}2\,(E+V_{00})\,Y_{2,0}\,(\theta,\phi)$ for $r<R$; 0 for $r>R$. The broken curves have the form $Krj_l(Kr)$ for $r<R$, with $l=3$ and 1 for the top and bottom curves respectively, where $K^2=8\pi^2M(E+V_{00})/h^2$.

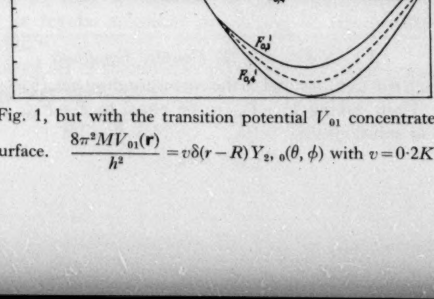

Fig. 2. As for Fig. 1, but with the transition potential V_{01} concentrated at the nuclear surface. $\dfrac{8\pi^2MV_{01}(\mathbf{r})}{h^2}=v\delta(r-R)\,Y_{2,0}(\theta,\phi)$ with $v=0{\cdot}2K$.

Eliminating one of the quantities $F_{0,\nu}^{1}$ and $F_{0,\nu}^{3}$ gives for the other quantity a fourth-order differential equation which has two regular solutions. Since p and q may be both positive or both negative, we obtain four regular solutions for $F_{0,\nu}^{1}$ and four corresponding regular solutions for $F_{0,\nu}^{3}$, i.e. ν takes the values 1, 2, 3, 4.

There are two extreme forms for V_{01} for easiest solution of the coupled equations: (*a*) a square well of radius R, (*b*) a Dirac δ-function at $r=R$, corresponding to (*a*) a simple form of volume interaction, and (*b*) a surface interaction. Form (*b*) is often used for the great simplicity it introduces in solving the coupled equations. Form (*a*) is our main concern, but the results given by form (*b*) are also presented for comparison.

(*a*) *Square well for* V_{01}. This makes s_1, s_3, p and q constant for $r<R$. Then the fourth-order differential equation obtained by eliminating $F_{0,\nu}^{1}$ or $F_{0,\nu}^{3}$ from (12) may readily be solved by expanding the solution in a power series in r. The indicial equation has roots differing by an integer, and therefore the regular solution for $F_{0,\nu}^{1}$ and for $F_{0,\nu}^{3}$ starting with the higher positive power of r contains an additional power series multiplied by $\ln r$. This series is laborious to calculate to many terms, so the solution is calculated in this way for small r only, and extended to $r=R$ by numerical solution of the coupled equations. The power series for the other solution may be used at $r=R$ without much labour. Pairs of solutions for F_0^{2} and F_0^{4} are found in exactly the same way. The numerical relation between the magnitudes of corresponding pairs of solutions $F_{0,\nu}^{l}$ and $F_{0,\nu}^{l+2}$ is found from one of the two coupled equations.

While the solutions are required only near $r=R$, for fitting on to the exterior solutions (7), the form of the interior solutions is of interest, and we now refer to Fig. 1. $F_{0,3}^{1}$ and $F_{0,4}^{1}$ correspond to the upper and lower sign respectively in (10) and (11), and as V_{01} tends to zero they merge together into the form $Kr\mathrm{j}_1(Kr)$. The amplitudes of the corresponding functions $F_{0,3}^{3}$ and $F_{0,4}^{3}$ approach exact proportionality to V_{01} as V_{01} tends to zero, and so get smaller and smaller (in comparison with $F_{0,3}^{1}$ and $F_{0,4}^{1}$). Vice versa, $F_{0,1}^{3}$ and $F_{0,2}^{3}$ merge together into the form $Kr\mathrm{j}_3(Kr)$ as V_{01} tends to zero, while $F_{0,1}^{1}$ and $F_{0,2}^{1}$ get smaller in comparison. For $r>R$, V_{00} and V_{01} are zero, and the form of the curves is that of a linear combination of $kr\mathrm{j}_l(kr)$ and $kr\mathrm{n}_l(kr)$.

Similar principles apply for $M=\pm 1, \pm 2$, but the corresponding a's and b's in (5) are no longer equal, and detailed calculations are more complicated.

(*b*) *Dirac* δ-*function for* V_{01}. We take

$$V_{01}(r)=v\delta(r-R). \qquad \ldots\ldots(13)$$

The p's and q's in (11) are also of form $\delta(r-R)$, so that the right-hand sides of (11*a*) and (11*b*) are zero for $r<R$. It follows, from the form of the solutions for case (*a*), that for $r<R$, $F_{0,3}^{1}$ and $F_{0,4}^{1}$ are of form $Kr\mathrm{j}_1(Kr)$; $F_{0,1}^{3}$ and $F_{0,2}^{3}$ are of form $Kr\mathrm{j}_3(Kr)$; $F_{0,3}^{3}$, $F_{0,4}^{3}$, $F_{0,1}^{1}$ and $F_{0,2}^{1}$ are zero.

At $r=R$, the right-hand sides of (11*a*) and (11*b*) suddenly rise and fall, hence the F's suddenly change slope by an amount proportional to v. For $r>R$, the same remarks apply as for case (*a*), but the amplitudes of $F_{0,1}^{1}$, $F_{0,2}^{1}$, $F_{0,3}^{3}$ and $F_{0,4}^{3}$ are now exactly proportional to V_{01}.

The curves in Fig. 2 may usefully be compared with the corresponding curves in Fig. 1. In Fig. 1 the difference between two curves corresponding to different signs in (11) gradually increases from $r=0$ to $r=R$, whereas in Fig. 2 the difference occurs suddenly at $r=R$. The four $F_{0,\nu}^{3}$ curves for $r>R$ are similar for the two forms of potential (the similarity would have been still closer for a more carefully chosen value of v); but the four $F_{0,\nu}{}^1$ curves are less similar for the two forms of potential, for with potential (*a*) they start rising at smaller values of r than the $F_{0,\nu}{}^3$ curves.

The modification required for $M \neq 0$ is fairly easily carried out, but to explain it in detail here would take a disproportionate amount of space.

(*c*) *General form for* V_{01}, V_{00} *and* V_{11}. More realistic forms for these potentials should be adopted than (*a*) or (*b*). The solution of the coupled equations would then be started off at small r by assuming the V's to be constant, and then extended to larger r by numerical integration. If there are co-operative effects from equivalent particles in the nucleus, the magnitude of V_{01} will be increased accordingly.

3.2. *Determination of* $\alpha_{l,0}$ *and* $\beta_{l,0}$

The neatest way of fitting together the complete interior solutions (6) and the exterior solutions (7), and the way least liable to numerical error, is to proceed as follows. The phase shifts at infinity $\eta_\nu{}^l$ of each of the component waves $F_{0,\nu}{}^l$ are determined by fitting each at $r=R$ to a linear combination of $kR\mathrm{j}_l(kR)$ and $kR\mathrm{n}_l(kR)$, so that we may write

$$F_{0,\nu}{}^1 \sim \sin(kr - \tfrac{1}{2}l\pi + \eta_\nu{}^1), \qquad \ldots\ldots(14\,a)$$

$$F_{0,\nu}{}^3 \sim f_\nu \sin(kr - \tfrac{1}{2}l\pi + \eta_\nu{}^3), \qquad \ldots\ldots(14\,b)$$

the four $F_{0,\nu}{}^1$ being normalized to unit amplitude at large r, and the amplitudes of the corresponding four $F_{0,\nu}{}^3$ determined through (11*a*) and denoted by f_ν. The four arbitrary constants to be taken with the four pairs $F_{0,\nu}{}^1$, $F_{0,\nu}{}^3$ are introduced in taking linear combinations of the F's as in (6), these constants being denoted by c_1, c_2, c_3 and c_4.

The asymptotic forms of the exterior $F_0{}^l$ and $F_1{}^l$ as given by (7) are well known, and involve the functions $\sin(kr-\tfrac{1}{2}l\pi)$ and $\cos(kr-\tfrac{1}{2}l\pi)$. We now equate the two asymptotic forms for $F_0{}^1$, $F_1{}^1$, $F_0{}^3$ and $F_1{}^3$, and for their derivatives, obtaining eight simultaneous algebraic equations containing the eight unknowns c_1, c_2, c_3, c_4, $\alpha_{1,M}$, $\beta_{1,M}$, $\alpha_{3,M}$ and $\beta_{3,M}$. The α's and β's are then given by the quotients of pairs of 8×8 determinants. The rows of each determinant are added and subtracted in pairs to eliminate the quantity kr, and the determinants are then readily reduced to give

$$\begin{aligned}2i\alpha_{1,0} = {}& [1 - \{\textstyle\sum' f_1 f_2 \exp[-i(\eta_1{}^3+\eta_2{}^3)]\cos(\eta_3{}^1-\eta_4{}^1)\\ &+ i(\tfrac{7}{3})^{1/2}\textstyle\sum' f_1 \exp[-i(\eta_1{}^3+\eta_2{}^1)]\sin(\eta_2{}^1-\eta_4{}^1)\}]\\ &\div\{\textstyle\sum' f_1 f_2 \exp[-i(\eta_1{}^3+\eta_2{}^3+\eta_3{}^1+\eta_4{}^1)]\}, \qquad \ldots\ldots(15\,a)\end{aligned}$$

$$\begin{aligned}-2\beta_{1,0} = {}& \{\textstyle\sum f_1 f_2 \exp[-i(\eta_1{}^3+\eta_2{}^3)]\sin(\eta_3{}^1-\eta_4{}^1)\\ &- (\tfrac{7}{3})^{1/2}\textstyle\sum f_1 \exp[-i(\eta_1{}^3+\eta_3{}^1)]\sin(\eta_2{}^1-\eta_4{}^1)\}\\ &\div\{\textstyle\sum' f_1 f_2 \exp[-i(\eta_1{}^3+\eta_2{}^3+\eta_3{}^1+\eta_4{}^1)]\}, \qquad \ldots\ldots(15\,b)\end{aligned}$$

where $\sum$ denotes the sum of four terms in which the lowered suffixes 1, 2, 3 and 4 are changed in cyclic order, while $\sum'$ denotes a similar expression with the second and fourth terms subtracted from the sum of the first and third terms. The expressions for $2i\alpha_{3,0}$ and $-2\beta_{3,0}$ are obtained from (15) by interchanging the raised suffixes 1 and 3, and replacing the quantities f_1, f_2, f_3, f_4 and $(\tfrac{7}{3})^{1/2}$ by their reciprocals. The expressions for $2i\alpha_{0\,0}$ and $-2\beta_{0\,0}$ are obtained from (15) by replacing the raised suffixes 1 and 3 by 0 and 2 respectively, and replacing the factor $(\frac{7}{3})^{1/2}$ by $5^{1/2}$ (remembering that the f's now have different numerical values). The expressions for $2i\alpha_{2,0}$ and $-2\beta_{2,0}$ are then obtained by interchanging the raised suffixes 0 and 2, and replacing the f's and the quantity $5^{1/2}$ by their reciprocals.

The expressions for the case of $M \neq 0$ are necessarily more complicated.

3.3. α_l *and* β_l *for* E0 *Excitations*

It makes a useful comparison to apply the method of § 3.2 to the much simpler case of E0 excitations. With the simplification of $k_1 = k$ and $V_{11} = V_{00}$ previously adopted, we have

$$F_0{}^l = c_1 F_{0,1}{}^l + c_2 F_{0,2}{}^l, \qquad \ldots\ldots (16\,a)$$

$$F_1{}^l = c_1 F_{1,1}{}^l + c_2 F_{1,2}{}^l, \qquad \ldots\ldots (16\,b)$$

with

$$F_{1,1}{}^l = F_{0,1}{}^l, \quad F_{1,2}{}^l = -F_{0,2}, \qquad \ldots\ldots (17)$$

and

$$F_{0,1}{}^l \sim \sin(kr - \tfrac{1}{2}l\pi + \eta_1{}^l), \qquad \ldots\ldots (18\,a)$$

$$F_{0,2}{}^l \sim \sin(kr - \tfrac{1}{2}l\pi + \eta_2{}^l), \qquad \ldots\ldots (18\,b)$$

where $\eta_1{}^l$ and $\eta_2{}^l$ are the lth-order phase shifts produced by square wells of radius R and depths $V_{00} + V_{01}$ and $V_{00} - V_{01}$ respectively. It is not difficult to show, by equating the asymptotic forms of the exterior solutions (7) with $M = 0$ and the asymptotic forms (18) of the interior solutions (16), (17), that

$$4i\alpha_l = \exp(2i\eta_1{}^l) + \exp(2i\eta_2{}^l) - 2, \qquad \ldots\ldots (19\,a)$$

$$4i\beta_l = \exp(2i\eta_1{}^l) - \exp(2i\eta_2{}^l). \qquad \ldots\ldots (19\,b)$$

As V_{01} tends to zero, $F_{0,1}{}^l$ and $F_{0,2}{}^l$ inside the nuclear radius merge into the form $Krj_l(Kr)$, while $\eta_1{}^l$ and $\eta_2{}^l$ merge into the phase shift η^l produced by a potential well of depth V_{00}. Then

$$2i\alpha_l = \exp(2i\eta^l) - 1, \qquad \ldots\ldots (20\,a)$$

$$2\beta_l = \eta_1{}^l - \eta_2{}^l, \qquad \ldots\ldots (20\,b)$$

where (20 *a*) is the result of the usual partial wave analysis for elastic collisions, and $\eta_1{}^l - \eta_2{}^l$ in (20 *b*) reduces to the value given by the distorted wave method for inelastic collisions.

§ 4. RESULTS AND DISCUSSION

4.1. E0 *Excitations*

For $V_{01} = 0$, $\eta_1{}^l = \eta^l = \eta_2{}^l$. As V_{01} increases, $\eta_1{}^l$ increases and $\eta_2{}^l$ decreases, so that $\eta_1{}^l - \eta_2{}^l$ increases through the value $\pi/2$ (except for sufficiently large l). Hence, from (19 *b*), $|\beta_l|^2$ rises to a maximum value of $\frac{1}{4}$ and falls again. Including an imaginary component in V_{01}—and hence in $\eta_1{}^l$ and $\eta_2{}^l$—to allow for absorption, reduces the value of $\exp(i\eta_1{}^l)$ and $\exp(i\eta_2{}^l)$, and hence reduces $|\beta_l|^2$. These general results were exhibited in curves given in I for the variation of $|\beta_l|^2$ with V_{01}.

4.2. E2 *Excitations*

The above simple feature of each $|\beta_{l,0}|^2$ rising regularly to the same maximum value is no longer to be expected for E2 excitations, since (15 *b*) is much more complicated than (19 *b*); and the curves shown in Figs 3 and 4 confirm this.

The maximum values reached are usually less than $\frac{1}{4}$, possibly much less, and in one curve an unexpected twist occurs. The same general features are to be excepted for the β's with $M \neq 0$.

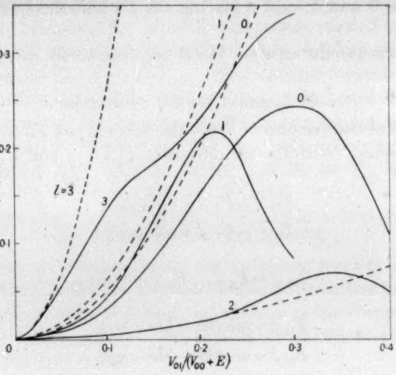

Fig. 3. $|\beta_{l,0}|^2$, the probability of inelastic scattering of lth order neutron waves, is plotted as a function of the transition potential V_{01}, which is taken to be constant for $r < R$ and to have angular dependence $Y_{2,0}(\theta, \phi)$. The other parameters have the same numerical values as for Fig. 1. The broken curves are for the distorted wave approximation.

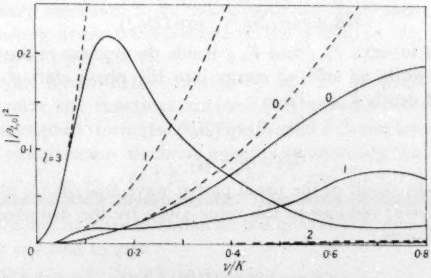

Fig. 4. As for Fig. 3, but with $\dfrac{8\pi^2 M V_{01}(\mathbf{r})}{h^2} = v\delta(r-R)\, Y_{2,0}(\theta, \phi)$. K is 2π times the interior wave number.

This irregular behaviour of the curves is more marked for the volume interaction (Fig. 3) than for the surface interaction (Fig. 4). Furthermore the curves for $l=1$ and 3 in Fig. 3 were found to be particularly sensitive to the values of the nuclear parameters for the larger values of V_{01}, and were terminated because of insufficient accuracy in the calculations.

The increased sensitivity in the case of E2 excitations may readily be understood. If we regard the right-hand side of (11 a) as a perturbation of a wave originally distorted only by the potential V_{00}, then for E0 excitations we have only the perturbation term $p_1 F_{0,\nu}{}^1$, and its magnitude rises and falls in step with the wave $F_{0,\nu}{}^1$ itself. But for E2 excitations the extra perturbation $p_3 F_{0,\nu}{}^3$ is involved, and this may be large at places where $F_{0,\nu}{}^1$ is small, causing a particularly marked effect on $F_{0,\nu}{}^1$ at larger r. We can likewise expect considerable sensitivity to the values of V_{00} and R.

A remark is necessary about the maximum possible value of $|\beta_{l,0}|^2$ in (15 *b*). At first sight it would appear possible to obtain large values by adjusting the terms in the denominator so that they nearly cancel out, but the f's and η's are not independent quantities. Fig. 3 shows values of $|\beta_{3,0}|^2$ exceeding $\frac{1}{4}$, but this does not contradict the conservation theorem, which requires only that the value of $|\beta_{l,M}|^2$ averaged over all M values may not exceed $k_1/4k$. Allowing for absorption by taking V_{00} complex, would be expected to reduce the magnitude of the β's, though this point has not been checked on account of the much greater amount of work involved.

For values of V_{01} large enough to produce inelastic cross sections comparable with the geometric cross section, the relative contributions of the different partial cross sections to the differential cross section will clearly be quite different in strong coupling and in the distorted wave approximation. Thus, in the present calculation, the contribution from the $l=3$ wave will be reduced below the distorted wave value by a far greater amount than the contribution from the other waves. A further difference arises because the ratio of the real and imaginary parts of each β depends markedly on V_{01} in strong coupling, whereas the ratio is independent of V_{01} in the distorted wave approximation.

Since these differences are in general greater for E2 than for E0 excitations, the differences in calculated angular distributions will also be greater; and the differences obtained in I for E0 excitations were already notable in some instances.

To calculate angular distributions for a more realistic form for V_{01} than those used here, and to include other complicating effects of importance, particularly spin–orbit forces, would seem a formidable undertaking, especially if one has to consider more than two channels. In addition, to vary nuclear parameters in an effort to obtain close—and unique—fits with experimental angular distributions would seem almost a hopeless task. On the other hand, efforts to obtain close fits using the distorted wave approximation seem of doubtful value, for the agreement may be completely spoilt by the effect of strong coupling.

Knock-on Electrons and Direct Electron Pair Production by Cosmic-ray Muons

By P. H. STOKER, C. HOFMEYR† and C. H. BORNMAN
Department of Physics, Potchefstroom University, South Africa

MS. received 1*st February* 1961, *in revised form* 26*th April* 1961

Abstract. Knock-on electrons and direct electron pair creation by cosmic-ray muons in thin lead plates were investigated with a multiplate cloud chamber. The muons traversing the cloud chamber were classified into two energy intervals, viz. 450 to 1700 MeV and higher than 1700 MeV. By comparing the experimental results with theoretical predictions which were derived for the knock-on process, an effective range–energy relationship was found for electrons in lead with energies up to about 200 MeV. The experimental distributions of the knock-on production as a function of the energy transfer compare well with theoretical distributions calculated from Bhabha's formula for muons in both of these energy ranges. The comparison between the theoretical and experimental results is also satisfactory for the energy distribution for direct pair production by muons with energy above 1700 MeV. The theoretical distribution was calculated from a formula deduced anew from the differential cross section given by Murota, Ueda and Tanaka. The experimental results favour a value between 1 and 2 for the indefinite constant α of the theory.

§ 1. INTRODUCTION

MANY experiments have been performed with nuclear emulsions and Wilson cloud chambers to investigate the knock-on secondaries produced by fast electrons and muons. The experimental results are in accordance with theory (cf. Fowler and Wolfendale 1958). Much work has also been done to investigate the process of direct electron pair production by fast electrons in emulsions, the so-called trident process (cf. Roe and Ozaki (1959) for references). The direct electron pair production by muons has received much less attention. Goldsack and Kannangara (1953) analysed 11 pairs produced in nuclear emulsions exposed underground to muons and classified them into the various cases covered by Bhabha's theory. Walker (1953) found two electron pairs in 13 000 traversals by cosmic-ray muons with energy above 1500 MeV of a 1 inch carbon plate, against 3·5 pairs predicted by Bhabha's theory. Avan and Avan (1957) have exposed nuclear emulsions at several depths underground and examined the direct pair production by muons in the emulsion. Good agreement with theoretical predictions was obtained for the meson groups with mean energies of 60 and 120 GeV. In cloud chamber experiments Roe and Ozaki (1959) and Gaebler, Hazen and Hendel (1961) recently investigated the pair production by energetic muons in lead plates having thicknesses of 0·6 cm and 0·32 cm respectively. They both found an electron pair cross section of a factor about 2 less than the value predicted by the calculations of Murota, Ueda and Tunaka (1956), taking the indefinite constant $\alpha = 2$.

† Bursar of the South African Atomic Energy Board.

The present experiment was set up to investigate the process of direct pair production by cosmic-ray muons as a function of the energy transfer. An analysis of the knock-on electrons produced will provide information on the method and reliability of the experimental procedure, and on the absorption of the electrons in the lead plates.

The theory for the direct pair production is based on quantum electrodynamics and assumes point interaction of the muon with the Coulomb field of the nucleus. A discrepancy may therefore be expected between theory and experiment for large energy transfer in the centre-of-mass system. The same would be true for the collision process between a muon and an electron. Because of the relatively small mass of the electron, the energy transferred in the centre-of-mass system by a relativistic muon to an electron at rest will always be much less than the energy transferred in the laboratory system. The validity of the electrodynamical theory describing muon–electron collisions may therefore be assumed up to high energy transfers in the laboratory system.

§ 2. THE EXPERIMENTAL SET-UP

In order to reduce the amount of absorption of the secondary electrons, thin lead plates were exposed to the cosmic-ray muons. The four upper lead plates in the cloud chamber were 1·5 mm thick, the next four were 3·3 mm, while the bottom plate was 13·3 mm. Thus the observed rate of production of secondary electrons in the two sets of thin plates may be compared, and the energy of an electron may be estimated roughly from its range or from the shower initiated by it. The thick bottom plate facilitates energy estimations, since it allows an electron shower to develop.

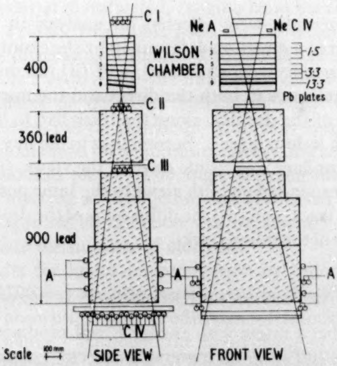

Fig. 1. The experimental set-up.

The cloud chamber was triggered by a triple coincidence between the counter layers CI, CII and CIII. The layer of counters CIV and the group of side counters A were both hodoscoped in coincidence with the triple coincidence pulse.

The hodoscope glowlamps NeCIV and NeA, for the respective groups of counters, were photographed together with the cloud chamber. Using Sternheimer's calculations (Sternheimer 1959) for the range of muons in lead, the first layer of lead (377 g cm^{-2}) determined a minimum energy of 450 Mev for the triggering of the cloud chamber. If all the lead (1354 g cm^{-2}) was traversed, the hodoscope lamp NeCIV lit up, indicating a minimum energy of 1700 Mev. All photographs in which the lamp NeA glowed were rejected.

The illuminated region of the cloud chamber was 400 mm × 400 mm × 200 mm. The nine lead plates were covered with bright aluminium plates, 0·5 mm thick, to prevent sagging of the thin lead plates, and to improve the illumination of the region between the plates. The effect of these aluminium coverings was taken into account when the absorption and the production of knock-on electrons were considered (knock-on probability is proportional to Z/A). It was not taken into account for direct pair production, because of the Z^2/A proportionality of this process.

The cloud tracks were photographed stereoscopically by means of a front silvered mirror placed at right angles to the front window of the cloud chamber. Both the direct view and the mirror view were recorded on a single frame of 35 mm Ferrania microfilm by a camera with a slightly tilted f/2·8 lens. The chamber was illuminated by the discharge of 800 μF condensers at 2000 v through two Mullard LSD 18 linear quartz flash tubes. In the chamber argon and a water–alcohol mixture were used. The size and front windows were kept fog free by thin heating wires across the windows. To prevent the heated gas from drying the upper part of the chamber, a tray with water was placed on top of the chamber, thus cooling the top by evaporation of the water to a fraction of a degree below room temperature. This assured uniform condensation along the tracks of the charged particles.

§ 3. SELECTION OF THE PHOTOGRAPHS

Only those photographs were selected for analysis in which (i) one muon traversed the chamber in a direction determined by the counter layers CI and CIII (as proved by stereoscopic reconstruction), and (ii) the muon track was clearly visible between all the plates in both the direct and the mirror views. Furthermore, the diffuseness of the droplets along the track had to be consistent with the delay time of the flash light trigger. Secondaries to the muon were accepted only when (i) the same secondary was visible on both the views, (ii) the points of origin of the secondary corresponded on both views to the same position in the lead plate in line with the muon track, and (iii) the diffuseness of the droplets corresponded to the age of the droplets of the muon track.

§ 4. THE ABSORPTION OF KNOCK-ON ELECTRONS IN LEAD

The probability that a muon with energy E will produce a knock-on electron with energy between ϵ and $\epsilon + d\epsilon$ on traversing dx g cm^{-2} of material is given by the Rutherford formula when only Coulomb interaction is considered, and by the Bhabha formula when additional terms due to spin–orbit and spin–spin interactions are taken into account (Rossi 1952). In order to calculate the probability that a knock-on electron produced in the lead will emerge from the plate, the absorption of the electrons in the lead plate must be taken into consideration when Bhabha's formula is integrated. No empirical results are available for the effective range of energetic electrons in lead. For aluminium the simple Feather rule

$$R = 530\,\epsilon - 106\ \mathrm{mg\,cm^{-2}} \qquad \ldots\ldots (1)$$

holds for electrons of energy ϵ ranging from 2·5 to about 20 MeV (Katz and Penfold 1952). From the absorption curves of Husain and Putman (1957) it appears that the maximum range in mg cm^{-2} for ^{32}P beta-particles is more or less independent of the material investigated, ranging from beryllium to gold. Let it be assumed that the Feather rule holds good for the mean range of low energy electrons in lead. By integrating Rutherford's formula and assuming a low energy limit determined by the Feather rule, the number of knock-on electrons that will emerge from lead plates of different thicknesses when energetic cosmic-ray muons traverse the plates, can be obtained. Curves A and B in Fig. 2 represent the results of these calculations for a minimum energy of ½ and 1 MeV, respectively, at emergence from the lead plate. The angle between the muon direction and that of the knock-on electron at production was also taken into account, but the scattering of the electron off its direction was neglected. Curves A and B will therefore underestimate the number of electrons.

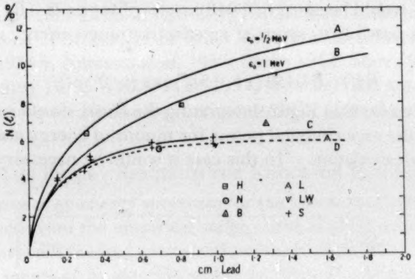

Fig. 2. The mean number of knock-on electrons emerging from a lead plate on the traversal of an energetic muon is represented as a function of the lead thickness. The solid curves were deduced from theory, taking into account absorption in the plate. The results of experiments with working conditions comparable with those of the present experiment are also represented: H, Hopkins, Nielsen and Nordheim (1939); N, Nassar and Hazen (1946); B, Brown, McKay and Palmatier (1949); L, Lovati *et al.* (1954 b); LW, Lloyd and Wolfendale (1959); S, present work. The lower crosses represent our results for all muons with energy above 450 MeV, and the upper crosses the results for all muons with energy above 1700 MeV.

Our present results for knock-on production by muons with energy above 450 MeV and above 1700 MeV are also represented in the Figure. These results were corrected for absorption and production of knock-on electrons in the aluminium covering plates. Although the cloud chamber contains only 0·15 and 0·33 cm lead plates, the mean number of knock-on electrons from thicker plates can be deduced by considering the number traversing one or more of the plates. Curve C in Fig. 2 was made to fit the experimental results for muons of energy higher than 1700 MeV. It is obvious from Fig. 2 that energetic electrons are absorbed much more strongly than given by the Feather rule, Eqn (1). For thin lead plates our results are not inconsistent with the absorption relationship (1) if the effective minimum energy at emergence from the lead plates is 1 Mev. Taking the energy loss of 0·5 Mev in the aluminium covering plate into account, this figure is reasonable as a low energy limit.

In order to arrive at an absorption relationship from which the experimental results can be deduced let us rewrite the Feather rule, Eqn (1):

$$\epsilon = \frac{R\,(\mathrm{cm})}{K} + 0{\cdot}25\ \text{Mev}. \qquad \ldots\ldots(2)$$

From Eqn (1), K would be equal to 0·048 cm Mev^{-1} for lead. By considering K as a parameter, it is possible to arrive at an effective range–energy relationship.

Taking

$$K(l) = 0{\cdot}0455\,(1 - 0{\cdot}58l)\exp(-0{\cdot}58l), \qquad \ldots\ldots(3)$$

we arrived at the curve C in Fig. 2, integrating the Rutherford formula. Curve D was traced to fit the experimental points for muons of energy above 450 Mev, but was not found by calculation. In this case it would be necessary to integrate the Bhabha formula.

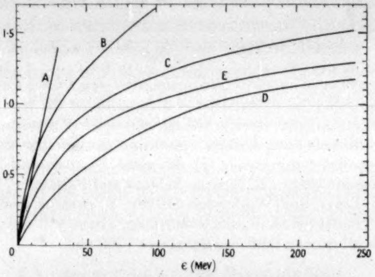

Fig. 3. The range of electrons in lead plotted against the energy in Mev. Curve B is taken from Bethe and Heitler (1934), C and D are from Wilson's Monte Carlo calculations (Wilson 1951) while E represents Eqn (2) with K defined by (3). Curve A is the Feather rule, Eqn (2), with $K = 0{\cdot}048$ cm Mev^{-1}.

The curve E in Fig. 3 represents the range–energy Eqn (2) with K substituted from Eqn (3). Curves C and D give the average range of the electrons for lead as calculated by Wilson (1951) using the Monte Carlo method. For curve C multiple scattering was not considered, while for curve D it was assumed that the electrons will proceed in the original direction until a critical energy (7·25 Mev for lead) is reached, whereafter the electrons will diffuse in a random manner. When comparing curves D and E the scattering correction used by Wilson is presumably too strong.

§ 5. DISCUSSION OF THE RESULTS OF OTHER EXPERIMENTS ON KNOCK-ON ELECTRONS

The value given by Lloyd and Wolfendale (1959) for the number of knock-on electrons produced from a 1 cm lead plate by cosmic-ray muons with energy above 500 Mev, is consistent with our results as represented by curve D (Fig. 2). The result obtained by Nasser and Hazen (1946) for electrons of 1 Mev and higher energy, produced in 0·7 cm lead, is also consistent with the curve, and so is the value obtained by Lovati, Mura and Succi (1954 a) at 55 m water equivalent underground. The values of Hopkins, Nielsen and Nordheim (1939) are too high. If their iron filter for the cosmic radiation had been beneath the cloud chamber, it would have defined a minimum traversal energy of 450 Mev for muons traversing the chamber. Presumably the iron was on top of the chamber, and their large production values may be due to secondary rays from the iron. The value found by Brown, McKay and Palmatier (1949) is also too large. Their experimental set-up defined a minimum energy of 270 Mev for the muons traversing the cloud chamber. The results of other experiments (Hazen 1943, Lovati, Mura and Succi 1954 b, Naranan *et al.* 1957, Seren 1942, Starr 1938, Tiffany and Hazen 1950, Trumpy 1938, Walker *et al.* 1951, Wilson 1938) are not considered, because the conditions set for these experiments differ from the conditions of the present experiment.

§ 6. THE ENERGY SPECTRUM FOR KNOCK-ON ELECTRONS

In order to arrive at an energy spectrum for the knock-on electrons, an average energy was ascribed from the empirical range curve E (Fig. 3) to each knock-on electron which traversed the lead plates without multiplication. It was estimated that the effective points of production and absorption of a knock-on electron are about one third of the thickness of a lead plate from the surface where the electron leaves the plate in which it is produced, or where it enters the plate in which it is absorbed. The energy of electrons which initiated cascade showers in the lead plates, was estimated from those transition curves of Wilson (1952) that include multiple Coulomb scattering (cf. also Roe and Ozaki 1959).

Table 1

Theoretical and experimental numbers of knock-on electrons produced in different energy ranges in the two sets of lead plates by (*a*) 1849 cosmic-ray muons in the energy ranges 450 to 1700 Mev and (*b*) 2344 muons with energy above 1700 Mev.

	(*b*) Theor.	1357	51·7	12·7	4·0	1·3
	Exp.	313	36	11	5	1

(1) Knock-on energy range (Mev); (2) mean number per muon $\times 10^4$ (cm^2 g^{-1}); (3) total number of knock-on electrons in four 0·15 cm Pb plates (1–4); (4) total number of knock-on electrons in three 0·33 cm Pb plates (5–7).

The number of knock-on electrons found and the number expected from theoretical calculations are given in Table 1. The secondary production in the eighth plate was not considered, since energy determination for electrons from this plate was difficult. The experimental numbers of single electrons emerging from the lead plates were corrected for the number of knock-on electrons produced in the aluminium coverings on both surfaces of the lead plates, as was calculated from Bhabha's formula by integration, using the Feather rule, Eqn (1). Only single electrons emerging from the plates were considered, since a rough estimate showed that the number of knock-on electrons appearing as pairs or multiples below a plate is more or less compensated by the number of directly produced electron pairs appearing as single electrons. The number of pairs due to double knock-on production was calculated from the experimental number of single emerging electrons and was found to be equal, within statistical limits, to the observed number of pairs for a total energy less than 20 MeV. Hence most of the directly produced electron pairs with total energy less than 20 MeV must have appeared as single electrons. The mean numbers of knock-on electrons for the energy ranges considered are also represented in Table 1 for cosmic-ray muons in the two energy ranges. For calculating the mean values, Rossi's differential intensity spectrum (Rossi 1948) of the cosmic-ray muons in the energy range of 450 to 1700 MeV was approximated by $(-0{\cdot}0011\,E+3{\cdot}5)\,dE$, and by the power law $E^{-1{\cdot}83}\,dE$ (Allkofer 1960) for energies higher than 1700 MeV.

In Fig. 4 the theoretical spectra for the knock-on electrons produced by the muons in the two energy ranges are represented as histograms together with the experimental results for the seven lead plates as summarized in Table 1. The statistical limits of the experimental points were calculated from the number of events found in each of the energy intervals and do not include variations due to fluctuations in range and in shower production of electrons (cf. Heitler 1954, Wilson 1952).

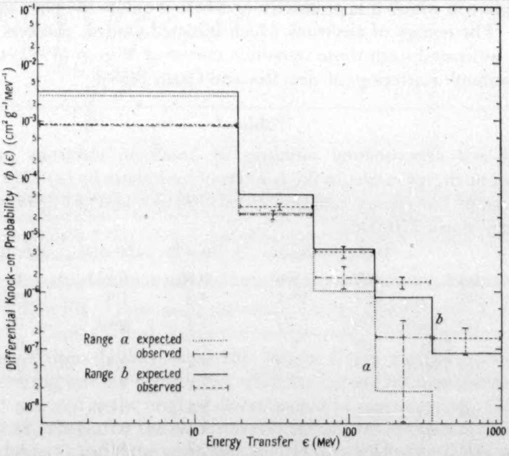

Fig. 4. The theoretical and experimental spectra for knock-on electrons produced in lead by cosmic-ray muons in the energy ranges: *a*, 450 to 1700 MeV, *b* above 1700 MeV.

The number of low energy electrons found experimentally is much less than that predicted by the theory due to absorption of the lead plates. For the other energy ranges the agreement between the theoretical and experimental results is satisfactory. The larger number of electrons found for the high energy ranges may be attributed to fluctuations in range and shower production of the electrons.

§ 7. THE ENERGY SPECTRUM FOR DIRECT PAIR PRODUCTION

For energy transfer of more than 20 MEV the probability for pair production by a muon in the lead plates of the cloud chamber is much larger than the probability for two knock-on electrons to be produced in the same lead plate, and the number of pairs observed may easily be corrected for double knock-on production. The probability of a pair produced by a gamma ray from a muon in the lead plates can be neglected. No heavy materials were directly above the cloud chamber. The chamber itself was constructed of aluminium.

The theoretical and experimental results are compared in Fig. 5 and in Table 2. The theoretical distributions were calculated from the formula (Stoker and Haarhoff 1960)

$$\phi = \frac{4N}{3\pi A}(Z\alpha')^2 r_e^2 \left[\ln\frac{\alpha\epsilon}{(1+R^2)^{1/2}} - 1\right]\left[(2+3R^2)\ln\left(1+\frac{1}{R^2}\right) - 3 + \frac{1}{1+R^2}\right] I(1+C)\frac{d\epsilon}{\epsilon}\ \mathrm{cm}^2\,\mathrm{g}^{-1}, \qquad \ldots\ldots (4)$$

where

$$R = \frac{\epsilon}{2mc^2}\frac{\mu c^2}{E} \simeq 100\frac{\epsilon}{E},$$

α' and r_e are, respectively, the fine structure constant and the classical radius of the electron. α is an undetermined parameter of the order of unity (Murota, Ueda and Tunaka 1956) and $I(1+C)=P$ is the energy partition factor (Stoker and Haarhoff 1960). To arrive at the mean distribution function for pairs produced by muons with energy above 1700 MEV, as represented in Table 2 and Fig. 5, extreme values of 1·3 and 1·0 were accepted for the energy partition factor in

Table 2

Predicted and observed number of electron pairs produced in the two sets of lead plates by 2344 cosmic-ray muons with energy above 1700 MEV. The true theoretical number must be between the extreme values for the energy partition factor $P=I(1+C)$.

(1)	20–45	45–200	200–1000	Sum	P	α
(2)	1·4	1·25	0·39		1·3	1
	1·04	0·96	0·30		1·0	1
(3)	2·2	2·0	0·63	4·8	1·3	1
	1·7	1·5	0·48	3·7	1·0	1
	3·4	2·6	0·78	6·8	1·3	2
	2·6	2·0	0·60	5·2	1·0	2
	2	2	2	6	Obs.	
(4)	3·6	3·3	1·03	7·9	1·3	1
	2·8	2·5	0·79	6·1	1·0	1
	5·6	4·3	1·28	11·2	1·3	2
	4·3	3·3	0·97	8·6	1·0	2
	3	2	6	11	Obs.	

(1) Energy transfer (MEV); (2) mean number per muon × 10^4 (cm^2 g^{-1}); (3) total number of pairs in four 0·15 cm lead plates (1–4); (4) total number of pairs in three 0·33 cm lead plates (5–7).

order to facilitate the integration of the function ϕ with respect to the energy spectrum of the cosmic-ray muons. It was not possible to approximate the cosmic-ray muon spectrum for muon energy above 1700 Mev by a simple power law, because muons with energy well above 10 Gev still contribute appreciably to the pair production rate in spite of reduced intensity. Because of the strong dependence on the muon spectrum, the function ϕ was integrated numerically for the muon intensity spectrum recorded by Ashton *et al.* (1960), and is represented as the histogram *b* in Fig. 5. The experimental points for the two sets of lead plates are represented separately.

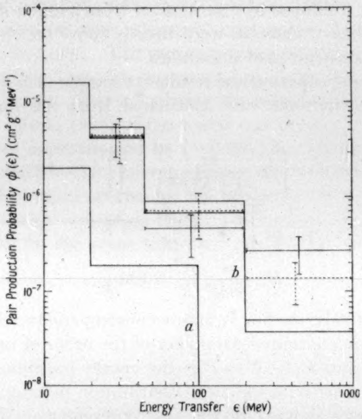

Fig. 5. The theoretical and experimental spectra for electron pairs produced in the lead plates by cosmic-ray muons. Histograms *b* represent the expected distributions for muons in the energy range above 1700 Mev and energy partition factors $P = 1{\cdot}3$ and $1{\cdot}0$, and histogram *a* the energy range 450 to 1700 Mev, both for $\alpha = 1$. The broken line points are the experimental results for the four 0·15 cm lead plates and the solid line points the results for the three 0·33 cm lead plates.

The histogram *a* represents the expected distribution for the lower muon energy range. This histogram was calculated, in fact, from the figures of Stoker and Haarhoff (1960) for the spectral distribution for 1500 Mev muons, because this distribution lies between the mean distributions for the extreme values of 1·0 and 1·3 for the energy partition factor *P*, for muons in the 450 to 1700 Mev range.

The 1849 muons traversing the cloud chamber in this energy range should have produced in the first 7 lead plates 0·5 pairs of energy ranging from 20 to 100 Mev. Six pairs, however, with an estimated energy between 20 and 100 Mev were found. It is possible that the energy ascribed to most of these pairs is too high due to fluctuation phenomena.

The experimental results represented in Table 2 and Fig. 5 were corrected for double knock-on production but not for absorption of one or both components of a pair. This is believed to be small for high energy transfer in the thin lead plates, notwithstanding the preferentially asymmetric energy partition between the pair electrons when the energy transfer is large. This asymmetric energy partition is obvious in the experimental results and is also brought out by the calculations of Stoker and Haarhoff (1960).

§ 8. Discussion of the Results and Conclusion

The experimental distributions for knock-on electrons agree within statistical limits with the theoretical distributions for the energy ranges considered. The results for the pair production agree with the theory with $\alpha = 1$ for the lower energy ranges, but then too many events were observed in the highest electron energy ranges for both the muon energy ranges. Fluctuations in range and shower production of electrons should tend to flatten the spectral distribution, an effect also observed for the knock-on electron distributions. Gaebler, Hazen and Hendel (1961) also found an increase in the number of pairs observed with the energy transfer with respect to the expected distribution. According to R. F. Deery (quoted by Gaebler *et al.* (1961)) knock-on and pair production cross sections might be larger for interactions at small distances. Better statistics and theoretical evaluations are required to settle this point. Both Roe and Ozaki (1959) and Gaebler *et al.* (1961) found the electron pair cross section a factor 2 less than predicted by the calculations of Murota, Ueda and Tunaka (1956), taking $\alpha = 2$. The formula (4) for the pair production cross section, which we have used, led to cross sections at least a factor 2 less than given by the formula of Murota *et al.* (Stoker and Haarhoff 1960).

The total number of pairs that we have observed with energy above 20 MeV and produced by muons with energy above 1700 MeV, agrees with theory if $\alpha = 2$. Our results seem to favour a value for α between 1 and 2.

Acknowledgments

Thanks are due to Mr. J. P. van der Walt for technical assistance and to Messrs. G. P. de Beer, J. Kruger and J. P. van der Merwe, who helped with the experimental set-up, the analysis and calculations. This experiment was performed with the financial assistance of the South African Council for Scientific and Industrial Research.

A Schematic Model for the Impact Excitation of Atoms

By B. L. MOISEIWITSCH

Department of Applied Mathematics, The Queen's University of Belfast

MS. received 18*th January* 1961, *in revised form* 17*th April* 1961

Abstract. The third-order approximation is used to derive simple analytical expressions for the partial cross sections corresponding to the scattering of high-energy charged particles by a schematic model atom involving matrix elements having a r^{-2} radial dependence.

---

§ 1. Introduction

Recently Kingston, Moiseiwitsch and Skinner (1960) and Kingston and Skinner (1961) have calculated the cross sections for the 1s–2s excitation of hydrogen atoms by electron and proton impact and for the elastic scattering of electrons by hydrogen atoms, respectively, using an approximate expression for the cross section which includes terms up to the third order in the interaction potential between the incident particle and the hydrogen atom and neglects all terms of higher order. In the case of the 1s–2s excitation by proton impact, by neglecting coupling to all states other than the initial and final states, they obtained good agreement with the calculations of Bates (1959) who employed an impact parameter treatment together with the distortion approximation.

In the present paper the third-order approximation is used to investigate the scattering of charged particles by atoms by employing a schematic model, first introduced by Seaton (1955), which involves matrix elements having a radial dependence of the form r^{-2}.

§ 2. Weak Coupling Approximations

The theory of the scattering of particles by hydrogen atoms involves the solution of an infinite set of coupled equations which have the form (Massey 1956)

$$[\nabla^2 + k_n{}^2]F_n(\mathbf{r}) = \mathop{\mathrm{S}}_{m} U_{nm}(\mathbf{r})F_m(\mathbf{r}) \qquad \ldots\ldots(1)$$

where

$$U_{nm}(\mathbf{r}_1) = \frac{2M}{\hbar^2}\int \phi_n{}^*(\mathbf{r}_2)V(\mathbf{r}_1, \mathbf{r}_2)\phi_m(\mathbf{r}_2)\, d\mathbf{r}_2 \qquad \ldots\ldots(2)$$

and

$$k_n{}^2 = \frac{2M}{\hbar^2}(E - \epsilon_n). \qquad \ldots\ldots(3)$$

M is the reduced mass and E is the total energy of the system, ϕ_n is the eigenfunction and ϵ_n is the eigenenergy of the nth state of a hydrogen atom, and $V(\mathbf{r}_1, \mathbf{r}_2)$ is the interaction potential between the incident particle and the atom.

If we denote the initial and final states of the atom by 1 and 2 respectively and if the coupling to all other states is neglected, the infinite set of equations (1) reduces to the pair of coupled equations

$$[\nabla^2 + k_1^2 - U_{11}(\mathbf{r})]F_1(\mathbf{r}) = U_{12}(\mathbf{r})F_2(\mathbf{r}) \qquad \ldots\ldots(4)$$

$$[\nabla^2 + k_2^2 - U_{22}(\mathbf{r})]F_2(\mathbf{r}) = U_{21}(\mathbf{r})F_1(\mathbf{r}) \qquad \ldots\ldots(5)$$

where F_1 and F_2 have the asymptotic forms for large r

$$F_1(\mathbf{r}) \sim \exp(ik_1\mathbf{n}_0 . \mathbf{r}) + r^{-1}\exp(ik_1r)f_1(\theta, \phi) \qquad \ldots\ldots(6)$$

$$F_2(\mathbf{r}) \sim r^{-1}\exp(ik_2r)f_2(\theta, \phi), \qquad \ldots\ldots(7)$$

$\mathbf{n}_0$ being a unit vector in the direction of the incident beam of particles.

Consider the weak coupling approximation known as the *method of distorted waves* which assumes that the back coupling term $U_{12}F_2$ on the right-hand side of Eqn (4) can be neglected. Then the pair of coupled equations (4) and (5) reduce to

$$[\nabla^2 + k_1^2 - U_{11}(\mathbf{r})]F_1(\mathbf{r}) = 0 \qquad \ldots\ldots(8)$$

$$[\nabla^2 + k_2^2 - U_{22}(\mathbf{r})]F_2(\mathbf{r}) = U_{21}(\mathbf{r})F_1(\mathbf{r}) \qquad \ldots\ldots(9)$$

and so

$$f_2(\theta, \phi) = -\frac{1}{4\pi}\int \mathscr{F}_2(r_1', \pi - \Theta')U_{21}(\mathbf{r}')F_1(\mathbf{r}')\,d\mathbf{r}' \qquad \ldots\ldots(10)$$

where the function $\mathscr{F}_2(\mathbf{r})$ satisfies the equation

$$[\nabla^2 + k_2^2 - U_{22}(\mathbf{r})]\mathscr{F}_2(\mathbf{r}) = 0 \qquad \ldots\ldots(11)$$

with the asymptotic form for large r

$$\mathscr{F}_2(\mathbf{r}) \sim \exp(ik_2\mathbf{n}_0 . \mathbf{r}) + r^{-1}\exp(ik_2r)\mathrm{f}_2(\theta, \phi) \qquad \ldots\ldots(12)$$

and

$$\cos\Theta' = \cos\theta\cos\theta' + \sin\theta\sin\theta'\cos(\phi - \phi'). \qquad \ldots\ldots(13)$$

Expanding F_1 and $\mathscr{F}_2$ in the forms

$$F_1(\mathbf{r}) = \frac{1}{r}\sum_{l=0}^{\infty} i^l(2l+1)\exp(i\eta_{1,l})\phi_{1,l}(r)\mathrm{P}_l(\cos\theta) \qquad \ldots\ldots(14)$$

$$\mathscr{F}_2(\mathbf{r}) = \frac{1}{r}\sum_{l=0}^{\infty} i^l(2l+1)\exp(i\eta_{2,l})\phi_{2,l}(r)\mathrm{P}_l(\cos\theta), \qquad \ldots\ldots(15)$$

$\mathbf{n}_0$ being chosen in the direction of the polar axis, and assuming that U_{11}, U_{22} and U_{12} are spherically symmetrical, as for s states, we obtain

$$\frac{d^2\phi_{n,l}}{dr^2} + \left\{k_n^2 - U_{nn}(r) - \frac{l(l+1)}{r^2}\right\}\phi_{n,l} = 0 \qquad (n = 1, 2) \qquad \ldots\ldots(16)$$

where $\phi_{n,l}$ has the asymptotic form for large r

$$\phi_{n,l}(r) \sim \frac{1}{k_n}\sin(k_nr - \tfrac{1}{2}l\pi + \eta_{n,l}). \qquad \ldots\ldots(17)$$

Then

$$f_2(\theta,\phi) = -\sum_{l=0}^{\infty}(2l+1)\mathrm{P}_l(\cos\theta)\exp\{i(\eta_{1,l}+\eta_{2,l})\} \times \int_0^\infty \phi_{2,l}(r)\phi_{1,l}(r)U_{21}(r)\,dr \qquad \ldots\ldots(18)$$

and so, to the distorted waves approximation, the cross section for the excitation of the state 2 from the state 1 of the target atomic system is given by

$$Q(1\to 2) = \frac{k_2}{k_1}\int_0^\pi\int_0^{2\pi} |f_2(\theta,\phi)|^2 \sin\theta\, d\theta\, d\phi \qquad \ldots\ldots(19)$$

$$= 4\pi\frac{k_2}{k_1}\sum_{l=0}^{\infty}(2l+1)\left|\int_0^\infty \phi_{2,l}(r)\phi_{1,l}(r)U_{21}(r)\,dr\right|^2. \qquad \ldots\ldots(20)$$

It may be shown that the distorted waves method, which neglects the back coupling term $U_{12}F_2$ in Eqn (4), gives rise to an error of the order of $(U_{12})^3$ in the scattering amplitude f_2 and thus an error of the order of $(U_{12})^4$ in the cross section $Q(1\to 2)$.

If only terms up to the third order in the interaction potential are retained in the expression (20) for the cross section we obtain the *third-order approximation*. Now the solution of Eqn (16) with asymptotic form (17) can be written in the integral equation form

$$\phi_{n,l}(r) = \cos\eta_{n,l}\, r\mathrm{j}_l(k_n r) + k_n r\int_0^\infty \mathrm{j}_l(k_n r_<)\mathrm{n}_l(k_n r_>)U_{nn}(r')\phi_{n,l}(r')r'\,dr' \quad \ldots\ldots(21)$$

where

$$\sin\eta_{n,l} = -k_n\int_0^\infty r'\mathrm{j}_l(k_n r')\phi_{n,l}(r')U_{nn}(r')\,dr', \qquad \ldots\ldots(22)$$

j_l and n_l being spherical Bessel and Neumann functions respectively and $r_<$, $r_>$ being the lesser and greater of r, r'. Hence to the first order in the interaction energy we have

$$\phi_{n,l}(r) = r\mathrm{j}_l(k_n r) + k_n r\int_0^\infty \mathrm{j}_l(k_n r_<)\mathrm{n}_l(k_n r_>)U_{nn}(r')\mathrm{j}_l(k_n r')r'^2\,dr' \quad \ldots\ldots(23)$$

and so the third-order approximation to the cross section is given by

$$Q(1\to 2) = 4\pi\frac{k_2}{k_1}\sum_{l=0}^{\infty}(2l+1)\{1+2(\alpha_{1,l}+\alpha_{2,l})\} \times\left[\int_0^\infty U_{21}(r)\mathrm{j}_l(k_2 r)\mathrm{j}_l(k_1 r)r^2\,dr\right]^2 \qquad \ldots\ldots(24)$$

where

$$\alpha_{n,l} = \frac{k_n\int_0^\infty\int_0^\infty U_{21}(r)\mathrm{j}_l(k_m r)\mathrm{j}_l(k_n r_<)\mathrm{n}_l(k_n r_>)\mathrm{j}_l(k_n r')U_{nn}(r')r^2 r'^2\,dr\,dr'}{\int_0^\infty U_{21}(r)\mathrm{j}_l(k_2 r)\mathrm{j}_l(k_1 r)r^2\,dr} \qquad \ldots\ldots(25)$$

with $n=1$, $m=2$ or $n=2$, $m=1$.

If we reject the third-order terms and retain only the second-order terms, expression (24) reduces to the *first Born approximation* formula

$$Q(1\to 2)=4\pi\frac{k_2}{k_1}\sum_{l=0}^{\infty}(2l+1)\left[\int_0^{\infty}U_{21}(r)\mathrm{j}_l(k_2r)\mathrm{j}_l(k_1r)r^2\,dr\right]^2. \quad \ldots\ldots(26)$$

To obtain the *second Born approximation* to the cross section we expand f_2 to the second order in the interaction potential. This gives

$$f_2(\theta,\phi)=-\sum_{l=0}^{\infty}(2l+1)\mathrm{P}_l(\cos\theta)\{1+\alpha_{1,l}+\alpha_{2,l}+i(\beta_{1,l}+\beta_{2,l})\}$$
$$\times\int_0^{\infty}U_{21}(r)\mathrm{j}_l(k_2r)\mathrm{j}_l(k_1r)r^2\,dr \quad \ldots\ldots(27)$$

where

$$\beta_{n,l}=-k_n\int_0^{\infty}U_{nn}(r')\{\mathrm{j}_l(k_nr')\}^2r'^2\,dr', \quad \ldots\ldots(28)$$

so that to the second Born approximation

$$Q(1\to 2)=4\pi\frac{k_2}{k_1}\sum_{l=0}^{\infty}(2l+1)\{(1+\alpha_{1,l}+\alpha_{2,l})^2+(\beta_{1,l}+\beta_{2,l})^2\}$$
$$\times\left[\int_0^{\infty}U_{21}(r)\mathrm{j}_l(k_2r)\mathrm{j}_l(k_1r)r^2\,dr\right]^2. \quad \ldots\ldots(29)$$

Thus some terms of the fourth order in the interaction potential have been retained in deriving this approximation to the excitation cross section. Referring to Eqns (18) and (27) we see that the term $(\beta_{1,l}+\beta_{2,l})^2$ in (29) arises from the expansion of the phase factor $\exp\{i(\eta_{1,l}+\eta_{2,l})\}$ to the first order in the interaction potential and is exactly cancelled if the expansion is carried out to a higher order. It should therefore be rejected from the second Born approximation. Other terms of the fourth order in the interaction potential have also been neglected in deriving the second Born approximation expression (29) and so the most consistent procedure is to employ the third-order approximation (24) which includes all terms up to the third order in the interaction potential and neglects all higher order terms. The Schwinger variational method for the scattering amplitude with plane wave trial functions also neglects some terms of the fourth order and so the same criticisms may be applied to it as have been applied above to the second Born approximation.

§ 3. SCHEMATIC MODEL

In the case of the scattering of particles by hydrogen atoms in the ground 1s state a useful approximation is to include coupling to all the states of principal quantum number $n\leqslant 2$, viz. 1s, 2s, $2\mathrm{p}_0$, $2\mathrm{p}_{+1}$, $2\mathrm{p}_{-1}$ and to neglect the coupling to all states with $n>2$ and the continuum states. Then the infinite set of coupled equations (1) reduces to the set of five coupled equations

$$[\nabla^2+k_1^2-U_{1\mathrm{s},1\mathrm{s}}(r)]F_{1\mathrm{s}}(\mathbf{r})=U_{1\mathrm{s},2\mathrm{s}}(r)F_{2\mathrm{s}}(\mathbf{r})+\sum_{m=0,\pm 1}U_{1\mathrm{s},2\mathrm{p}_m}(\mathbf{r})F_{2\mathrm{p}_m}(\mathbf{r}) \quad \ldots\ldots(30)$$

$$[\nabla^2 + k_2{}^2 - U_{2s,\,2s}(r)]F_{2s}(\mathbf{r}) = U_{2s,\,1s}(r)F_{1s}(\mathbf{r}) + \sum_{m=0,\,\pm 1} U_{2s,\,2p_m}(\mathbf{r})F_{2p_m}(\mathbf{r}) \qquad \ldots\ldots(31)$$

$$\begin{aligned}[\nabla^2 + k_2{}^2 - U_{2p_0,\,2p_0}(\mathbf{r})F_{2p_0}(\mathbf{r}) &= U_{2p_0,\,1s}(\mathbf{r})F_{1s}(\mathbf{r}) + U_{2p_0,\,2s}(\mathbf{r})F_{2s}(\mathbf{r}) \\ &\quad + \sum_{m=\pm 1} U_{2p_0,\,2p_m}(\mathbf{r})F_{2p_m}(\mathbf{r}) \qquad \ldots\ldots(32)\end{aligned}$$

$$\begin{aligned}&[\nabla^2 + k_2{}^2 - U_{2p_{\pm 1},\,2p_{\pm 1}}(\mathbf{r})]F_{2p_{\pm 1}}(\mathbf{r}) \\ &\qquad = U_{2p_{\pm 1},\,1s}(\mathbf{r})F_{1s}(\mathbf{r}) + U_{2p_{\pm 1},\,2s}(\mathbf{r})F_{2s}(\mathbf{r}) + U_{2p_{\pm 1},\,2p_0}(\mathbf{r})F_{2p_0}(\mathbf{r}) \\ &\qquad\quad + U_{2p_{\pm 1},\,2p_{\mp 1}}(\mathbf{r})F_{2p_{\mp 1}}(\mathbf{r}) \qquad ,\ldots\ldots(33)\end{aligned}$$

where, for electron impact, the matrix elements $U_{nm}(\mathbf{r})$ have the asymptotic forms for large r

$$\left.\begin{aligned}
U_{1s,\,1s}(r) &\sim -\frac{2}{a_0}\frac{1}{r}\exp(-2r/a_0), \\
U_{2s,\,2s}(r) &\sim -\frac{2}{a_0}\frac{1}{r}\exp(-r/a_0), \\
U_{2p_0,\,2p_0}(\mathbf{r}) &\sim -\frac{2}{a_0}\frac{1}{r}\exp(-r/a_0) + \frac{24a_0}{r^3}\mathrm{P}_2(\cos\theta), \\
U_{2p_{\pm 1},\,2p_{\pm 1}}(\mathbf{r}) &\sim -\frac{2}{a_0}\frac{1}{r}\exp(-r/a_0) - \frac{12a_0}{r^3}\mathrm{P}_2(\cos\theta), \\
U_{1s,\,2s}(r) &\sim \frac{\sqrt{2}}{a_0{}^3}\left(\frac{2}{3}\right)^2 r\exp(-3r/2a_0), \\
U_{1s,\,2p_0}(\mathbf{r}) &\sim 8\sqrt{2}\left(\frac{2}{3}\right)^5\frac{1}{r^2}\mathrm{P}_1(\cos\theta), \\
U_{1s,\,2p_{\pm 1}}(\mathbf{r}) &\sim 8\sqrt{2}\left(\frac{2}{3}\right)^5\frac{1}{r^2}\frac{1}{\sqrt{2}}\mathrm{P}_1{}^1(\cos\theta)\mathrm{e}^{\pm i\phi}, \\
U_{2s,\,2p_0}(\mathbf{r}) &\sim -\frac{6}{r^2}\mathrm{P}_1(\cos\theta), \\
U_{2s,\,2p_{\pm 1}}(\mathbf{r}) &\sim -\frac{6}{r^2}\frac{1}{\sqrt{2}}\mathrm{P}_1{}^1(\cos\theta)\mathrm{e}^{\pm i\phi}, \\
U_{2p_0,\,2p_{\pm 1}}(\mathbf{r}) &\sim \frac{12a_0}{r^3}\frac{1}{\sqrt{2}}\mathrm{P}_2{}^1(\cos\theta)\mathrm{e}^{\pm i\phi}, \\
U_{2p_{\mp 1},\,2p_{\pm 1}}(\mathbf{r}) &\sim \frac{6a_0}{r^3}\mathrm{P}_2{}^2(\cos\theta)\mathrm{e}^{\pm 2i\phi},
\end{aligned}\right\} \qquad \ldots\ldots(34)$$

the polar axis of the coordinate system being chosen in the direction of the incident beam of particles.

In the present investigation we are concerned with the use of a schematic model to examine the effects of distortion and polarization on the scattering of particles by atoms. The schematic model replaces the matrix elements (34) by

$$\left.\begin{aligned}
U_{1s,1s}(r) &= -\frac{A_1}{r^2},\\
U_{2s,2s}(r) &= -\frac{A_2}{r^2},\\
U_{2p_0,2p_0}(\mathbf{r}) &= -\frac{A_2}{r^2}+\frac{2B}{r^2}\,\mathrm{P}_2(\cos\theta),\\
U_{2p\pm1,2p\pm1}(\mathbf{r}) &= -\frac{A_2}{r^2}-\frac{B}{r^2}\,\mathrm{P}_2(\cos\theta),\\
U_{1s,2s}(r) &= \frac{A_{1s,2s}}{r^2},\\
U_{1s,2p_0}(\mathbf{r}) &= \frac{A_{1s,2p}}{r^2}\,\mathrm{P}_1(\cos\theta),\\
U_{1s,2p\pm1}(\mathbf{r}) &= \frac{A_{1s,2p}}{r^2}\frac{1}{\sqrt{2}}\,\mathrm{P}_1{}^1(\cos\theta)\mathrm{e}^{\pm i\phi},\\
U_{2s,2p_0}(\mathbf{r}) &= -\frac{A_{2s,2p}}{r^2}\,\mathrm{P}_1(\cos\theta),\\
U_{2s,2p\pm1}(\mathbf{r}) &= -\frac{A_{2s,2p}}{r^2}\frac{1}{\sqrt{2}}\,\mathrm{P}_1{}^1(\cos\theta)\mathrm{e}^{\pm i\phi},\\
U_{2p_0,2p\pm1}(\mathbf{r}) &= \frac{B}{r^2}\frac{1}{\sqrt{2}}\,\mathrm{P}_2{}^1(\cos\theta)\mathrm{e}^{\pm i\phi},\\
U_{2p\mp1,2p\pm1}(\mathbf{r}) &= \frac{\frac{1}{2}B}{r^2}\,\mathrm{P}_2{}^2(\cos\theta)\mathrm{e}^{\pm 2i\phi}.
\end{aligned}\right\} \quad \ldots\ldots(35)$$

These matrix elements have the same dependence on the angular coordinates θ, ϕ and the same signs as the matrix elements (34) for large r if all the coefficients A and B are chosen to be positive constants for incident particles of negative charge, e.g. electrons, and negative constants for incident particles of positive charge, e.g. positrons, protons, and α-particles.

In order to obtain simple analytical expressions for the third-order approximation to the partial cross section we also put $k_1=k_2=k$.

3.1. *Method of Distorted Waves*

In this section we neglect coupling to all states except the initial and final states and, in addition, neglect back coupling.

We first consider the *elastic scattering* of particles by the ground 1s state of the model atom. Then we require the solution of the equation

$$[\nabla^2+k^2-U_{1s,1s}(r)]F_{1s}(\mathbf{r})=0 \quad \ldots\ldots(36)$$

where F_{1s} has the asymptotic form (6) for large r.

Expanding F_{1s} in the form (14) we obtain

$$\left[\frac{d^2}{dr^2}+k^2-\frac{l(l+1)-A_1}{r^2}\right]\phi_{1,l}=0. \quad \ldots\ldots(37)$$

Hence

$$\phi_{1,l}(r)=r\mathrm{j}_{l_1}(kr) \quad \ldots\ldots(38)$$

where

$$l_1(l_1+1)=l(l+1)-A_1 \qquad \ldots\ldots(39)$$

i.e.

$$l_1=\tfrac{1}{2}[-1+\{(2l+1)^2-4A_1\}^{1/2}]. \qquad \ldots\ldots(40)$$

In order that $r^{-1}\phi_{1,l}(r)$ should be finite at the origin we require that $l_1 \geqslant 0$. This is always satisfied if $A_1 \leqslant 0$ i.e. for positively charged particles. However, if $A_1>0$ then $l_1 \geqslant 0$ only if $A_1 \leqslant l(l+1)$. A difficulty occurs in the latter case when $l=0$ for then $l_1<0$. Nevertheless, provided that $A_1<\frac{1}{4}$, i.e. $l_1>-\frac{1}{2}$, an expression for the cross section can still be obtained even though the solution is unbounded at the origin (Mott and Massey 1949).

Now

$$\eta_{1,l}=\tfrac{1}{2}\pi(l-l_1) \qquad \ldots\ldots(41)$$

and so it follows from (40) that

$$\eta_{1,l}=\tfrac{1}{4}\pi(2l+1)\left[1-\left\{1-\frac{4A_1}{(2l+1)^2}\right\}^{1/2}\right]. \qquad \ldots\ldots(42)$$

Since

$$f_{1s}(\theta)=\frac{1}{k}\sum_{l=0}^{\infty}(2l+1)\exp(i\eta_{1,l})\sin\eta_{1,l}\mathrm{P}_l(\cos\theta) \qquad \ldots\ldots(43)$$

we see that the lth order partial cross section for elastic scattering is given by

$$Q_l(1s\to 1s)=\frac{4\pi}{k^2}(2l+1)\sin^2\eta_{1,l}. \qquad \ldots\ldots(44)$$

Hence the third-order distortion approximation to the elastic partial cross section is

$$Q_l(1s\to 1s)=\frac{\pi^3}{k^2}\frac{A_1{}^2}{2l+1}\left\{1+\frac{2A_1}{(2l+1)^2}\right\}. \qquad \ldots\ldots(45)$$

To the second order in A this reduces to the first Born approximation expression

$$Q_l(1s\to 1s)=\frac{\pi^3}{k^2}\frac{A_1{}^2}{2l+1}. \qquad \ldots\ldots(46)$$

Because the partial cross sections fall off as l^{-1} for large l the sum of the series of partial cross sections diverges for the schematic model. We shall therefore confine our investigations to the individual partial cross sections only.

We now consider the 1s–2s excitation case for which we require the solution of the pair of equations

$$[\nabla^2+k^2-U_{1s,1s}(r)]F_{1s}(\mathbf{r})=0 \qquad \ldots\ldots(47)$$

$$[\nabla^2+k^2-U_{2s,2s}(r)]F_{2s}(\mathbf{r})=U_{2s,1s}(r)F_{1s}(\mathbf{r}), \qquad \ldots\ldots(48)$$

where F_{2s} has the asymptotic form (7) for large r.

Referring to § 2 we see that $f_{2s}(\theta)$ is given by (18) where

$$\phi_{2,l}(r)=r\mathrm{j}_{l_2}(kr) \qquad \ldots\ldots(49)$$

with

$$l_2=\tfrac{1}{2}[-1+\{(2l+1)^2-4A_2\}^{1/2}] \qquad \ldots\ldots(50)$$

and

$$\eta_{2,l}=\tfrac{1}{4}\pi(2l+1)\left[1-\left\{1-\frac{4A_2}{(2l+1)^2}\right\}^{1/2}\right]. \qquad \ldots\ldots(51)$$

Hence

$$f_{2s}(\theta) = -A_{2s,1s}\sum_{l=0}^{\infty}(2l+1)\mathrm{P}_l(\cos\theta)\exp\{i(\eta_{1,l}+\eta_{2,l})\}\int_0^{\infty}\mathrm{j}_{l_1}(kr)\mathrm{j}_{l_2}(kr)\,dr \qquad \ldots\ldots(52)$$

giving for the 1s–2s excitation lth order partial cross section

$$Q_l(1\mathrm{s}\rightarrow 2\mathrm{s}) = 4\pi(2l+1)(A_{2s,1s})^2\left[\int_0^{\infty}\mathrm{j}_{l_1}(kr)\mathrm{j}_{l_2}(kr)\,dr\right]^2. \qquad \ldots\ldots(53)$$

Since (Watson 1944)

$$\int_0^{\infty}\mathrm{j}_{l_1}(kr)\mathrm{j}_{l_2}(kr)\,dr = \frac{\sin(l_1-l_2)\frac{1}{2}\pi}{k(l_1-l_2)(l_1+l_2+1)} \qquad (l_1+l_2+1>0) \qquad \ldots\ldots(54)$$

it follows that, to the distorted waves approximation,

$$Q_l(1\mathrm{s}\rightarrow 2\mathrm{s}) = 4\pi(2l+1)(A_{2s,1s})^2 \times\left[\frac{1}{k(A_2-A_1)}\sin\tfrac{1}{4}\pi(2l+1)\left\{\left(1-\frac{4A_1}{(2l+1)^2}\right)^{1/2}-\left(1-\frac{4A_2}{(2l+1)^2}\right)^{1/2}\right\}\right]^2. \qquad \ldots\ldots(55)$$

The third-order distortion approximation is obtained by expanding to the third order in A and is given by

$$Q_l(1\mathrm{s}\rightarrow 2\mathrm{s}) = \frac{\pi^3}{k^2(2l+1)}(A_{2s,1s})^2\left\{1+\frac{2(A_1+A_2)}{(2l+1)^2}\right\} \qquad \ldots\ldots(56)$$

while the first Born approximation has the form

$$Q_l(1\mathrm{s}\rightarrow 2\mathrm{s}) = \frac{\pi^3}{k^2}\frac{(A_{2s,1s})^2}{2l+1}. \qquad \ldots\ldots(57)$$

We now turn our attention to the 1s–2p$_0$ excitation case which involves the solution of the pair of equations

$$[\nabla^2+k^2-U_{1s,1s}(r)]F_{1s}(\mathbf{r}) = 0 \qquad \ldots\ldots(58)$$

$$[\nabla^2+k^2-U_{2p_0,2p_0}(\mathbf{r})]F_{2p_0}(\mathbf{r}) = U_{2p_0,1s}(\mathbf{r})F_{1s}(\mathbf{r}) \qquad \ldots\ldots(59)$$

where F_{2p_0} has the asymptotic form for large r given by (7). From Eqn (10) it follows that

$$f_{2p_0}(\theta) = -\frac{1}{4\pi}A_{2p,1s}\int\mathscr{F}_2(r',\pi-\Theta')F_{1s}(\mathbf{r}')\mathrm{P}_1(\cos\theta')\frac{1}{r'^2}\,d\mathbf{r}'. \qquad \ldots\ldots(60)$$

In the first instance let us neglect the term involving $\mathrm{P}_2(\cos\theta)$ in $U_{2p_0,2p_0}$. Then it can be readily shown that

$$f_{2p_0}(\theta) = -iA_{2p,1s}\sum_{l=0}^{\infty}\exp(i\eta_{2,l})\mathrm{P}_l(\cos\theta) \times\left[(l+1)\exp(i\eta_{1,l+1})\int_0^{\infty}\phi_{2,l}(r)\phi_{1,l+1}(r)\frac{1}{r^2}\,dr - l\exp(i\eta_{1,l-1})\int_0^{\infty}\phi_{2,l}(r)\phi_{1,l-1}(r)\frac{1}{r^2}\,dr\right]. \qquad \ldots\ldots(61)$$

Using the integral (54) we find that to the third order in A

$$Q_0(1\mathrm{s}\to 2\mathrm{p}_0)=\frac{\pi}{k^2}(A_{2\mathrm{p},1\mathrm{s}})^2\{1+A_1-A_2\} \qquad \ldots\ldots(62)$$

and

$$Q_l(1\mathrm{s}\to 2\mathrm{p}_0)=0 \qquad (l\neq 0). \qquad \ldots\ldots(63)$$

Similarly for the case of the 1s–$2\mathrm{p}_{\pm 1}$ excitation we obtain

$$\begin{aligned} f_{2\mathrm{p}_{\pm 1}}(\theta,\phi)=iA_{2\mathrm{p},1\mathrm{s}}\sum_{l=1}^{\infty}\exp(i\eta_{2,l})\frac{1}{\sqrt{2}}\mathrm{P}_l^1(\cos\theta)e^{\mp i\phi} \\ \times\left[\exp(i\eta_{1,l+1})\int_0^\infty \phi_{2,l}(r)\phi_{1,l+1}(r)\frac{1}{r^2}\,dr\right. \\ \left.+\exp(i\eta_{1,l-1})\int_0^\infty \phi_{2,l}(r)\phi_{1,l-1}(r)\frac{1}{r^2}\,dr\right] \end{aligned} \qquad \ldots\ldots(64)$$

if the term involving $\mathrm{P}_2(\cos\theta)$ in $U_{2\mathrm{p}_{\pm 1},2\mathrm{p}_{\pm 1}}$ is neglected. To the third order in A this gives

$$Q_0(1\mathrm{s}\to 2\mathrm{p}_{\pm 1})=0 \qquad \ldots\ldots(65)$$

and

$$Q_l(1\mathrm{s}\to 2\mathrm{p}_{\pm 1})=\frac{\pi}{k^2}(A_{2\mathrm{p},1\mathrm{s}})^2\frac{2l+1}{2l(l+1)}\left\{1+\frac{A_2-A_1}{l(l+1)}\right\} \quad (l\neq 0). \qquad \ldots\ldots(66)$$

These partial cross sections reduce to the first Born approximation expressions if only terms up to the second order in A are retained. They are in agreement with the formula for the first Born partial cross section $\sum_{m=0,\pm 1}Q_l(1\mathrm{s}\to 2\mathrm{p}_m)$ derived by Seaton (1955) in the limit of large k.

For the 1s–$2\mathrm{p}_0$ excitation the partial cross section vanishes to the third order in A for all positive integral values of l while in the case of the 1s–$2\mathrm{p}_{\pm 1}$ excitation the partial cross section vanishes for $l=0$, attains a maximum value for $l=1$, and then decreases with increasing l.

3.2. *Distortion-polarization Approximation*

We now turn our attention to the effect of polarization resulting from coupling to states which are neither the initial nor the final state, and to the effect of the terms involving $\mathrm{P}_2(\cos\theta)$ in $U_{2\mathrm{p}_0,2\mathrm{p}_0}(\mathbf{r})$ and $U_{2\mathrm{p}_{\pm 1},2\mathrm{p}_{\pm 1}}(\mathbf{r})$. The analysis is of an elementary nature involving integrations of products of spherical Bessel and Neumann functions all of which can be evaluated in closed form (Watson 1944). However, the analysis is too lengthy to reproduce here so we shall only quote the final results. When coupling to all the states 1s, 2s, $2\mathrm{p}_0$, $2\mathrm{p}_{+1}$, $2\mathrm{p}_{-1}$ is taken into account to the third order in A and B, we obtain the third-order distortion-polarization approximation (Kingston, Moiseiwitsch and Skinner 1960). To this approximation the lth order partial cross sections are given by

$$Q_l(1\mathrm{s}\to 1\mathrm{s})=\frac{\pi^3}{k^2}\frac{A_1^2}{2l+1}\left[1+\frac{2A_1}{(2l+1)^2}+\frac{2(A_{2\mathrm{s},1\mathrm{s}})^2}{A_1}\frac{1}{(2l+1)^2}+\frac{(A_{2\mathrm{p},1\mathrm{s}})^2}{A_1}\delta_{0l}\right], \qquad \ldots\ldots(67)$$

$$Q_l(1\mathrm{s}\to 2\mathrm{s})=\frac{\pi^3}{k^2}\frac{(A_{2\mathrm{s},1\mathrm{s}})^2}{2l+1}\left[1+\frac{2(A_1+A_2)}{(2l+1)^2}+\frac{A_{2\mathrm{p},2\mathrm{s}}A_{2\mathrm{p},1\mathrm{s}}}{A_{2\mathrm{s},1\mathrm{s}}}\delta_{0l}\right], \qquad \ldots\ldots(68)$$

$$Q_0(1s\to 2p_0)=\frac{\pi}{k^2}(A_{2p,1s})^2\left[1+A_1-A_2+\frac{A_{2p,2s}A_{2s,1s}}{A_{2p,1s}}-B\right], \qquad \ldots\ldots(69)$$

$$Q_l(1s\to 2p_0)=0 \qquad (l\neq 0), \qquad \ldots\ldots(70)$$

$$Q_0(1s\to 2p_{\pm1})=0, \qquad \ldots\ldots(71)$$

$$Q_l(1s\to 2p_{\pm1})=\frac{\pi}{k^2}(A_{2p,1s})^2\,\frac{2l+1}{2l(l+1)} \times\left[1+\frac{A_2-A_1}{l(l+1)}-\frac{A_{2p,2s}A_{2s,1s}}{A_{2p,1s}}\frac{1}{l(l+1)}+\frac{1-4\delta_{1l}}{l(l+1)}B\right] \qquad (l\neq 0). \qquad \ldots\ldots(72)$$

The quantities involving the coefficient B in expressions (69) and (72) arise from two sources. The $(2B/r^2)P_2(\cos\theta)$ term of $U_{2p_0,2p_0}(\mathbf{r})$ introduces the quantity $-\frac{1}{3}B$ while the coupling to the $2p_{+1}$ and $2p_{-1}$ states introduces $-\frac{2}{3}B$. Together they give rise to the quantity $-B$ within the square brackets of expression (69) thus resulting in a contribution to the partial cross section for the 1s–$2p_0$ excitation having the same sign as that due to the $-A_2/r^2$ term of $U_{2p_0,2p_0}(\mathbf{r})$.

In the case of the 1s–$2p_{\pm1}$ excitation the $-(B/r^2)P_2(\cos\theta)$ term of $U_{2p_{\pm1},2p_{\pm1}}(\mathbf{r})$ introduces within the square brackets of expression (72) the quantities $-B/6$, $-B/30$ and $B/l(l+1)$ for $l=1, 2$ and $l\geqslant 3$ respectively, while the coupling to the $2p_0$ and $2p_{\mp1}$ states introduces $-4B/3$, $B/5$ and 0 for $l=1, 2$ and $l\geqslant 3$ respectively. Together they give rise to $B(1-4\delta_{1l})/l(l+1)$ which, for $l>1$, has the same sign as the contribution from the $-A_2/r^2$ term of $U_{2p_{\pm1},2p_{\pm1}}(\mathbf{r})$.

§ 4. DISCUSSION

In the special case of exact resonance for which $k_1=k_2=k$, $U_{11}=U_{22}$ and $U_{12}=U_{21}$, the pair of equations (4) and (5) can be rewritten in the uncoupled form (Massey 1956)

$$[\nabla^2+k^2-(U_{11}\pm U_{12})]F^{\pm}(\mathbf{r})=0 \qquad \ldots\ldots(73)$$

where

$$F^{\pm}(\mathbf{r})=F_1(\mathbf{r})\pm F_2(\mathbf{r}). \qquad \ldots\ldots(74)$$

Putting

$$U_{11}=-\frac{A}{r^2} \quad \ldots\ldots(75) \qquad \text{and} \qquad U_{12}=\frac{A_{12}}{r^2} \quad \ldots\ldots(76)$$

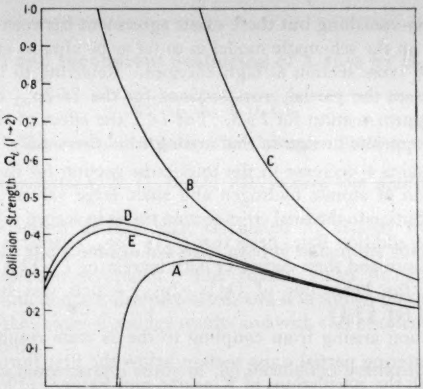
it can be readily shown, using the method of § 3.1, that

$$Q_l(1\to 2)=\frac{\pi}{k^2}(2l+1)\sin^2(\eta_l^+-\eta_l^-) \qquad \ldots\ldots(77)$$

where

$$\eta_l^{\pm}=\tfrac{1}{4}\pi(2l+1)\left[1-\left\{1-\frac{4(A\pm A_{12})}{(2l+1)^2}\right\}^{1/2}\right]. \qquad \ldots\ldots(78)$$

In order to assess the accuracy of the various approximations to the partial cross section we assign numerical values to A and A_{12}. A suitable choice of values is $A=-2$ and $A_{12}=-\frac{1}{2}$ which corresponds to the scattering of positively charged particles. In the Figure a comparison is made between the exact values of the collision strength $\Omega_l=(k^2/\pi)Q_l$ and the values of Ω_l obtained with the first and second Born approximations, the third-order approximation and the distorted waves approximation. Very good agreement is obtained between the distorted



Collision strength $\Omega_l\,(1 \to 2)$. A, third-order approximation; B, first Born approximation; C, second Born approximation; D, distorted waves approximation; E, exact calculation.

waves approximation and the exact calculations for all l since $A_{12} = -\frac{1}{2}$ gives rise to weak coupling. The first Born approximation is decidedly inferior to the third-order approximation for $l \geqslant 2$ while for $l = 0, 1$ both approximations are unsatisfactory since $A/(2l+1)^2$ is not sufficiently small for $A = 2$ and $l \leqslant 1$. The second Born approximation is unsatisfactory for all l as was predicted in § 2.

In the absence of exact resonance it is no longer possible to obtain an exact analytical expression for the partial cross section. However, the type of effect to be expected from distortion and polarization can still be determined by examining the third-order approximation expressions (67) to (72) for the partial cross sections.

If we again consider the case of the scattering of positively charged particles all the coefficients A and B will be negative in sign. Then it can be readily verified from expression (67) that the effect of distortion on the elastic scattering partial cross section is to reduce it below that given by the first Born approximation. This is in accord with the calculations of Kingston and Skinner (1961) on the elastic scattering of positrons by hydrogen atoms. Referring to the asymptotic expressions (34) we see that the range of the actual potential $U_{1s,\,1s}$ is less than that of the actual potentials $U_{2s,\,2s}$ $U_{2p_0,\,2p_0}$ and $U_{2p_{\pm 1},\,2p_{\pm 1}}$. Hence in the case of excitation we are justified in omitting the effect of the distortion due to the 1s state by putting $A_1 = 0$. It follows from (68) that the effect of distortion on the 1s–2s excitation partial cross section is to reduce it below the value given by the first Born approximation in agreement with the calculations of Smith (1960) and of Kingston, Moiseiwitsch and Skinner (1960).

To the third-order approximation all the partial cross sections for the 1s–2p$_0$ excitation of the schematic model atom vanish except for the zero-order partial wave. From (69) it can be seen that the effect of distortion on $Q_0(1s \to 2p_0)$ is to increase it above the first Born approximation. Bates (1961) finds that all the partial cross sections for the proton impact 1s–2p$_0$ excitation of atomic hydrogen are non-vanishing but there exists agreement between his calculations and those based on the schematic model in so far as he obtains an increase in the 1s–$2\mathrm{p}_0$ excitation cross section at high energies. Referring to (72) we see that distortion decreases the partial cross sections for the 1s–$2\mathrm{p}_{\pm 1}$ excitation below the first Born approximation for $l \geqslant 3$. For $l \leqslant 2$ the effect of the $-A_2/r^2$ term of $U_{2\mathrm{p}_{\pm 1}, 2\mathrm{p}_{\pm 1}}$ is opposite in sign to that arising from the $-(B/r^2)\mathrm{P}_2(\cos\theta)$ term. Bates (1961) obtains a decrease in the total cross section for the proton impact 1s–$2\mathrm{p}_{\pm 1}$ excitation of atomic hydrogen and since large values of l provide the dominant contribution to the total cross section this is in accord with the schematic model result. In addition Bates finds that $Q_l(1\mathrm{s} \to 2\mathrm{p}_{\pm 1})$ vanishes for $l = 0$, passes through a maximum and then decreases with increasing l. This is in qualitative agreement with the behaviour of $Q_l(1\mathrm{s} \to 2\mathrm{p}_{\pm 1})$ which was found using the schematic model (cf. § 3.1).

The polarization arising from coupling to the 2s state results in a decrease in the elastic scattering partial cross section below the first Born approximation in agreement with the calculations of Kingston and Skinner (1961). From (69) and (72) we see, also, that $Q_0(1\mathrm{s} \to 2\mathrm{p}_0)$ is decreased and $Q_l(1\mathrm{s} \to 2\mathrm{p}_{\pm 1})$ is increased by the coupling to the 2s state.

Only the zero-order partial cross sections for elastic scattering, the 1s–2s excitation and the 1s–$2\mathrm{p}_0$ excitation, and the $l = 1, 2$ partial cross sections for the 1s–$2\mathrm{p}_{\pm 1}$ excitation are affected by coupling to the 2p states. From expressions (67) to (72) we see that $Q_0(1\mathrm{s} \to 1\mathrm{s})$, $Q_0(1\mathrm{s} \to 2\mathrm{s})$ and $Q_2(1\mathrm{s} \to 2\mathrm{p}_{\pm 1})$ are decreased below the first Born approximation and $Q_0(1\mathrm{s} \to 2\mathrm{p}_0)$ and $Q_1(1\mathrm{s} \to 2\mathrm{p}_{\pm 1})$ are increased above the first Born approximation by the polarization due to the 2p states. However, since the partial cross sections for large values of l determine the behaviour of the total cross section it is unlikely that these trends will be reflected in the total cross sections. Thus, although Kingston and Skinner (1961) find that coupling to the 2p states decreases the total cross section for the elastic scattering of positrons by hydrogen atoms, Kingston, Moiseiwitsch and Skinner (1960) obtain an increase in the total cross section for the 1s–2s excitation of hydrogen atoms by proton impact.

Coherent and Incoherent Scattering of X-rays by H_2 and He

By G. E. KILBY

Department of Physics, The University, Sheffield

Communicated by N. H. March; MS. received 13th April 1961

Abstract. An electron density map calculated by Rollett from an accurate function of James and Coolidge has been used to obtain the coherent x-ray scattering from molecular hydrogen. The results given by the Coulson self-consistent field function are also presented, and it is shown that there is excellent agreement with the James–Coolidge results and with earlier calculations of Carter, March and Vincent.

In addition a more careful study of the incoherent scattering has been made than has previously been attempted. By considering two correlated wave functions, that of Eckart and Hylleraas for helium and that of Gurnee and Magee for hydrogen, previous approximations are shown to lead to somewhat high estimates of the total scattered intensity. For hydrogen, a maximum reduction of about 4% brings theoretical results to within 1% of the experimental values of Wollan.

The momentum distribution and the corresponding shapes of the Compton lines have also been considered for hydrogen and helium. It is suggested from the results obtained for molecular hydrogen that more accurate measurements of the Compton profile might afford a useful method of studying bonding electrons.

§ 1. INTRODUCTION

RECENTLY a theoretical study of the x-ray scattering to be expected from molecular hydrogen was carried out by Carter, March and Vincent (1958, to be referred to as CMV). These workers used a number of approximate wave functions, the most accurate of which was that due to Gurnee and Magee (1950, see also Hurley 1954), which leads to a binding energy of 4·2 ev. However, more recently the electron density in H_2 has been computed by Dr. J. S. Rollett (private communication) using the very accurate 5-term wave function (binding energy 4·5 ev) due to James and Coolidge (1933). In view of this, and with access to an electronic computer, it now proves possible to examine how the approximations made by CMV affect the charge distribution and the coherent x-ray scattering. As the calculation of the incoherent scattering requires the full wave function, not only the electron density, it becomes impractical to use the James and Coolidge function to determine this incoherent component. However by use of the Gurnee and Magee function and appeal to the simpler two-electron problem, the helium atom, two checks are afforded of the approximations used by CMV in their calculation of the incoherent scattering.

In addition to information on the electron density in direct space, we also felt it of interest to consider the momentum distribution in H_2 and the corresponding shape of the Compton line in x-ray scattering. Again a comparison with the He results proves somewhat illuminating.

§ 2. CHARGE DISTRIBUTIONS AND X-RAY SCATTERING

The expressions of Waller and Hartree (1929) for the total and coherent intensities may be written for gaseous hydrogen and helium,

$$\frac{I_T}{I_e} = 2 + 2 \iint |\psi(\mathbf{r}_1, \mathbf{r}_2)|^2 \frac{\sin \kappa r_{12}}{\kappa r_{12}} d\tau_1 \, d\tau_2 \qquad \ldots\ldots(1)$$

$$\frac{I_{\text{coh}}}{I_e} = f^2(\kappa) = 4 \iint \rho(\mathbf{r}_1)\, \rho(\mathbf{r}_2) \frac{\sin \kappa r_{12}}{\kappa r_{12}} d\tau_1 \, d\tau_2 \qquad \ldots\ldots(2)$$

where I_e is the Thomson scattering intensity for a single electron, $\psi(\mathbf{r}_1, \mathbf{r}_2)$ is the spatial part of the wave function and $\rho(\mathbf{r})$ the electron density, both normalized to unity and $\kappa = 4\pi (r_{12}/\lambda) \sin \frac{1}{2}\theta$ where θ is the angle of scattering.

The expected form of $f^2(\kappa)$ for H_2 has been calculated using electron densities derived from the James and Coolidge wave functions and also from the self-consistent field wave function of Coulson (1938, binding energy 3·6 ev). Since $\rho(\mathbf{r})$ is not spherically symmetric Eqn (2) was evaluated by the method developed by Banyard and March (1957) in which the electron density is first expanded in spherical harmonics. CMV showed that the s term alone largely determines the coherent scattering of H_2 over the range in which this is a significant part of the total scattered radiation. The radial electron distributions† from the James and Coolidge electron density, the self-consistent field and the Gurnee and Magee functions are shown in Fig. 1. It is seen that to graphical accuracy the first two curves are almost identical. The two $f^2(\kappa)$ curves corresponding to these functions are also almost identical, even when the d terms in the expansion of

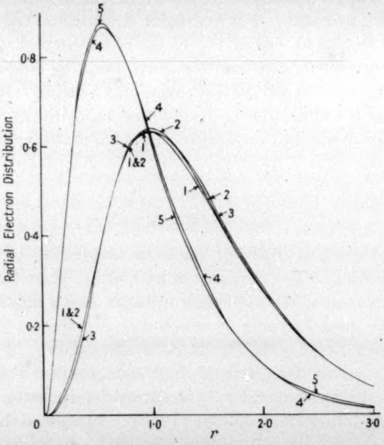

Fig. 1. Radial electron distributions for helium and the hydrogen molecule (atomic units used). Hydrogen: 1, from Rollett's map of the James–Coolidge electron density; 2, from Coulson's self-consistent field function; 3, from the Gurnee and Magee function. Helium: 4, from the self-consistent field function; 5, from the Eckart–Hylleraas function.

---

† The definition of radial electron distributions adopted here is $r^2 \iint \rho(\mathbf{r}) \sin \theta \, d\theta d\phi$.

$\rho(\mathbf{r})$ are also included in the calculation. Whilst these two d terms differ to a greater extent than the corresponding s terms they are still very similar and also in good agreement with those obtained earlier by CMV for the Gurnee and Magee and the LCAO molecular orbital wave functions†. The d terms in fact make only a very small contribution to the scattering factor curves.

The two sets of results for $f^2(\kappa)/4$ agree to within ± 2 in the third decimal place and lie on or between the curves obtained by CMV from the Gurnee and Magee and the LCAO molecular orbital functions. Since the James and Coolidge density is expected to give almost the exact form of $f^2(\kappa)$ these results show that the calculation of $f^2(\kappa)$ by CMV is essentially correct. It follows that the discrepancy (about 5% around $\kappa = 1{\cdot}6$ A.U. between the results of CMV and the experimental results of Wollan (1931) for the total scattering is not due to the calculation of the coherent component.

Apart from the use of approximate wave functions CMV made a further approximation in their calculation of I_{T}, namely the one involved in the use of the formula (see, for example, Herzog 1931),

$$I_{\mathrm{inc}}/I_{\mathrm{e}} = 2 - \tfrac{1}{2}f^2(\kappa) \qquad \ldots\ldots(3)$$

for the calculation of the incoherent intensity. Only if the exact wave function for hydrogen had the form $\phi(\mathbf{r}_1)\,\phi(\mathbf{r}_2)$ would the difference between Eqns (1) and (2) reduce to the expression (3). Of course the self-consistent field, the LCAO molecular orbital and the 'best' spherical molecular orbital wave funtions have this simple form and if they are used in the calculation of I_{T} then Eqn (3) follows. Although CMV used the correlated wave function of Gurnee and Magee they also assumed the validity of Eqn (3).

It was decided to test Eqn (3) by comparing results from this expression with the difference between Eqns (1) and (2) for some correlated wave functions. Inspection of (1) shows that the full wave function is required in the determination of $I_{\mathrm{T}}/I_{\mathrm{e}}$; on grounds of practical difficulty this ruled out the use of the James and Coolidge wave function.

In the light of this difficulty a test of Eqn (3) has been made for hydrogen using the Gurnee and Magee function. Also, in order not to generalize from one instance, a similar test has been made in the case of helium using the correlated wave function of Eckart (1930) and Hylleraas (1929). In both cases I_{T} has been obtained directly from (1) and also from (2) in conjunction with (3)‡.

The Eckart–Hylleraas function is

$$\psi(\mathbf{r}_1, \mathbf{r}_2) = N\{\exp(-ar_1)\exp(-br_2) + \exp(-br_1)\exp(-ar_2)\}$$

where N is a normalizing constant, $a = 2{\cdot}1832$, $b = 1{\cdot}1886$, these values being those obtained by Shull and Löwdin (1956). In this case,

$$\frac{I_{\mathrm{T}}}{I_{\mathrm{e}}} = \frac{4}{\frac{1}{64}a^{-3}b^{-3} + (a+b)^{-6}}\left[\frac{4ab}{(4a^2+\kappa^2)^2(4b^2+\kappa^2)^2} + \frac{(a+b)^2}{\{(a+b)^2+\kappa^2\}^4}\right] \qquad \ldots\ldots(4)$$

$$\frac{I_{\mathrm{coh}}}{I_{\mathrm{e}}} = \frac{4}{[\frac{1}{64}a^{-3}b^{-3} + (a+b)^{-6}]^2}\left[\frac{a}{8b^3(4a^2+\kappa^2)^2} + \frac{b}{8a^3(4b^2+\kappa^2)^2} + \frac{1}{(a+b)^2[(a+b)^2+\kappa^2]^2}\right]^2. \qquad \ldots\ldots(5)$$

---

† The ordinates of Fig. 3 of CMV have been incorrectly labelled. They should be divided by 4π.

‡ The usual relativistic correction (see, for example, Pirenne 1946, p. 34) corresponding to a value of λ of 1·34 A.U. has been applied to all curves shown in Fig. 2.

The expression (5) agrees with the result of Hurst, Miller and Matsen (1958), but to our knowledge (4) has not previously been recorded.

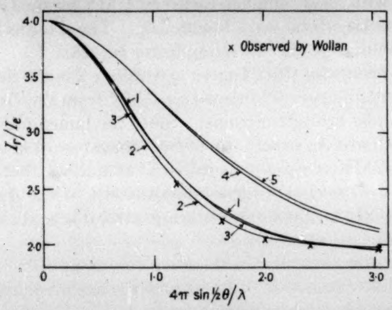

Fig. 2. Total intensities for x-ray scattering by helium and the hydrogen molecule (atomic units used). Hydrogen: 1, calculated from the Gurnee and Magee electron density using expression (3); 2, calculated from the Gurnee and Magee wave function using expression (1); 3, calculated from the self-consistent field function and the James–Coolidge electron densities using expression (3). Helium: 4, calculated from the Eckart–Hylleraas wave function using expression (1); 5, from the Eckart–Hylleraas electron density using expression (3).

In the two instances (see Fig. 2) the values of I_T from Eqn (1) are lower than those obtained by use of the approximate expression (3). Comparison of the two sets of results for helium shows them to agree to within 1·5%. The use of the approximate expression leads to a slightly too high value for all κ, with the maximum discrepancy occurring at $\kappa = 2{\cdot}4$ A.U. but the two agree for high and low κ. In the case of H_2 the use of (1) leads to values of I_T which are, in the region around $\kappa = 1{\cdot}7$ A.U., some 3 to 4% lower than the results obtained by CMV. In fact, using the Gurnee and Magee function and making no further approximation almost resolves the discrepancy between theory and experiment noted by CMV. Whilst, in view of the approximate nature of the Gurnee and Magee function, some slight reservation must still be made it seems from the present results for He and H_2 that the use of correlated wave functions in (1) will lead to values of I_T somewhat lower than those obtained from uncorrelated functions. In particular the eventual use of the James–Coolidge wave function is very likely to remove the discrepancies which have previously existed between the experimental results of Wollan and the theoretical scattering curves.

§ 3. MOMENTUM DISTRIBUTION AND COMPTON PROFILE

The momentum distribution function $I(p)$ is defined such that $I(p)dp$ is the probability of finding an electron with momentum magnitude between p and $p+dp$. It is determined by a knowledge of the first order, spinless density matrix in direct space:

$$I(p) = \frac{p^2}{2\pi^2} \int\int G(\mathbf{r}, \mathbf{r}') \frac{\sin p\,|\mathbf{r}-\mathbf{r}'|}{p\,|\mathbf{r}-\mathbf{r}'|}\, d\tau\, d\tau' \qquad \ldots\ldots (6)$$

where

$$G(\mathbf{r}, \mathbf{r}') = \int \psi^*(\mathbf{r}_1\sigma_1, \ldots \mathbf{r}_n\sigma_n)\psi(\mathbf{r}_1'\sigma_1, \ldots \mathbf{r}_n\sigma_n)\, d\sigma_1\, d\mathbf{x}_2 \ldots d\mathbf{x}_n; \qquad \ldots\ldots (7)$$

σ represents the spin coordinate and $\mathbf{x}$ a space and spin coordinate. If ψ is normalized to unity so is $I(p)$.

It becomes practical to evaluate the integrals involved in (6) if $G(\mathbf{r}, \mathbf{r}')$ is a product or a sum of products of the form $\phi(\mathbf{r})\,\phi(\mathbf{r}')$, in which case the method of Banyard and March (1957) may be used. The necessary integrals have been evaluated for H_2 using the self-consistent field function to give an approximation to $G(\mathbf{r}, \mathbf{r}')$ (see Fig. 3). The corresponding calculation using the James and Coolidge function is too lengthy to have been undertaken. For helium similar calculations have been completed, based on the self-consistent field function of Wilson and Lindsay (1935) and the Eckart–Hylleraas function (see Fig. 2). Use of the latter function leads to an analytic expression for $I(p)$:

Fig. 3. Momentum distribution functions for helium and the hydrogen molecule (atomic units used). Hydrogen: 1, from Coulson's self-consistent field wave function. Helium: 2, from the self-consistent field wave function; 3, from the Eckart–Hylleraas wave function.

$$I(p) = \frac{p^2}{4\pi[\frac{1}{64}a^{-3}b^{-3} + (a+b)^{-6}]} \left\{ \frac{a^2}{b^3(a^2+p^2)^4} + \frac{16ab}{(a+b)^3(a^2+p^2)^2(b^2+p^2)^2} + \frac{b^2}{a^3(b^2+p^2)^4} \right\}.$$

These momentum distribution functions may be used to determine the shape of the Compton profiles to be expected in the incoherent X-ray scattering by gaseous hydrogen and helium (see, for example, Dumond 1933). The shape of this profile is most conveniently expressed in terms of the function $J(q)$ (Duncanson and Coulson 1945) which is independent of the scattering angle and wavelength.

For a system of randomly oriented scatterers

$$J(q)=\int_q^\infty \frac{I(p)}{p}\,dp. \qquad \ldots\ldots(8)$$

The line shapes corresponding to the $I(p)$ functions discussed above are shown in Fig. 4. Again the Eckart–Hylleraas function leads to an analytic expression,

$$2J(q)=\frac{1}{4\pi[\frac{1}{64}a^{-3}b^{-3}+(a+b)^{-6}]}\left\{\frac{a^2}{3b^3(a^2+q^2)^3}+\frac{b^2}{3a^3(b^2+q^2)^3}\right.$$
$$\left.+\frac{16ab}{(a+b)^3}\left[\frac{a^2+b^2+q^2}{(a^2+q^2)(b^2+q^2)(a^2-b^2)^2}+\frac{2}{(a^2-b^2)^3}\ln\frac{b^2+q^2}{a^2+q^2}\right]\right\}.$$

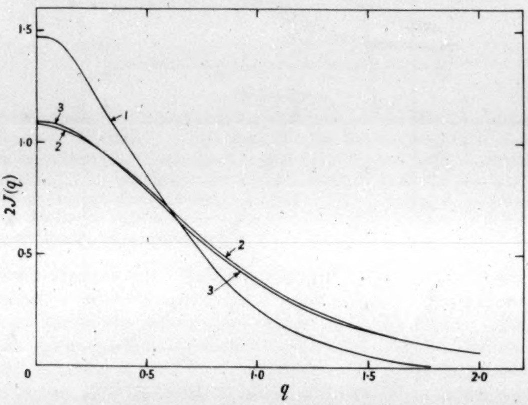

Fig. 4. Compton half-profiles for helium and the hydrogen molecule (atomic units used). Hydrogen: 1, from Coulson's self-consistent field wave function. Helium: 2, from the self-consistent field wave function; 3, from the Eckart–Hylleraas wave function.

Although the two $I(p)$ curves obtained for He differ appreciably in comparison with the differences in the corresponding electron densities, the two $J(q)$ curves do not differ to an extent which would be experimentally significant. The half-widths of the $J(q)$ curves† corresponding to the Eckart–Hylleraas and self-consistent field functions are 1·52 A.U. and 1·58 A.U. respectively. These results agree with the experimental ones of Dumond and Kirkpatrick (1937, half-width 1·5 A.U.). They also agree with the calculated results of Hicks (1937) who obtained a half-width of 1·50 A.U. and also found that his better wave functions gave smaller half-widths.

The half-width obtained here for hydrogen is 1·09 A.U. This is to be compared with the experimental value of Hughes and Starr (1938) of 1·3 A.U. obtained by electron scattering, the theoretical results of Hicks (1937) of 1·17 A.U. and the half-width for atomic hydrogen 1·02 A.U. Here, in contrast to the above result, the better function of Hicks (binding energy 4 ev) leads to a broader Compton profile than the self-consistent field function (binding energy 3·6 ev).

† In the approximation used here the Compton profile is symmetric about $q=0$, for this reason only half-profiles are shown in Fig. 4.

This difference between atomic and molecular wave functions may be observed in other calculations. Duncanson and Coulson (1945) calculated the half-width of the $J(q)$ curves for atomic helium and neon; in both cases these are greater than the experimental values (see Duncanson and Coulson 1945). Yet it seems to be generally true that experimental half-widths, where they exist, for solids and molecules are significantly greater than calculated values. As the $J(q)$ curve weights the low momentum part of $I(p)$, a $J(q)$ curve which is too narrow indicates the use of a wave function which over-estimates the probability of finding an electron with small momentum.

§ 4. CONCLUSION

The calculation, based on the James and Coolidge density map of Rollett, of the coherent X-ray scattering for hydrogen and its comparison with similar calculations based on other functions shows that the effect of correlations on this scattering is small. From this it follows that if the use of Eqn (3) is allowed in the evaluation of the incoherent component then this also must be equally insensitive to correlation. However, use of two correlated functions, the Eckart–Hylleraas function for helium and the Gurnee and Magee function for hydrogen, in Eqn (1) shows that expression (3) leads to an over-estimate of the total intensity in these cases by up to 1·5 and 4% respectively. It thus seems quite possible that the use of the James and Coolidge function in (1) to determine I_T would resolve the discrepancy hitherto thought to exist between theory and Wollan's experimental scattering curve.

To provide additional information on the influence of electronic correlation, results for densities in momentum space have been considered for helium and hydrogen. There is some indication that correlations show up rather more here than in direct space; in the case of helium the effects on X-ray scattering are quite small but for H_2 the influence seems rather more marked. Comparison of the half-width of the Compton profile of H_2 obtained here from the self-consistent field function with that of Hicks and the experimental result of Hughes and Starr suggests that correlation effects may lead to a profile some 10 per cent greater than ours.

It was pointed out at the end of § 3 that the shape of the central part of the Compton profile, in particular how rapidly it falls off, is fairly sensitive to the low momentum region of the $I(p)$ curve. This suggests that an accurate measurement of the Compton profile might be a useful method of studying bonding electrons.

ACKNOWLEDGMENTS

I am greatly indebted to my supervisor, Dr. N. H. March, for suggesting the work and for his unfailing help and encouragement. I would also like to thank Dr. J. S. Rollett for supplying his unpublished electron density map of the hydrogen molecule. Thanks are due to Mr. P. H. Blundell for allowing the use of the Ferranti PEGASUS computer which is available to the University Computation Laboratory. I also wish to acknowledge that Dr. A. M. Murray made available some computer programmes, and that Miss M. Barlow helped in the preparation of the manuscript. The work was carried out during the tenure of a Research Studentship from the Department of Scientific and Industrial Research.

Gamma Radiation from the Medium Energy Proton Bombardment of Lithium, Beryllium, Boron, Carbon and Nitrogen

By A. B. CLEGG, K. J. FOLEY, G. L. SALMON AND R. E. SEGEL†
Clarendon Laboratory, Oxford

MS. received 15*th February* 1961

Abstract. Measurements are presented of the gamma radiation produced when lithium, beryllium, boron, carbon and nitrogen are bombarded with 150 MeV protons, and the results are discussed with reference to the information they provide about the structure of the nuclei involved. The results include measurements of the residual states produced in (p, 2p) and (p, pn) reactions, which are, to a first approximation, measurements of the parentage of the ground state of the bombarded nucleus. These results are not consistent with a simple *jj*-coupling model of these nuclei and in one case where calculations are available, are consistent with an intermediate coupling model. It is shown that inelastic scattering cross sections are determined by the same matrix element as radiative transitions so that inelastic scattering is a powerful tool for picking out strong radiative transitions to nuclear ground states.

§ 1. INTRODUCTION

In recent years many measurements have been made on the outgoing charged particles from nuclear reactions induced by protons of 100–200 MeV. In particular, studies of (p, p′) (Strauch and Titus 1956 a, b, Dickson and Salter 1957, Tyrén and Maris 1957 a, b, 1958) and (p, 2p) reactions (Tyrén, Hillman and Maris 1958, Gooding and Pugh 1960) cast much light on nuclear structure problems. In the work described in this paper measurements have been made of the yield of gamma radiation from excited states of residual nuclei produced in the bombardment of p-shell nuclei with 140 MeV protons. This work complements the charged particle results by providing what are, in effect, measurements with better energy resolution than is possible by observing charged particles alone. In particular, it is possible to make measurements of the fine structure of the pronounced peaks seen in the excitation spectra of residual nuclei in (p, 2p) reactions (Tyrén, Hillman and Maris 1958, Gooding and Pugh 1960) and in the mirror (p, pn) reactions.

§ 2. EXPERIMENTAL METHODS

A proton beam of energy 153 MeV from the Harwell synchrocyclotron is focused by quadrupole magnets on to a target at approximately 17 metres from the cyclotron. The protons travel in vacuum up to a point about 50 cm in

---

† Now at Aeronautical Research Laboratories, Wright-Patterson Air Force Base, Ohio, U.S.A.

front of the target. A beam intensity (time average) of 1 to 3×10^5 protons/sec has been found adequate for this work (the duty ratio being approximately 2%).

The beam is monitored by a thin ionization chamber placed 50 cm in front of the target; this monitor is calibrated by comparing measurements of the production of ^{11}C (Crandall *et al.* 1956) and the elastic scattering of protons from ^{12}C at forward angles (Dickson and Salter 1957) with the known cross sections; these two normalizations agreed.

The targets were usually about 20 or 40 MeV thick and were normally of natural isotopic abundance. We were fortunately also able to borrow targets of separated ^{6}Li and ^{10}B†. These enabled us not only to make measurements on these isotopes but also to correct the results for natural lithium and natural boron to obtain the cross sections for ^{7}Li and ^{11}B. For a ^{14}N target liquid nitrogen was contained, for different runs, in a ' Styrofoam ' box and in a vacuum-jacketed target. The small concentrations of ^{13}C in carbon and ^{15}N in nitrogen were ignored.

The gamma-ray counter was a thallium-activated sodium iodide crystal, 12·5 cm in diameter and 15 cm long, viewed by an EMI photomultiplier type 9530 run at 900 volts. The pulses produced were transmitted by a cathode follower through fifty yards of cable to the counting room where they were amplified and displayed on a hundred-channel pulse-height analyser, which was gated to count only during the cyclotron beam pulse. With this system there was no evidence for any appreciable gain shift due to counting rate: this was checked both by observing the same gamma ray at different beam intensities, and also by comparing the 4·43 MeV gamma ray from the ^{12}C(p, p′) reaction and a much lower counting rate from a polonium–beryllium source. Thus it was possible to use calibration sources (^{22}Na, radiothorium, polonium–beryllium) in between runs to identify the observed gamma rays. In every case the energy corresponding to the experimental peak (determined with an accuracy ranging from ± 1% to ± 5% depending on how well the peak stands out from the background) agreed with the energy of a gamma ray that would be expected from the reaction under study.

The gamma-ray counter was shielded by 10 cm of lead on all sides except towards the target and there was approximately 4 m of concrete between the counter and the cyclotron. With this shielding, the background with no target was between one-quarter and one-tenth, depending on the pulse height, of the counting rate due to the target; this background was smooth with no indication of any peaks. The spectrum due to a target was made up of peaks due to gamma rays superimposed on a smooth background due presumably to neutrons produced in the target. The yield of a gamma ray was obtained by continuing the smooth background under the peak so that the residual gamma-ray spectrum had the proper shape, as determined by comparison with gamma rays from calibration sources. The counter efficiency was then obtained from calculated tables (Miller, Reynolds and Snow 1958) and the cross section for production of the gamma ray calculated. In the case of the ^{11}B(p, p′) reaction where our cross section can be compared with those obtained by integrating proton angular distributions (adjusted to our energy by assuming the differential cross section to vary as a function of $\theta E^{1/2}$, E being the kinetic energy of the incident proton) the agreement is excellent.

---

† The ^{10}B was lent by Mr. B. Rose of the Atomic Energy Research Establishment, Harwell, and the sample containing ^{6}Li was lent by Mr. P. A. White of the Atomic Weapons Research Establishment, Aldermaston.

One has to be careful that the peaks observed are due to gamma rays produced in the target and not due to neutrons interacting in the crystal or in surrounding material. This was checked by inserting lead between the target and the crystal. All peaks at 0·7 MeV and above were attenuated suitably and are thus ascribed to gamma rays produced in the target. Below that energy peaks at about 0·45 and 0·63 MeV were produced by all targets and were found not to be attenuated by the inserted lead. Thus it is impossible to study gamma radiation of less than 0·7 MeV in this work.

§ 3. GAMMA-RAY DATA

A list of gamma rays observed is given in Table 1 with assignments to nuclear transitions and observed cross sections (the information on nuclear energy levels is taken from Ajzenberg-Selove and Lauritsen 1959). Upper limits on the cross section for producing a few gamma rays of particular interest are quoted; these gamma rays were not observed in this work and the upper limit quoted refers to an intensity which would have been evident. Pulse-height spectra corresponding to the gamma rays observed are shown in the figures listed in Table 1. In all cases measurements were made at both 90° and 135° with respect to the proton beam: no evidence was seen for any departure from isotropy of the order of magnitude of the errors quoted on the cross sections. The errors are largely due to the uncertainties in subtracting backgrounds.

In the cases of gamma-ray transitions between states in ^{10}B and ^{14}N both cascades and cross-over transitions are involved. The feeding of states to produce the observed gamma-ray intensities are given in Table 2 for ^{10}B and Table 3 for ^{14}N. For some entries no positive result is recorded: these cross sections were taken to be zero in calculating the remainder.

As will be seen from Figs 5 and 6, the gamma-ray spectra from bombardment of ^{12}C are rather complicated in three energy regions. The energy of the peak at 2 MeV is found to be $2{\cdot}00 \pm 0{\cdot}02$ MeV. This accuracy was obtained by using the 4·43 MeV gamma ray from inelastic scattering on the same run as a calibration; in this way there could be no question of a gain shift between run and calibration. Thus the strongest gamma ray present in the 2 MeV region is the transition from the first excited state of ^{11}C at 1·99 MeV. However the peak is asymmetric, the asymmetry being consistent with the presence of gamma rays of 2·13 MeV from the first excited state of ^{11}B and 2·15 MeV from the state of that energy in ^{10}B. Using the spectrum shapes of known gamma rays we find the ratio of intensities of 2·13 plus 2·15 MeV to 1·99 MeV to be $0{\cdot}40 \pm 0{\cdot}05$. Taking the cross section for the 2·15 MeV gamma ray to be $0{\cdot}3 \pm 0{\cdot}18$ mbn (see Table 2) we find the cross section for production of the first excited state of ^{11}B to be $0{\cdot}8 \pm 0{\cdot}3$ mbn and for production of the first excited state of ^{11}C to be $2{\cdot}8 \pm 0{\cdot}4$ mbn, a ratio of $0{\cdot}29 \pm 0{\cdot}13$.

The spectrum corresponding to the 4·43 MeV gamma ray from inelastic scattering in ^{12}C is very evident in Figs 5 and 6. However there is definite evidence for the presence of higher energy gamma rays around 4·85 MeV. That this higher energy tail is not due to pile-up or some similar experimental effect is seen by comparing the ^{12}C spectrum with that due to a 4·43 MeV gamma ray produced in the bombardment of ^{14}N shown in Fig. 8, where the high energy side of the 4·43 MeV spectrum falls steeply and continuously to the background. These data were taken under the same conditions with the same counting rate. The intensity of the 4·43 MeV gamma ray from carbon has been estimated from

the height of the steep fall-off on the high energy side. On then subtracting the spectrum due to this gamma ray the remainder was found to correspond to a gamma ray or gamma rays of about 4·85 MEV; it is ascribed to transitions from the 4·75 MEV state of ^{11}C and the 5·03 MEV state of ^{11}B. The 4·43 MEV spectrum presumably also contains counts due to a 4·25 MEV gamma ray in ^{11}C and a 4·46 MEV gamma ray in ^{11}B; our cross section of 6·6 ± 1·0 mbn for 4·4 MEV gamma rays is higher than those found by integrating angular distributions from the ^{12}C(p, p′) reaction. Such cross sections, adjusted to our energy, are 5·0 mbn (Dickson and Salter 1957) and 4·8 mbn (Garron *et al.* 1960). Experiments are in progress

to measure the individual yields of these gamma rays by observing coincidences between low energy protons and gamma rays produced in both proton and neutron bombardment of carbon. The broad peak at 6·5 Mev is presumably due to transitions from states of ^{11}C at 6·50 and 6·77 Mev and from states of ^{11}B at 6·76 and 6·81 Mev. There may be a small contribution from ^{16}O impurity in the target, as this produces a spectrum peaked at about 6·1 Mev with a cross section of about 30 mbn, due to the (p, pn) and (p, 2p) reactions (A. B. Clegg, P. S. Fisher, K. J. Foley, D. J. Rowe and G. L. Salmon 1960, unpublished work); however the bulk of the peak in Fig. 6 is above this energy and is thus due to ^{12}C. Our limit of 0·1 mbn for the production of a 15·1 Mev gamma ray is consistent with the result of 0·06 mbn found at this energy by Waddell (1957) but inconsistent with the result of 1·8 mbn of Garron *et al.* (1960).

Table 2. Cross Sections (mbn) for Feeding States in ^{10}B in Various Reactions

State in ^{10}B (Mev)	^{10}B + p	^{11}B + p	^{12}C + p	^{14}N + p
3·58	—	$<1·7$	$1·5 \pm 0·7$	—
2·15	$2·1 \pm 0·65$	$7·3 \pm 1·5$	$1·0 \pm 0·55$	—
1·74	$0·4 \pm 0·4$	$5·6 \pm 1·1$	$1·5 \pm 0·3$	$1·0 \pm 0·2$
0·72	$0 \pm 1·1$	$1·1 \pm 2·0$	$1·5 \pm 0·55$	$2·0 \pm 0·55$

Table 3. Cross Section for Feeding States in ^{14}N(p, p′) Reaction

State (Mev)	2·31	3·95
Cross section (mbn)	$0·2 \pm 0·22$	$0·4 \pm 0·1$

The inelastic scattering from the 4·46 Mev state of ^{11}B has been studied by Tyrén and Maris (1958). Integrating their angular distribution, and adjusting to our energy, we find 3·7 mbn in excellent agreement with our result of $3·8 \pm 0·6$ mbn.

An excitation function of the 4·43 Mev gamma ray produced in the bombardment of ^{14}N has been measured, the proton energy being degraded by carbon absorbers placed approximately 30 cm in front of the target and well shielded from the gamma-ray counter by lead. The relative cross sections are given in Table 4, accurate to ±10%.

Table 4. Relative Cross Sections for Production of 4·43 MeV Gamma Ray in $^{14}N+p$ Reaction

Mean proton energy (MeV)	Relative cross section
85	1·3
105	1·2
125	1·1
145	1·0

§ 4. ACTIVATION DATA

Several activation cross sections have been measured as a complement to the gamma-ray work. The sample was irradiated for one to two half-lives in a known proton beam and then carried to the counting room where the resulting gamma rays (positron annihilation quanta in the cases of ^{11}C and ^{13}N and gamma rays in ^{10}B in the case of ^{10}C) were counted with a thallium-activated sodium iodide crystal for several half-lives.

The samples used were

^{12}C: natural carbon;

^{14}N: both liquid nitrogen and boron nitride (the latter for ^{13}N activation only).

The yields of the individual activities were then found by separating the decay curve by a least squares method into exponentials of known half-lives, using the Ferranti MERCURY computer of the Computer Laboratory, Oxford. The results are shown in Table 5.

Table 5. Results of Activation Measurements

Reaction	$p+^{12}C$	$p+^{14}N$	
Mean proton energy (MeV)	143	145	
Activity	^{10}C	^{13}N	^{11}C
Yield (mbn)	$2{\cdot}6\pm1{\cdot}3$	14 ± 1	$7{\cdot}0\pm1{\cdot}5$

The only results with which these can be compared are those of Symonds, Warren and Young (1957) who used protons of 420–980 MeV. To make a comparison we assume that cross sections for (p, pn) reactions fall off in the same way as in the $^{12}C(p,pn)$ reaction: if this assumption is made the agreement between the $^{14}N(p,pn)$ result presented here and those of Symonds, Warren and Young is good. Symonds *et al.* find an approximately constant cross section as the proton energy varies for the production of ^{10}C from $^{12}C+p$. Our result suggests this constancy extends down to 140 MeV. Our cross section for the production of ^{11}C from $^{14}N+p$ is apparently about half of what it is at the higher energies.

Symonds, Warren and Young (1957) suggest that the lower cross section for the $^{14}N(p,pn)$ reaction compared with that for the $^{12}C(p,pn)$ reaction, as measured by activation methods, is because there is only one bound state in ^{13}N while there are approximately eight in ^{11}C. This explanation obviously does not hold at our energy as the gamma-ray data show that most of the production of ^{11}C in the $^{12}C(p,pn)$ reaction is direct production of the ground state, so that the cross section for production of the ground state of ^{11}C is approximately 2·5 times that for the production of the ground state of ^{13}N. This difference presumably reflects a difference in the structures of ^{12}C and ^{14}N.

§ 5. Discussion of Knockout Reaction Results

On the usual direct interaction model of the reactions A (p, 2p) or (p, pn) A − 1 we are measuring the parentage of nucleus A (Lane and Wilkinson 1955), when we measure the relative populations of states of nucleus A − 1 produced in these reactions. In measurements of the energies of the outgoing protons in (p, 2p) reactions in the p-shell it has been found (Tyrén, Hillman and Maris 1958, Gooding and Pugh 1960) that the excitation spectra in nuclei A − 1 show pronounced peaks implying strong excitation of one or a few states in the residual nuclei. These peaks have been interpreted using a simple *jj*-coupling shell model, which interpretation would seem to conflict with the intermediate coupling picture which has been based on a wide range of work at lower energies (e.g. Inglis 1953, Kurath 1956, Lane 1953, 1955). In the work described here some details of the excitation spectra have been investigated in somewhat more detail and show lack of support for the *jj*-coupling interpretation; in the one case where calculations are available there is agreement with the intermediate coupling picture.

One has to be careful in applying the simple knockout model and not use it in cases where multiple collisions are important: for example, they are probably important in determining the polarization of neutrons produced in proton bombardment (Squires 1958 a). However the main effect of a second collision would be to evict further nucleons so our observation of bound states in nucleus A − 1 should select events where only a single collision has taken place; similarly the angular correlations of Gooding and Pugh (1960) should not be perturbed by multiple collisions as they restrict their attention to low excitation in ^{11}B. The main causes of disturbance should be inelastic scattering of the incident nucleon before the knockout collision exciting nucleus A to an excited state and the inelastic scattering of either of the outgoing nucleons after the knockout collision exciting nucleus A − 1 to a bound excited state. One can argue qualitatively that such processes would only contribute a very small amount to the (p, 2p) and (p, pn) reactions, as typical cross sections for inelastic scattering leaving nuclei in bound excited states are about 6 mbn to be compared with typical total reaction cross sections of about 250 mbn (we ignore elastic scattering as this does not change the ratio of states produced), so we can hope that they will not change our main conclusions. However detailed calculation of these effects would be valuable.

Now let us consider specific reactions, starting with ^{12}C for which most detail is available, both experimental and theoretical. The cross section for producing ^{11}C in its bound states is 44 mbn (Crandall *et al.* 1956) and of this the ^{12}C(p, d) cross section is 4 mbn (Cooper and Wilson 1960) so the ^{12}C(p, pn) cross section is 40 mbn; for both these reactions the ratio of population of states in ^{11}C should be the same. For production of bound excited states we find: 1·99 Mev, 3 mbn; 4·8 Mev, 2 mbn; 6·5 Mev, 2 mbn, leaving 37 mbn for the ground state. This agrees with the ^{12}C(p, d) measurements where only a group to the ground state is seen; weak groups of the relative strength seen here would not have been noticed in the (p, d) measurements. So we find for the ratio of population of first excited state ($J = 1/2^-$) to ground state ($J = 3/2^-$) in ^{11}C a result $0{\cdot}08 \pm 0{\cdot}03$. This agrees with neither the result for *jj*-coupling wave functions of zero nor the *LS*-coupling result of 0·5. Comparing with unpublished intermediate coupling calculations by Kurath† we find this result implies an intermediate coupling parameter of $a/K = 6{\cdot}4 \pm 1{\cdot}0$ (see Fig. 9), which is consistent with the values ($a/K \simeq 5{\cdot}5$) found in the lower energy work. Our result that most of the ^{12}C(p, pn) reaction feeds the ground state of ^{11}C agrees with the result that the ground state of ^{11}B is the main state fed in the mirror (p, 2p) reaction (Tyrén, Hillman and Maris 1958, Gooding and Pugh 1960).

Gooding and Pugh quote 16 ± 4 mbn for the total cross section for the ^{12}C(p, 2p) reaction leaving ^{11}B in low states. This is in agreement with the ^{12}C(n, 2n)^{11}C cross sections that have been measured as averages over neutron spectra peaked at various energies in this range (see for example results quoted by Rosenfeld, Swanson and Warshaw 1956). We have measured the ^{11}C production in the ^{12}C(n, 2n) reaction for a neutron spectrum with a peak at 130 MeV and a maximum energy of 155 MeV. If one assumes the (n, 2n) cross section to vary with energy in the same way as the (p, pn) cross section the results correspond to a ^{12}C(n, 2n)^{11}C cross section at 143 MeV of 17 ± 3 mbn. This agreement with the (p, 2p) result of Gooding and Pugh confirms their assumption that there is no major contribution to the cross section from angular regions they have neglected. This gives a ratio of $\sigma(\mathrm{p, 2p})/[\sigma(\mathrm{p, pn}) + \sigma(\mathrm{p, d})] = 0{\cdot}36 \pm 0{\cdot}06$ in agreement with our result of $0{\cdot}29 \pm 0{\cdot}13$ for the relative production of the first excited states of ^{11}B and ^{11}C, thus lending support to the model discussed here. Finally we note that the ratio $\sigma(\mathrm{p, 2p})/\sigma(\mathrm{p, pn}) = 0{\cdot}40 \pm 0{\cdot}06$ to be compared with a ratio of 0·56 for the corresponding free-nucleon cross sections (Hess 1958).

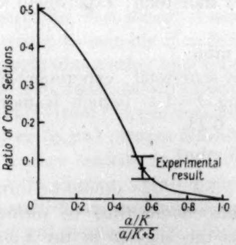

Fig. 9. Ratio of cross sections for producing first excited state and ground state in the ^{12}C(p, pn)^{11}C reaction as a function of $(a/k)/(a/k + 5)$.

One could argue that, as the relative feeding of the excited states is small, the main reaction is a simple feeding of the ground state, as predicted for *jj*-coupling wave functions, with weak excitation of excited states due to inelastic scattering before and after the knockout collision. In this case, inelastic scattering before knockout would produce the four states of the $\mathrm{p}_{3/2}{}^{7}\mathrm{p}_{1/2}$ configuration, and on knocking out a $\mathrm{p}_{3/2}$ nucleon one gets ten states, so that each of them would be fed by a cross section of only a fraction of a millibarn (an estimate based on typical inelastic scattering cross sections). Inelastic scattering after knock-out should produce the same states as the ^{11}B(p, p′) reaction and we see from the measurements presented here that the first excited state is fed weakly, if at all, compared to the second excited state, in this reaction. Thus it seems unlikely that it would be possible to explain the observed feeding in this way, starting from *jj*-coupling wave functions.

---

† We are indebted to Dr. Kurath for his permission to quote his unpublished results.

For the ^{11}B ground state in *jj*-coupling there are four parent states. Writing them as (J, T) the relative feeding of these states in ^{10}B is: (3, 0), 7/16; (1, 0), 3/16; (0, 1), 1/16; (2, 1), 5/16†. As the 0·72 and the 2·15 MeV states have $J=1$, $T=0$, while the 1·74 MeV state has $J=0$, $T=1$, we see that no *jj*-coupling assignment to these states will give agreement with cross sections found in this work. It would be interesting to be able to compare the experimental results with intermediate coupling calculations.

In the other (p, 2p) and (p, pn) reactions observed in this work there are no actual ratios of states to compare with predictions for *jj*-coupling wave functions. It is interesting however to compare the cross sections found with the total cross sections for the p-shell estimated from a simple model where the cross section for ejecting a $p_{3/2}$ nucleon is taken to be the number of $p_{3/2}$ neutrons or protons present, multiplied by the corresponding free-nucleon cross section (Hess 1958) and a nuclear absorption factor taken to be $\exp(-kA^{1/3})$. The value of k is found by taking 44 mbn for the cross section for ^{12}C(p, pn) and ^{12}C(p, d) and 16 mbn for the cross section for ^{12}C(p, 2p). (Such a model agrees quite well with the relative cross sections found by Tyrén, Hillman and Maris (1958) if we assume their results to be the same sample of the angular correlations in each case.) For such a model we find:

^{7}Li(p, pn)^{6}Li	$\sigma_{\text{tot}} \sim 28$ mbn,
ratio	3·56 MeV state/total; experiment, 0·05; prediction of model‡, 0·21
^{9}Be(p, 2p)^{8}Li	$\sigma_{\text{tot}} \sim 9$ mbn,
ratio	0·98 MeV state/total; experiment, 0·27; prediction of model‡, assuming $J=1+$ (which is more likely), 0·10; assuming $J=3+$, 0·23
^{14}N(p, 2p)^{13}C	$\sigma_{\text{tot}} \sim 15$ mbn.

Three states with $J=1/2^-$, $3/2^-$, $5/2^-$ should be formed with relative intensities 1 : 2 : 3. The $J=3/2^-$ state should thus be formed with a cross section of 5 mbn. One would expect this state to be the 3/2 state at 3·68 MeV for which the cross section is found to be less than or equal to 1·5 mbn.

Thus in all of the three cases there are large discrepancies. Such a simple model cannot be accurate but one would be surprised if there were such large departures from it as would be needed to produce the ratios predicted for *jj*-coupling wave functions. Added to the direct evidence from the ^{12}C(p, pn) and ^{11}B(p, pn) reactions it does not seem that the simple *jj*-coupling interpretation is valid. One can speculate that the very localized excitation found in the residual nuclei in these reactions displays some particular property of the intermediate coupling wave functions. A similar simplicity is seen in the inelastic scattering reactions at these energies as is discussed in § 6 where it is suggested that inelastic scattering picks out certain states with particular properties in intermediate coupling. Perhaps similarly some particular states are picked out in the (p, pn) and (p, 2p) reactions.

---

† These have been calculated by taking the ground state of ^{5}Li to be the sole parent of the corresponding states in ^{6}Li and using the relation between particles and holes given by Lane (1960), his formula (71). A further factor of 1/3 for the $T=1$ states comes from the coupling of the isotopic spins.

‡ In calculating the predicted ratios the fractional parentage coefficients of Edmonds and Flowers (1952) were used. In the case of ^{9}Be the relation between particles and holes (Lane 1960) was also needed.

The high yield of 4·43 MeV gamma rays from the bombardment of nitrogen is probably due to the $^{14}N(p, pn)$ reaction producing an excited state or states of ^{13}N which decay an appreciable part of the time by emitting a proton and leaving the first excited state of ^{12}C. From the $^{14}N(p, 2p)$ measurements (Tyrén, Hillman and Maris 1958), it is known that states around 7·5 MeV in ^{13}C are produced strongly in this reaction, so presumably mirror states are produced at the same energy in ^{13}N in the $^{14}N(p, pn)$ reaction. Such states in ^{13}N can decay leaving ^{12}C in either its ground state or first excited state (the states in ^{13}C at this energy can decay only to the ground state of ^{12}C). Thus it is not surprising that these states apparently decay about half the time to leave ^{12}C in its first excited state, thus producing the 4·43 MeV gamma ray seen in this work. The alternative is that it is just one of the states that is formed when two nucleons are ejected by the incident proton from ^{14}N; it would however seem surprising that there would be such a large cross section for producing one particular state in ^{12}C. The difficulty in the former hypothesis is that one would expect negative parity states to be produced in ^{13}C and ^{13}N and there are no recorded states of negative parity at an excitation of about 7·5 MeV in these nuclei. However this is also a problem in understanding the results of Tyrén, Hillman and Maris, and we can only conclude that not all the states in this energy range in these nuclei are known. It would be interesting to search for these states; it would seem that the $^{14}N(p, d)$, $(^3He, \alpha)$ or (t, α) reactions would be suitable if sufficient energy were available.

One can make some remarks about other knockout reactions observed in this work. For reactions where two nucleons are ejected from the target nucleus, for example the production of ^{10}B from ^{12}C, one would expect that one contributing process would be a (p, 2p) or (p, pn) process followed by one of the outgoing nucleons interacting with another nucleon and ejecting it. If this process was the only one responsible for the ejection of two nucleons one would expect that, as the ground states of ^{11}B and ^{11}C are produced approximately 0·81 of the time in the $^{12}C(p, 2p)$ and $^{12}C(p, pn)$ reactions, the relative feeding of states of ^{10}B produced in the bombardment of ^{12}C would be much the same as the relative feeding produced in bombardment of ^{11}B. From Table 2 one sees that this is definitely not so, implying that other processes must also contribute, for example the interaction of the incident proton with two-nucleon correlations in the nucleus.

§ 6. DISCUSSION OF INELASTIC SCATTERING REACTIONS

This work also provides some inelastic scattering cross sections which would be hard to measure otherwise. It is easy to show that the matrix elements determining radiative transition rates of electric multipole transitions are approximately the same as the direct interaction inelastic scattering matrix elements for these transitions. For radiative transitions the decay rate is given by

$$T = \frac{8\pi(l+1)}{l[(2l+1)!!]}\frac{1}{\hbar}\left(\frac{E\gamma}{\hbar c}\right)^{2l+1}\frac{|\langle I_f||M(l)||I_1\rangle|^2}{2I_1+1}$$

while the differential cross section for inelastic scattering for small momentum transfer in the plane-wave approximation is

$$\frac{d\sigma}{d\Omega}=\frac{k_{\mathrm{f}}}{k_{\mathrm{i}}}\left(|M_0|^2+\lambda|M_1|^2\right)\left[\frac{(q)l}{(2l+1)!!}\right]^2(2l+1)^{-1}\frac{|\langle I_{\mathrm{f}}||M(l)||I_{\mathrm{i}}\rangle|^2}{2I_{\mathrm{i}}+1}$$

where $\langle I_{\mathrm{f}}||M(l)||I_{\mathrm{i}}\rangle$ is the reduced matrix element for the transition from state of spin I_{i} to state of spin I_{f} corresponding to the interaction operator

$$M(l,\mu)=\sum_k r_k{}^l Y_{l\mu}(\theta_k,\phi_k),$$

the summation being over protons for the radiative decay and over all nucleons for the inelastic scattering (one presumes this difference is unimportant in the 1p-shell). M_0, M_1 are the matrix elements of the nucleon–nucleon interaction corresponding to no-spin–flip and spin–flip respectively and λ is the ratio of the nuclear spin–flip and no-spin–flip matrix elements (Kerman, McManus and Thaler 1959). $\mathbf{q}=\mathbf{k}_{\mathrm{i}}-\mathbf{k}_{\mathrm{f}}$ is the momentum transfer in the inelastic scattering.

One can attempt to relate these matrix elements quantitatively, as has been done by Squires (1958 b) who showed that the matrix element for exciting the 4·43 Mev state of ^{12}C in the ^{12}C(p, p′) reaction is the same as the radiative matrix element determined by Coulomb excitation (Morpurgo 1956) but to do this the amount of calculation is considerable. Here we attempt a simpler analysis taking ratios of inelastic scattering cross sections to equal the corresponding ratios of radiative decay rates. We can expect this might work if we choose pairs of transitions of the same multipolarity, where the angular distributions are closely similar, and in the same shell, where the change in cross section is going from the plane-wave approximation to the true distorted-wave theory should be much the same. We follow Wilkinson (1956) in quoting $|M|^2$, the ratio of the experimental decay rate to Weisskopf's extreme single particle result. Thus from the known mean life of the 4·43 Mev state of ^{12}C, corresponding to $|M|^2=1{\cdot}74$ (all the gamma-ray data used here are taken from Ajzenberg-Selove and Lauritsen (1959) except where other references are given), and the inelastic scattering cross sections for exciting the 4·43 Mev state of ^{12}C and the 4·46 Mev state of ^{11}B, we find for the electric quadrupole decay of the ^{11}B state: $|M|^2=4{\cdot}5$. To compare with this we find the rate of electric quadrupole decay of this state from the known rate of decay, which is largely magnetic dipole, and the E2/M1 ratio of the order of 0·05 determined from angular distributions in the ^{7}Li(α,γ) reaction (Jones, Johnson and Wilkinson 1959), finding for the electric quadrupole radiative decay of the 4·46 Mev state of ^{11}B: $|M|^2=6{\cdot}7$. This agreement is remarkable, particularly when one considers the uncertainty in extracting E2/M1 ratios from angular distributions. A similar comparison of the measured lifetimes of the 4·43 Mev state of ^{12}C and the $J=2^+$ state of ^{16}O at 6·92 Mev predicts an inelastic scattering cross section of $2{\cdot}8\pm0{\cdot}85$ mbn for the latter to be compared with the observed 1·5 mbn (Clegg *et al.* 1960, unpublished). Thus one sees that with this naïve method one can apparently, from inelastic scattering cross sections, determine electric multipole radiative widths of states within an acuraccy of a factor or two†. A more refined analysis would be desirable taking into account the absorption of protons in the inelastic scattering, which must cause the inner parts of the nucleus to be weighted less in the inelastic scattering matrix elements than they are in the radiative matrix elements.

---

† A similar relation between inelastic scattering cross sections and radiative transition rates has been noted in the inelastic scattering of 23 Mev protons from medium-weight nuclei (Cohen and Rubin 1958).

We apply this procedure to the electric quadrupole transition from the 2·15 MeV state of ^{10}B to the ground state comparing its excitation with the 4·43 MeV state of ^{12}C, for which both the inelastic scattering cross section and the radiative lifetime are best determined, finding an estimate for the radiative decay of this state of $|M|^2=11$ corresponding to a radiative width of $9{\cdot}7\times10^{-4}$ ev. From the known branching ratios of transitions from this state one then finds radiative widths for the magnetic dipole transitions to the 0·72 and 1·74 MeV states, giving $|M|^2=0{\cdot}66$ for the transition to the 1·74 MeV state and $|M|^2=0{\cdot}02$ for the transition to the 0·72 MeV state, which are very respectable results for magnetic dipole transitions in the 1p-shell (Wilkinson 1956)†. From the known mean life of the radiative transition from the 0·72 MeV state of ^{10}B we estimate a cross section of 0·3 mbn for the excitation of this state in inelastic scattering which does not disagree with our measurements.

The excitation of the 3·95 MeV state of ^{14}N is due to both the monopole and quadrupole matrix elements. The latter presumably contributes most strongly to the total inelastic scattering cross section, as the former will only contribute to the angular distribution at forward angles. Making this assumption the electric quadrupole radiative width of this state corresponds to $|M|^2=0{\cdot}57$.

One sees that inelastic scattering apparently provides a method for picking out these states which make strong electric multipole radiative transitions to the ground state and one can ask what are the particular properties of the states so selected. It is found that these results fit well with a distorted nucleus model of the 1p-shell where states in the rotational band based on the ground state are strongly excited in inelastic scattering while rotational bands based on excited states are not. This model, which is presumably an approximation to the procedures of Kurath and Pičman (1959) and thus an aspect of the intermediate coupling shell model, is described fully elsewhere (Clegg 1961).

ACKNOWLEDGMENTS

We wish to thank B. Rose and all members of the Atomic Energy Research Establishment cyclotron group for their considerable help to us, which it is impossible to detail, and the Director, Atomic Energy Research Establishment, Harwell, for permission to use the cyclotron. We also wish to thank P. S. Fisher and D. J. Rowe for their help in the latter part of this work. Finally we would like to thank Professor D. H. Wilkinson for his encouragement during this investigation.

The Importance of Conservation Conditions in Distorted Wave Calculations

By W. B. SOMERVILLE

Department of Physics, University College, London

Communicated by M. J. Seaton; *MS. received 29th May* 1961

Abstract. Some recent results of Vainstein, using the distorted wave approximation for the 3s–3p transition in electron–sodium atom collisions are modified on the basis of a method introduced by Seaton in 1961 which ensures that the conservation condition is satisfied. The resulting cross sections lie much closer to those obtained by experiment.

In a treatment of a collision process based on an analysis of the motion of the incident particle in terms of its partial wave components, the cross sections for the individual partial waves should satisfy the condition for conservation of flux; any formulation which gives large departures from the conservation condition cannot be expected to give reasonable agreement with experimental results. This matter has recently been discussed by Seaton (1961), and reference is made to his paper for fuller details of the analysis.

For the transition in which an atom is excited from state α to state α', the total cross section is

$$Q(\alpha,\alpha') = \frac{1}{\omega k^2}\sum_{ll'L}(2L+1)\,|T(\alpha lL,\alpha' l'L)|^2, \qquad \ldots\ldots(1)$$

in units of $\pi a_0{}^2$, where ω is the statistical weight of state α, k is the initial wave number of the colliding particle and l and l' its initial and final angular momentum quantum numbers, respectively, and L is the total angular momentum. T is an element of the transmission matrix $\mathbf{T}$, and the conservation condition requires that

$$\sum_{\alpha'\neq\alpha}\ \sum_{l'}\ |T(\alpha lL,\alpha' l'L)|^2 \leqslant 1. \qquad \ldots\ldots(2)$$

For the special case of excitation from an S-state, $\omega = 1$ and $L = l$, and the condition on the lth partial cross section becomes

$$\sum_{\alpha'\neq\alpha}\ \sum_{l'}\ Q(\alpha l,\alpha' l') \leqslant \frac{2l+1}{k^2}, \qquad \ldots\ldots(3)$$

summed over all energetically possible excitations.

Percival (1960) and Seaton (1961) have described in detail two approximations which satisfy the conservation condition, based on the use of the reactance matrix $\mathbf{R}$. If the results of some approximate calculation, ‘approximation I’, which do not necessarily satisfy (3) are given by

$$\mathbf{T}_{\mathrm{I}} = -2i\mathbf{R}, \qquad \ldots\ldots(4)$$

we consider the alternative approximations

$$\mathbf{T}_{\rm II}=\frac{-2i\mathbf{R}}{1-i\mathbf{R}}, \qquad \ldots\ldots(5)$$

$$\mathbf{T}_{\rm III}=1-e^{2i\mathbf{R}}; \qquad \ldots\ldots(6)$$

these yield cross sections which automatically obey (3). If the results $Q_{\rm I}$ already satisfy the conservation condition, the results $Q_{\rm II}$ and $Q_{\rm III}$ are usually only slightly smaller. In cases where conservation is violated in approximation I, approximations II and III should afford better agreement with experiment.

Recently, Vainstein (1960) has reported extensive calculations, using the Born and non-exchange distorted wave approximations for a variety of electron-induced transitions in several atoms and ions. In certain cases, Vainstein provides graphs of the first few partial wave cross sections, which may be examined from the point of view of conservation violation. For the 3s–3p transition in sodium in the distorted wave approximation (the total cross section is reproduced in the Figure), several of the partial wave cross sections do not satisfy the conservation condition; most notably, the spurious maximum at $k^2=0{\cdot}21$ is largely due to the $l\to l'=0\to 1$ cross section, which has a value at this point of about $68\,\pi a_0^2$, whereas condition (3) requires that it should not be greater than $4{\cdot}76\pi a_0^2$.

The results for the first seven partial waves have been modified by introducing approximation II. In this case, considering only coupling between the (3s, l) and (3p, $l\pm 1$) states, the reactance matrix is a 3×3 matrix and Eqns (4) and (5) give the new partial cross section

$$Q_{\rm II}(l\to l')=Q_{\rm I}(l\to l')\left[1+\frac{k^2}{4(2l+1)}\{Q_{\rm I}(l\to l-1)+Q_{\rm I}(l\to l+1)\}\right]^{-2},\ l'=l\pm 1, \qquad \ldots\ldots(7)$$

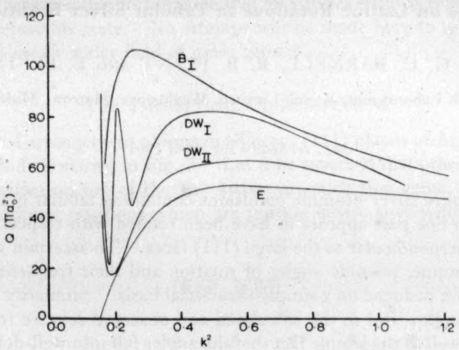
where $Q_{\rm I}$ is Vainstein's result. The new total cross section is obtained from the relation

$$Q_{\rm II}=Q_{\rm I}-\sum_{l=0}^{6}\sum_{l'}\{Q_{\rm I}(l\to l')-Q_{\rm II}(l\to l')\}. \qquad \ldots\ldots(8)$$

The results are presented in the Figure, which contains also Vainstein's results (approximation I) for the total Born and total distorted wave cross sections and the experimental curve of Haft (1933) and Christoph (1935). A substantial improvement has been effected by the introduction of approximation II; there is fairly close agreement with experiment over most of the range and the maximum at $k^2=0{\cdot}21$ has disappeared. The other sharp maximum, just above threshold, persists and is therefore not entirely associated with conservation violation; it is made up of the 1 → 0 and 2 → 1 cross sections only. The presence of this maximum would appear to be in agreement with the measurements of Michels (1931), who reported sharp peaks at threshold for this and other transitions in sodium; however, he obtained vanishing cross sections for energies between these threshold regions for successive excitations, and so his results are generally disregarded (cf. Bates, Fundaminsky, Leech and Massey 1950). A sharp maximum very close to threshold could be consistent with Haft's measured points; more experimental work in the region of threshold is required before a definite conclusion can be reached.

Approximation III, based on Eqn (6), gives in this case results which for all values of k are very close to those of approximation II.

From the work of Salmona and Seaton (1961) on the Bethe cross section for this transition in approximation II, it appears probable that approximation II to the Born cross section will be very similar to that obtained using distorted waves, but apparently without the initial maximum.



Cross sections for the Na(3s–3p) transition. B_I and DW_I are Vainstein's results using the Born and distorted wave approximations respectively, DW_{II} is approximation II to the distorted wave cross section and E is the experimental curve. k is in atomic units, so that $13{\cdot}6k^2$ is the incident energy in electron volts.

ACKNOWLEDGMENTS

I am indebted to Dr. M. J. Seaton for valuable discussions. Thanks are due to Dr. Vainstein for sending us a copy of his paper in advance of publication.

This work is supported by the Atomic Energy Research Establishment, Harwell, and permission to publish is gratefully acknowledged.

Observations on Lattice Rotations in Tabular Silver Bromide Grains

By G. C. FARNELL, R. B. FLINT and E. PITTS

Research Laboratories, Kodak Limited, Wealdstone, Harrow, Middlesex

MS. received 13*th April* 1961

Abstract. In pure silver bromide emulsions containing tabular grains some are found in which one part appears to have been rotated with respect to the other about an axis perpendicular to the large (111) faces. To ascertain whether such grains were genuine, possible angles of rotation and their frequency relative to one another were deduced on a simple theoretical basis. Similarity in calculated and observed angles, and in the calculated and observed relative frequencies of occurrence, as well as the simple fact that the angles fall into well-defined groups, show without doubt that such grains are not artefacts but special forms of misorientation. It is shown that the distribution of photolytic silver is profoundly different in such grains from that observed in normal grains.

---

§ 1. Introduction

In the course of photographic studies involving silver bromide emulsions with tabular grains, occasional instances have been observed where one half of a grain appeared to be rotated with respect to the other half about an axis perpendicular to a large (111) face. A carbon replica electron micrograph of such a grain is shown in Fig. 1 (Plate I). Until recently there had been some tendency to dismiss such entities as being produced simply by the chance overlapping of one grain by another, perhaps occurring during specimen preparation, though it must be admitted that their reality was strongly suggested by the observation of Evans and Mitchell (1955) that the fraction of such grains could be deliberately increased by the use of turbulent conditions in dilution of saturated ammoniacal solutions of silver bromide. It became clear, however, that there was a considerable similarity in the angles of rotation between the two halves among many specimens encountered, and that the two parts were usually similar in size, as though they were not the result of chance but represented single grains. A systematic study of such entities was therefore made with the aim of confirming this point.

The first step was to deduce by a simple theoretical analysis the possible angles of rotation, about an axis perpendicular to the (111) plane of silver bromide, which could represent metastable states. The ratio of the number of ions in normal lattice positions following rotation to the total number of ions in the (111) plane was also deduced for the various possible angles. It was argued that this ratio should indicate the relative frequencies of occurrence of the various angles and in turn provide a further test of whether the observed entities were genuine single grains. Micrographs of a number of such grains were then made from which the apparent angles of rotation could be determined. These angles were then compared in value and frequency with those expected on theoretical grounds. In this way it was possible to conclude that all entities studied represented single grains in a metastable state. No attempt will be made here to relate the observations to the much wider field of grain growth.

§ 2. THEORETICAL CONSIDERATIONS

The normal arrangement of ions in adjacent (111) planes of Ag^+ and Br^- ions in silver bromide is shown in Fig. 2. Let it be assumed that other arrangements of the Ag^+ lattice on top of the Br^- lattice are such that some, at least, of the former ions occupy positions which are normal lattice sites with respect to the

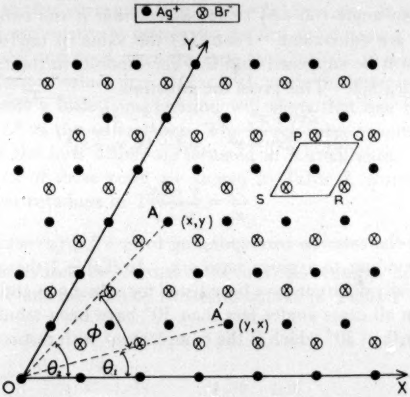

Fig. 2. Diagram showing the normal arrangement of the Ag^+ ion lattice with respect to the Br^- ion lattice in adjacent (111) planes of silver bromide, and illustrating the simple theory whereby permissible angles of rotation may be deduced.

Br^- ions. Such an arrangement would be obtained if for example the plane of ions were rotated about O until the ion labelled A coincided with the site A′. This basic argument is identical with that proposed by Wilman (1951) in his discussion of rotational slip, while our method of calculation broadly resembles his. Since there are certain subtleties in the derivation of possible angles and the associated ratios of ions in normal lattice positions to the total number of ions in the plane of rotation, it was considered worth while to present our calculations and conclusions therefrom in some detail.

All of the arrangements of the Ag^+ ion lattice on the Br^- ion lattice may be derived systematically by choosing any site and performing a rotation until it again coincides exactly with a previous lattice position. If we use coordinates as shown in Fig. 2 and suppose that the coordinates of A are in general (x, y)

then the rotation is such that this site finally occupies the coordinate position (y, x). Elementary geometry shows that

$$\tan\Theta_1 = \frac{x\sqrt{3}}{2y+x} \text{ and } \tan\Theta_2 = \frac{y\sqrt{3}}{2x+y}.$$

Hence the angle of rotation ϕ, i.e. $\Theta_2 - \Theta_1$ is given by the expression

$$\tan\phi = \frac{(y^2-x^2)\sqrt{3}}{y^2+4yx+x^2}. \qquad \ldots\ldots(1)$$

By dividing both the numerator and denominator of (1) by x^2, it is obvious that $\tan\phi$ depends on the ratio y/x, and hence rotations will only differ when y and x are relatively prime.

There is a further reason which makes many of the rotations calculated from (1) essentially equivalent. Suppose in Fig. 2 that the y axis is rotated towards the x axis through an angle (corresponding to the rotation A to A′). An essentially equivalent rotation would be obtained by turning the x axis towards the y axis through an angle $(60-\phi)°$. It is clear that if the two rotations add to make 60°, they are equivalent. From (1) the value of $\tan(60-\phi)°$ is readily obtained, and let it be supposed that this corresponds to the rotation of (x_1, y_1) to the position (y_1, x_1). This gives the equation

$$\frac{2xy+x^2}{2y^2+2xy-x^2} = \frac{y_1^2-x_1^2}{y_1^2+4x_1y_1+x_1^2},$$

from which

$$\frac{y_1}{x_1} = \frac{y+2x}{y-x}.$$

This shows that the rotation corresponding to $(y+2x)/(y-x)$ is equivalent to a rotation corresponding to a given ratio y/x. In Table 1 the angles of rotation which are essentially different have been listed for values of x and y up to 12 and 11 respectively. In all cases angles less than 30° have been tabulated, rather than the angle greater than 30° which is the complement with respect to 60°.

Table 1. Calculated Permissible Angles of Rotation in the (111) Plane

$y\backslash x$	1	2	3	4	5	6	7	8	9	10	11	12
1		21° 47′

6							5° 5′				19° 16′	
7								4° 24′	8° 15′	11° 38′	14° 37′	17° 14′
8									3° 54′		10° 25′	
9										3° 29′	6° 37′	
10											3° 9′	
11												2° 53′

After any rotation some of the ions will be in normal lattice sites, while the remainder are displaced. It is reasonable to suppose that at large angles, at least, the ratio of ions in normal sites to the total number will provide some indication of the relative frequency of occurrence of various angles. Consideration of the threefold symmetry of the lattice shows that after a rotation such that A moves to A′, the ions at the vertices of a regular hexagon of which OA′ is one side will be in correct positions, together with the ion at the centre of this hexagon. An ion at each vertex is shared between three such hexagons, and hence the total number of ions in their correct positions is $6(\frac{1}{3})+1$, i.e. 3 for each hexagon. The number of ions in the hexagon is found by dividing its area by the area associated with each ion, namely PQRS. In terms of the unit length PQ, this area is $\sqrt{3}/2$ and if OA is L units of PQ, the area of the large hexagon is $3L^2\sqrt{3}/2$. There are thus $3L^2$ ions in all, 3 of which are in their correct positions. In terms of these coordinates (x, y) of A, the ratio

$$\frac{\text{ions in correct lattice positions}}{\text{total number of ions}} = \frac{1}{L^2} = \frac{1}{y^2+xy+x^2}. \qquad \ldots\ldots(3)$$

In using this result the equivalence of many rotations corresponding to apparently different choices of y and x must be remembered. Rotations differ only when y and x are relatively prime; if they possess a common factor this must be removed before (3) is used. Further, the rotation corresponding to y/x is equivalent to that corresponding to $(y+2x)/(y-x)$. It may happen that although y and x are relatively prime, $y+2x$ and $y-x$ have a common factor. For example, if $y=7$ and $x=4$, then the ratio $(y+2x)/(y-x)$ is equivalent to the ratio 5 : 1. The former values give $1/L^2=1/93$, while the latter gives $1/L^2=1/31$.

In all such cases a little consideration will show that one must choose the smaller value of L^2 as the correct one. The larger value results from counting only one third of the ions which are situated at normal sites. Values of $1/L^2$ with account taken of these rules are shown in Table 2, corresponding to the essentially different rotations in Table 1.

Table 2. Ratio of Ions in Normal Sites to Total Number of Ions in (111) Plane for Lattice Rotations shown in Table 1

$y \backslash x$	1	2	3	4	5	6	7	8	9	10	11	12
1		1:7										
2			1:19		1:13							
3				1:37	1:49		1:79	1:97				
4					1:61		1:31		1:133			
5						1:91	1:109	1:43	1:151		1:67	1:229
6							1:127				1:223	
7								1:169	1:193	1:73	1:247	1:277
8									1:217		1:91	
9										1:271	1:301	
10											1:331	
11												1:397

Taking the view that the frequency with which a rotation occurs decreases with decreasing ratio of ions in correct lattice positions to the total number of ions, we find that the angles most likely to be encountered in order of decreasing frequency will be 21° 47′, 27° 48′ and 13° 10′.

§ 3. OBSERVATIONS AND DISCUSSION

The majority of observations were made using an electron microscope (Metropolitan Vickers EM-2). Specimens of the emulsion were first treated with enzyme (Gelatase 'C'), to remove the gelatin, and then placed in a vacuum chamber. After gold–palladium alloy had been evaporated at an angle of 45°

on to the slide carrying the grains, carbon was evaporated normal to the surface of the specimen. Photomicrographs prepared in previous work were also studied for any occurrence of apparently rotated grains. Many thousands of grains from silver bromide emulsions of tabular grain shape were scanned in the electron microscope, and records made of any grain which appeared to represent a rotation of the two halves.

Table 3. Summary of Measured Angles of Rotation

All emulsions were of the neutral pure silver bromide type

† Photomicrographs. The remainder were on electron micrographs.

(1) Emulsion number; (2) mean grain size (μ^2); (3) specimen; (4) number of angles measured; (5) average value of rotation.

The first emulsion specifically examined (No. 4 in Table 3) had a mean grain projective area of the order of $2{\cdot}0\mu^2$. Approximately one grain in 10^5 appeared to possess a rotation. When it did occur it took the form of two hexagons rotated with respect to one another with their centres on the same axis. Fig. 1 is an example of a rotation found in this emulsion. Certain other grains were found in this emulsion growing out of the rotated state to form grains of less distinctive shape. An example of this form is shown in Fig. 3 (Plate I).

This growth out of the rotated state suggested that rotations might be found more frequently in an emulsion of smaller grain size. Examinations were therefore made of a second emulsion (No. 3 in Table 3) having a mean grain projective area of $1{\cdot}0\mu^2$. Here about one grain in 2×10^4 was found to exhibit lattice rotations, but the effect differed in character to that observed in the previous emulsion. The general form was of a triangle rotated with respect to a hexagon, again the centres being on a common axis. An example of a grain from this emulsion exhibiting lattice rotation is shown in Fig. 4 (Plate II).

Angles of rotation were measured on all examples encountered of this effect, and are summarized in Table 3, the smaller of the two possible angles being measured. Individual angles were determined to within $\pm \frac{1}{2}^{\circ}$ on electron micrographs but on light micrographs it was usually only possible to determine angles to within $\pm 1^{\circ}$.

The mean value of angles around 22° (11 in all) is 21° 49′ which compares well with the theoretical value for $(x=2, y=1)$ of 21° 47′. The mean of those near 28° (5 in all) is 27° 38′, which is in good agreement with the theoretical value of 27° 48′ for $(x=5, y=2)$. From the information presented in Table 2 this would be expected to be the next most frequently occurring angle of rotation. On the basis of the simple theory the angle of third highest frequency should be that of 13° 10′ for $(x=3, y=2)$ and indeed 3 values close to this, having a mean of 13° 23′ were observed. This accounts for all but two angles having a mean value of 15° 30′. This is close to the theoretical value of 15° 11′ for $(x=8, y=5)$, but in view of the fact that the two experimental values were obtained from light micrographs another possibility is a correspondence to 16° 25′ for $(x=5, y=3)$. Uncertainties in experimental determination are considered to be responsible for the small deviations from theoretical values for the angles of rotation in the other comparisons based mainly on electron micrographs. From the close grouping of the angles of rotation, the agreement between calculated and observed values for rotation and the reasonable consistency between frequency of occurrence and that expected from the value of the ratio for ions in normal lattice positions to the total number of ions in the plane of rotation, there can be no doubt that the entities examined represent single grains.

In the course of recent examinations of print-out silver distribution in emulsion grains of the type examined in this work, it has been found that in grains having a lattice rotation there is a marked difference in the manner in which photolytic silver is deposited. In the usual type of grain heavy print-out exposure produces a distribution of small specks on an internal (111) plane. In a grain possessing lattice rotations, however, far larger masses of silver are formed, and associated mounds of halide are extruded, while a system of etch pits due to halogen evolution appears around the mounds. An ordinary silver bromide grain and one possessing a lattice rotation which were given equal print-out exposures in the absence of bulk gelatin are compared in Figs 5 and 6 (Plate III). This difference in response to print-out exposure provides further evidence that the grains under consideration are not simply chance combinations of two ordinary tabular silver bromide grains. The significance of the protrusions of silver halide produced under these conditions of photolysis had been discussed recently by Hamilton and Brady (1960).

§ 4. CONCLUSIONS

(*a*) Grains in tabular silver bromide emulsions in which one half appears rotated with respect to the other half about an axis perpendicular to their (111) faces are single grains and not a consequence of overlapping of one grain by another. The proportion obviously possessing such rotations in the emulsions examined is quite small (1 in 10^4–10^5).

(*b*) On the supposition that stable lattice arrangement other than the normal require some ions to be in their normal positions, it is possible to account for all the observed angles with quite high precision. Moreover the relative frequency of occurrence of the various possible angles of rotation is substantially that expected from this concept.

(*c*) The inherent instability of grains possessing these lattice rotations is demonstrated by the observation of a number of grains in course of transition to other tabular forms.

(*d*) The presence of a lattice rotation in a grain profoundly modifies the distribution of photolytic silver.

Time Resolved Absorption Studies in a Shock Tube: A New Band System of BaO

BY W. H. PARKINSON†

Department of Chemical Engineering, Imperial College, London

Communicated by A. G. Gaydon; *MS. received 24th April* 1961

Abstract. Time resolved absorption studies have been carried out through the hot gas behind reflected shock waves during their interaction with powdered barium compounds. A capillary-type flash tube with a short pulse duration and high brightness temperature was used as the background source.

A new system of BaO, probably resulting from a B(?$^1\Pi$)–X$^1\Sigma$ transition, has been found in absorption, and vibrationally analysed. The constants derived for the upper state of the system were $T_e = 32\,866{\cdot}4\ \mathrm{cm}^{-1}$, $\omega_e = 488\ \mathrm{cm}^{-1}$ and $\omega_e x_e = 3{\cdot}6\ \mathrm{cm}^{-1}$.

A band of zinc oxide possibly due to a polyatomic emitter has been recorded in emission from the luminosity produced during the shock excitation of powdered zinc compounds.

---

§ 1. INTRODUCTION

SPECTROSCOPIC emission studies of the luminosity which results during the shock excitation of powdered solids have shown that the shock tube is particularly suitable as a laboratory source of high temperature atomic and molecular spectra (Nicholls and Parkinson 1957). In addition, absorption spectra similar to those observed in some cool stars have been recorded during the interaction of shock waves with astrophysically important metallic oxides (Parkinson and Nicholls 1959). A further investigation of the production of diatomic and polyatomic molecular spectra has been made in emission and in absorption. Time resolved absorption spectra were taken through the gas behind reflected shock waves using the continuum from a high intensity, short duration, flash tube. The absorption experiments were carried out on a number of solid barium compounds and a new barium oxide system was found. Emission studies were also made on the luminosity resulting from shock excited hydroxide and oxide compounds of copper, magnesium, barium, iron, manganese and zinc.

This paper reports the vibrational analysis of the new band system of barium oxide and discusses a band of zinc oxide which is due possibly to a polyatomic emitter resembling those found with the alkaline earths.

§ 2. EXPERIMENTAL

The shock waves were produced in a conventional shock tube consisting of a three-foot copper driving section separated by an aluminium diaphragm from a nine-foot copper low pressure section. The low pressure section or channel was closed at one end with a short section, 1½ feet in length, which held two fused quartz windows through which the luminosity behind the reflected shock waves was observed transverse to the flow direction.

† Now at Harvard College Observatory, Cambridge, Massachusetts.

The aluminium diaphragm was broken by the excess pressure of the hydrogen driver gas. Argon was normally used as the carrier gas but a small percentage of oxygen or hydrogen was added to the argon in particular experiments.

The powdered materials were positioned in the channel of the shock tube about 12 in. before the closed end. A small sample was placed either on a steel platform protruding across the diameter of the channel or on a ½ in. wide strip of 'Kleenex' tissue clamped in the channel union near the window. The impurities in the spectra resulting from the 'Kleenex' consisted only of sodium and calcium resonance lines but the intensity of the important features in the spectrum was much higher than with the platform mounting.

In addition to emission studies, absorption spectra were taken through the hot gas behind the reflected shock waves at various times. The background continuum was produced from a high current density quartz-capillary flash tube filled with 10 cm pressure of tank argon. The flash tube was connected in series with two 1 μF condensers at 7 kv and a hydrogen thyratron. It was fired by an amplified pulse arriving at the thyratron grid from an amplifier and variable delay circuit. The initiating pulse was produced from a platinum heat transfer gauge in the end of the shock tube.

The light pulse from the flash tube falls to one half of its peak intensity in about 5 μsec whereas the light from the shock wave lasts for approximately 1500 μsec. In order to obtain useful absorption spectra it was necessary to keep the light from the shock wave from masking the absorption. This was accomplished by using a fuse-fired shutter similar to that described by Wurster (1957). The shutter, which consisted of a piece of black electrical tape over a blast channel, is opened (or closed) by the blast from an exploding 5 amp lead fuse strip. The fuse strip was in series with a hydrogen thyratron and a 0·5 μF condenser at 5 kv. The shutter opened or closed in 35 ± 5 μsec.

The pulse from the heat transfer gauge in the shock tube was divided and delayed so that one pulse fired the flash tube while the other pulse fired the shutter. Absorption pictures could be taken from 0 to 200 μsec after the reflection of the shock wave. An additional 0 to 50 μsec delay was used with the main delay to allow for the opening or closing time of the shutter.

The spectra from the shock tube were recorded by a medium quartz prism spectrograph or a 2 metre concave grating spectrograph with a reciprocal dispersion of about 5 Å/mm. The arc spectra of barium and zinc were recorded by a 2 metre Littrow-mounted plane grating with a reciprocal dispersion of 0·8 Å/mm in the second order. Ilford Zenith and H.P.S. plates were used.

§ 3. Results

3.1. *Barium Oxide in Absorption*

Absorption spectra of shocked barium peroxide were taken through the gas behind the reflected shock wave at 100 μsec intervals over a range of incident Mach numbers from 4 to 6 in argon at 40–60 mm pressure. Plates I *a* to I *f* show spectra recorded at times 100, 200, 400, 800 and 1000 μsec during the flow. From this plate it can be seen that for about the first 200 μsec the spectra consisted of atomic lines of Ba I, Ba II and impurity lines of Ca I, Na I, Cu I and Al I in absorption. After 200 μsec the bands of the $A^1\Sigma$–$X^1\Sigma$ system of BaO (Mahanti 1934), the polyatomic band of BaOH (4870, 5120 Å) and Ba_2O_2 (?) (4800, 5020, 5500 Å) and a new band system in the 2900–3800 Å region appeared with the atomic lines. The molecular absorption increased until it reached maximum intensity at about 1000 μsec with the intensity of atomic lines then reduced.

Plates I *g* and I *i* show absorption spectra obtained with $BaCl_2$ and BaO_2 respectively in the shock tube. The bands in the 2900–3800 Å region and the $A^1\Sigma$–$X^1\Sigma$ system were recorded only when both barium and oxygen were present.

The new bands appeared weakly in emission in the shock tube and also were photographed after a 30 minute exposure using the outer 'flame' from barium peroxide or barium nitrate on the poles of a carbon arc (Plate I *h*).

The wave number data for the band heads are shown in the Deslandres table (Table 1). Table 2 lists the wavelength and eye-estimated intensities of the band heads.

3344·5	7	1, 5	2922·6	7	5, 1
3320·0	4	0, 4			

Weak bands were also observed at 2900, 2866, 2776, 2765, 2738, 2711, 2686, 2638 and 2615 Å but the diffuse nature of the bands and the presence of overlapping bands of the O_2 Schumann–Runge system in absorption did not permit the use of these heads in the vibrational analysis. The uncertainty in precisely locating the relatively weak heads of the bands of this system made the assignment of the vibrational quantum number difficult. The ground state of the system however appeared to be the same ground state as in the transition $A^1\Sigma$–$X^1\Sigma$ which results in the orange bands of BaO. The vibrational constants from the array are shown in Table 3 together with the constants of the $A^1\Sigma$–$X^1\Sigma$ system of BaO (Lagerqvist, Lind and Barrow 1950).

Table 3

State	T_e	ω_e	$\omega_e x_e$	
B($^1\Pi$)	32866·4	488	3·6	(present work) band head
A$^1\Sigma$	16807·7	498·8	1·5	band origin
X$^1\Sigma$	0	670·2	1·95	(present work) band head
		669·8	2·05	band origin

The bands of the B–X$^1\Sigma$ system were investigated at a reciprocal dispersion of 0·8 Å/mm on a 2 metre plane grating but the low intensity of the bands and background radiation did not permit a rotation analysis. The rotational line distribution did appear however to consist of at least three branches. It is suggested therefore that the system comes from transitions between an excited $^1\Pi$ state and the X$^1\Sigma$ ground state.

3.2. *Polyatomic Spectra in Emission*

The diatomic molecular spectra of calcium, magnesium, strontium and barium oxides (which are observed in arcs and flames containing salts of these compounds) are well known in emission and have been analysed for some time. In addition to their diatomic spectra, however, there has been considerable work done on the polyatomic oxides and hydroxide spectra.

Gaydon and co-workers have studied the spectra of CaOH, CaOD (Gaydon 1955), MgOH, MgOD (Charton and Gaydon 1956), SrOH, SrOD, BaOH and BaOD (Pesic and Gaydon 1959) excited in a 'vacuum' arc in water and heavy water vapour. In addition, when salts of the alkaline earths were excited in an arc in air, complex systems were observed and it has been suggested that these may be due to polyatomic oxides.

The correspondence in spectral region of the polyatomic hydroxide and oxide spectra of these metals with their diatomic fluoride spectra has been pointed out by Charton and Gaydon (1956) and by James and Sugden (1955). These researches have also reported the excitation of hydroxide bands of copper and manganese in oxygen–hydrogen flames.

Emission spectra were recorded from the luminosity produced during the interaction of shock waves with powdered $Cu(OH)_2$, MgO, $Mg(OH)_2$, BaO_2, $Ba(OH)_2$, Fe, $Fe(OH)_2$, Mn, $Mn(OH)_2$ and Zn, ZnO and $Zn(OH)_2$.

The hydroxide spectra of copper, magnesium, barium, iron and manganese were obtained as well as the polyatomic oxide spectra of magnesium and barium.

When powdered zinc oxide was subjected to shock-excitation at primary Mach numbers from 4 to 6 in argon, a narrow, red degraded band was observed at 3435 Å. The addition of 5–10% oxygen to the argon, in the same range of Mach numbers, increased the intensity of the band. The intensity decreased with a corresponding addition of hydrogen but the bands of ZnH at 4301 Å, 4240 Å etc. appeared.

Egerton and Rudrakanchana (1954) have reported a weak red-degraded band at this wavelength in the spectrum of zinc dimethyl burning as a diffusion flame.

Spectra taken in the 'flame' of a zinc arc in air gave the same band with considerable background radiation. Plate I *i* shows the band recorded in the second order of a Littrow-mounted plane grating.

Only one band was obtained from shock excited zinc oxide. Since oxygen was required to produce the band in all of the sources this appears to rule out Zn_2 as the emitter. The unresolved rotational structure suggested either a diatomic oxide molecule of ZnO with high multiplicity or a polyatomic oxide of the metal. One would expect however to be able to resolve the rotational structure of a band ZnO of triplet multiplicity, since other diatomic molecules of similar reduced mass and multiplicity have been well analysed. It is suggested therefore that the band at 3435 Å is due to a polyatomic zinc oxide which is similar to the polyatomic oxide spectrum of the alkaline earth metals (Charton and Gaydon 1956).

§ 4. DISCUSSION

The vibrational constants of the ground state of the new system corresponded to those of the ground state of the $A^1\Sigma$–$X^1\Sigma$ BaO system (Herzberg 1950). It is possible that the present system arises through a $^1\Sigma$–$^1\Sigma$ transition but a $^1\Pi$–$^1\Sigma$ transition seems more probable in view of the complex rotational structure. In either case an intercombination system is possible through a transition to the $A^1\Sigma$ state. One would expect a red degraded band system in the region of 6280 Å. The spectrum in this region however was masked with the BaO $A^1\Sigma$–$X^1\Sigma$ system and it was not possible to identify an intercombination system.

The time resolved absorption spectra showed that molecular absorption was not present over the full flow time but began at about 200 μsec and increased until reaching a maximum 1000 μsec after the incident shock wave had been reflected. The atomic absorption however began early in the first 50 μsec but after 200 μsec was greatly reduced with the molecular absorption at a maximum. Earlier spectroscopic observation in emission and microscopic and x-ray powder photographs of the shocked powder samples (Parkinson and Nicholls 1959) indicated a high concentration of atoms early in the interaction between the shock wave and the powder particles. It was suggested that the atoms were either the result of severe atomic ablation or dissociation of diatomic molecules from the original powdered particles. The present observation supports these suggestions.

ACKNOWLEDGMENTS

The author would like to express his gratitude to Dr. A. G. Gaydon for his many helpful discussions and suggestions and for providing the experimental facilities for these investigations. Particular appreciation goes to Dr. Ian R. Hurle for his help in constructing the flash tube and associated electronics.

The author is also very grateful to the National Research Council of Canada for the award of a post-doctoral overseas fellowship.

The Dependence of Capture Rate on Electric Field and the Possibility of Negative Resistance in Semiconductors

BY B. K. RIDLEY AND T. B. WATKINS

Mullard Research Laboratories, Salfords, nr. Redhill, Surrey

MS. received 9th May 1961

Abstract. It is pointed out that the rate of capture of electrons and holes by charged centres should depend markedly on electric field strength when this is high enough to produce hot electrons. In particular the capture rate for an attractive centre should decrease while the rate for a repulsive centre should increase as the field rises. Each effect will alter the steady state density of carriers. For the case of repulsive centres a decrease in carrier density will occur and the possibility of using this phenomenon to produce a negative resistance state in the semiconductor is discussed. Suitably compensated n-type germanium crystals containing copper, nickel or gold appear to have the requisite properties for exhibiting negative resistance at temperatures low enough for the thermal ionization rate of the centre to be small. It is pointed out that the long time constants involved in the process preclude the use of short pulse fields.

---

§ 1. INTRODUCTION

THE rate of capture of an electron (or hole) by an impurity centre in a semiconductor is generally dependent on the energy of the electron. Since an electric field can increase the energy of an electron the capture rates must generally depend on the electric field strength. As a consequence the steady state density of electrons can change as the field is increased (Conwell 1961, Ridley and Watkins, to be published) and in some cases this effect may give rise to negative resistance effects (Ridley and Watkins 1961), a necessary condition being that the capture rate must increase with field (leading to de-ionization). Such an increase in capture rate with field ought to occur when the traps present a repulsive Coulomb force to the electron so that the electron must surmount a potential barrier before capture is possible. An increase of the field allows more electrons to have the necessary energy to surmount the barrier and hence the capture rate increases. If the lattice temperature remains constant and no impact ionization occurs the generation rate does not change with field and the net result is a drop in electron density. For copper, nickel and gold in germanium, barriers up to 0·2 ev have been measured (Battey and Baum 1955, Shulman and Wyluda 1956, Johnston and Levinstein 1960).

To obtain an idea of the order of magnitudes involved in the change of capture cross section for charged impurities the following argument may be followed. For low energy electrons the charge on an impurity centre has a great effect, e.g. impurity scattering becomes important at low temperatures. As the electron energy rises the effect of the charge lessens and in the limit the centre appears to the electron virtually as a neutral centre. For repulsive centres the capture cross section for thermal electrons is of the order of 10^{-22} cm^2 and for attractive centres it can be as high as 10^{-12} cm^2, while for neutral centres it is about 10^{-17} cm^2. Changes in cross section with mean electron velocity over five orders of magnitude are therefore possible. The actual maximum change will, of course, depend on the structure of the particular centre and also on the temperature, but it is clear that large changes of carrier density can occur.

§ 2. CAPTURE RATE FOR REPULSIVE CENTRE

Consider the case of an extrinsic n-type semiconductor in which the extrinsic electrons derive from thermal ionization of an impurity level in the upper half of the forbidden band. We shall assume that the impurity after losing an electron to the conduction band is nevertheless negatively charged. Many of the deep level acceptors in n-type germanium behave in this way (see, for example, Woodbury and Tyler 1957). We shall also assume that the lattice temperature is low enough to make all effective thermal generation rates other than rate of generation from the impurity level so low that they can be neglected. Consequently all other effective capture rates can be neglected since these are equal to the effective thermal generation rates at equilibrium. The density of electrons in the conduction band is then governed solely by the rates of transition associated with the impurity level. The rate of increase of electron density is then

$$\frac{dn}{dt} = gN^- - BnN^0 \qquad \ldots\ldots(1)$$

where n is the density of electrons in the conduction band, N^- is the density of filled traps, N^0 is the density of unfilled traps, and g and B are the thermal ionization and capture rates respectively averaged over the electron distribution and are, in general, field dependent.

Denoting thermal equilibrium (low field) values by suffix zero we have

$$g_0N_0^- - B_0n_0N_0^0 = 0$$

from which

$$g_0 = B_0n_1$$

where

$$n_1 = 2\left(\frac{2\pi m^* kT}{h^2}\right)^{3/2} \exp\left(-\frac{E_t}{kT}\right)$$

and E_t is the trap activation energy measured from the conduction band edge. The generation rate depends solely on the lattice temperature. Assuming this to be constant for all fields we have at the steady state

$$B_0n_1N^- - BnN^0 = 0. \qquad \ldots\ldots(2)$$

If Δn is the increase in electron density due to the field, we obtain, by substituting $n = n_0 + \Delta n$, $N^- = N_0^- - \Delta n$, and $N^0 = N_0^0 + \Delta n$

$$\Delta n = \tfrac{1}{2}[\{(N_0^0 + n_0 + \gamma n_1)^2 - 4n_0N_0^0(1-\gamma)\}^{1/2} - (N_0^0 + n_0 + \gamma n_1)] \qquad \ldots\ldots(3)$$

where $\gamma = B_0/B$. For a repulsive centre $\gamma \leqslant 1$.

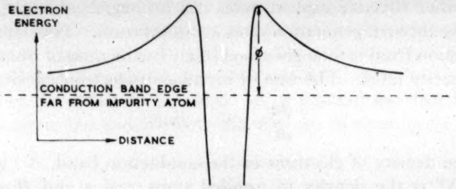
Eqn (3) can be simplified for the special case when the doping is such that at absolute zero the density of occupied levels is less than or of the same order as the density of unoccupied levels. This means that at zero temperature the Fermi level lies on or below the impurity level but never above, so that at all temperatures a substantial density of unoccupied levels is available for electron capture. This, in fact, is the usual degree of compensation attainable in practice. At a temperature when only about 10% of the electrons are in the conduction band we can put $n_0 \lesssim n_1 \ll N_0{}^0$. Since $\gamma \leqslant 1$, γn_1 will also be negligible and Eqn (3) simplifies to give

$$\Delta n = -n_0(1-\gamma). \qquad \ldots\ldots(4)$$

Since the empty centre is negatively charged the density of electrons in the immediate vicinity of the trap will be different from the average density by a factor $\exp(-\phi/kT)$ at thermal equilibrium (Pekar 1950), neglecting any density of states contribution. ϕ is the potential barrier presented to the electrons (see Figure). If β_0 is the capture rate of thermal electrons which have surmounted the barrier the measured capture rate B_0 is given by

$$B_0 = \beta_0 e^{-\phi/kT}.$$

At high fields the electron distribution function changes from the Maxwellian f_0 to f_F, and $B = \beta f_F(\phi)$ where β, in general, is a function of the field.



Schematic diagram of potential around a negatively charged impurity centre.

§ 3. Negative Resistance

The condition for negative resistance when electrons change from one state with mobility μ_a to another state with mobility μ_b is (Ridley and Watkins 1961)

$$\left[\left(\frac{\mu_a - \mu_b}{\mu_a + f\mu_b}\right)\left(-\frac{F}{n_a}\frac{dn_a}{dF}\right) - p\right] > 1, \qquad \ldots\ldots(5)$$

where n_a is the density of electrons in the first state, F is the electric field, f is n_b/n_a where n_b is the density of electrons in the second state, and p arises from the assumption that the mobilities are proportional to F^p.

When the second state is a localized state, μ_b is zero, provided impurity conduction is negligible, and the first bracket in the inequality is unity. With phonon scattering predominant, p is negative, thus negative resistance is possible if the field induces de-ionization.

The condition when Eqn (4) is applicable becomes, with $n_a = n_0 + \Delta n$,

$$\frac{F}{B}\frac{dB}{dF} - p > 1. \qquad \ldots\ldots(6)$$

In the most demanding case for lattice scattering, that is, when $p = -\frac{1}{2}$, the above condition is satisfied if the capture rate increases more rapidly than the square root of the field (i.e. $(F/B)\,dB/dF > \frac{1}{2}$)—not a very stringent condition.

For potential barriers greater than kT the term which varies most rapidly with field is likely to be the distribution function $f_F(\phi)$. In the region of field strengths where $p = -\frac{1}{2}$ to a reasonable approximation the distribution function f_F is of the form (Yamashita and Watanabe 1954) $f_F = \exp\{-a(\epsilon/kT_e)^2\}$, where ϵ is electron energy, the electron temperature T_e is proportional to field strength, and $\frac{3}{2}kT_e$ is defined as the mean kinetic energy of the electrons thus making $a = 0{\cdot}243$. Condition (6) becomes, with $T_e = \text{const.} \times F$ and $B = \beta_0 \exp\{-a(\phi/kT_e)^2\}$,

$$\frac{\phi}{kT_e} > 1{\cdot}01. \qquad \ldots\ldots(7)$$

Since the mean energy of the hot electrons is roughly three or four times the thermal equilibrium mean energy in this region an approximate condition is $\phi/kT > 5$. For trap activation energies of the order of 0·1 ev the condition that thermal generation is not too high to make Eqn (4) inapplicable means that $kT \lesssim 0{\cdot}01$ ev and so $\phi > 0{\cdot}05$ ev. Observed values for the barrier satisfy this condition easily.

Since the interaction between carrier and trap charge has to be substantial it means that an appreciable energy variation over a free carrier wavelength can occur and hence the concept of bending of the conduction band near the centre, which is used to obtain the density factor in § 2, is scarcely valid. The quantitative condition for the barrier height given above must therefore be regarded as a rough estimate.

When the electron temperature is high enough to excite optical phonons the drift velocity becomes independent of field ($\mu \propto F^{-1}$, therefore $p = -1$) and any increase of capture rate with field will produce negative resistance. If the barrier is less than or of the same order as the optical phonon energy the variation of β becomes important and without knowing how this varies with field it is impossible to predict whether negative resistance will occur. All the measured barriers are, however, much greater than $\hbar\omega_{\text{opt}}$ in germanium so that a considerable increase of capture rate ought to occur in the current saturation region.

§ 4. DISCUSSION

It must be emphasized that these considerations apply to the steady state. The time constants involved in transitions between 'repulsive impurity' states and the conduction band can be of the order of seconds at low fields and still of the order of tens of microseconds at high fields. The use of short field pulses of the order of 1 μsec would merely show the mobility variation with field since the carrier concentration would not vary much in 1 μsec (unless the impurity concentration were extremely high); d.c. fields are therefore desirable but heating effects must be avoided since the thermal generation rate must be kept low. Heating effects can be delayed to high fields by working at a low temperature. At too low a temperature however impurity conduction may become an appreciable factor. At high fields millisecond pulses may be adequate since the time constant for trapping should be much reduced from the thermal equilibrium value.

As regards material, germanium, containing as impurity any one of copper, silver, gold, platinum, iron, cobalt or nickel, and suitably doped with a shallow level donor, should be adequate. Copper, for instance, gives three acceptor levels in germanium. Enough donor should be present to compensate completely the two lower levels and about half-fill the uppermost level.

Impact ionization, of course, will destroy any negative resistance effects. An electron to produce impact ionization must not only surmount a higher barrier, since the filled trap will have an extra negative charge, but must have sufficient energy left over to ionize the centre. This effect, if present, will occur at higher fields than those necessary to affect the capture rate, so that its influence will be to reduce the range of fields over which negative resistance is possible rather than to eliminate the possibility altogether. The centre may have excited localized levels which can be significantly populated at temperatures which make the thermal ionization rate low. This increases the probability of impact ionization. It may be expedient, therefore, to work at lower temperatures and excite the electrons in the centre optically. The same conditions for the height of the barrier apply and are even more easily satisfied at lower temperatures. If the temperature is below about 20°K, trapping of the optically excited electrons by the empty donor levels will occur and this will delay the onset of the negative resistance region to fields sufficient to cause substantial impact ionization of the donors.

The influence of the donor levels in this case emphasizes the fact that in this paper we have neglected the effect of other impurity centres, and also the interband transitions. This neglect should be justified at low temperatures when the activation energies of the other levels are greater than the activation energy of our repulsive centre by a few times kT for then the effective transition rates associated with these levels will be very small and can be ignored in Eqn (1). The donors, however, have smaller activation energies and high capture rates. They are positively charged, so that the effect of the field on the capture rate will be to cause ionization, the reverse of the case of repulsive centres. This, coupled with the relative ease with which impact ionization takes place, makes it certain that donors will contribute electrons to the conduction band as the field is increased. There is therefore a tendency to oppose the effect of the field on the repulsive centres unless saturation of the electron concentration due to donor ionization occurs fairly rapidly. But this tendency will have little effect above about 20°K since very few donor levels will be occupied to begin with. Thus, the condition for Eqn (1) to hold when other levels are present is that these levels must be either substantially filled or substantially empty. The breakdown of this condition does not necessarily rule out the possibility of negative resistance; it merely complicates the process.

§ 5. CONCLUSION

In this paper we have shown that the achievement of the negative resistance state by making use of the electric field dependence of capture rate is feasible. The idea of relating the capture rate to the density of electrons in the immediate vicinity of the trap rather than to the average density has led us to the prediction that the effective capture rate for attractive centres should decrease with field, while the opposite effect should occur for repulsive centres when the energy of the carriers is low compared with the energy of interaction between carrier and centre. A necessary condition for obtaining negative resistance in this way is to have repulsive traps present in the crystal.

On the Change of Activation Energy with Impurity Concentration in Semiconductors

By J. F. BARNES and R. H. TREDGOLD
Department of Physics, University College of North Wales, Bangor

MS. received 15*th May* 1961, *in revised form* 8*th June* 1961

Abstract. The existing theories of change in activation energy with impurity concentration are discussed and their limitations pointed out. The ionization energy of a pair of impurities in a dielectric medium is calculated as a function of impurity separation. Assuming a random distribution of impurities, an averaging process is employed to calculate the mean change in activation energy with concentration. This approximation should be poor for high impurity densities but good for low densities. Specific calculations have been made for the case of phosphorus impurities in silicon and satisfactory agreement is obtained with experimental results.

§ 1. Introduction

The work of Pearson and Bardeen on silicon (1949) and Debye and Conwell (1954) on germanium shows that, for low concentrations of impurity atoms, the donor or acceptor atoms behave as isolated independent centres having electrons or holes bound to them with definite activation energies. However, as the concentration is increased, the activation energies decrease continuously and become zero at about 10^{17} centres/cm^3 in germanium, and at about 10^{19}/cm^3 in silicon. More recent work on germanium and silicon by Fritzsche (1955), Blakemore (1959) and Atkins, Donovan and Walmsley (1960), who took measurements to very low temperatures, shows that the conductivity is of the form

$$\sigma = \sigma_1 \exp(-\epsilon_1/kT) + c_2\sigma_2 \qquad \ldots\ldots(1)$$

where the first term represents the ordinary semiconductor process of activation of donor electrons into the conduction band and ϵ_1 is the activation energy, which depends strongly on impurity concentration. This term is dominant at high temperatures. The second term is dominant at low temperatures ($<10^\circ$K) and is dependent on temperature and impurity concentration. This term is said to be due to conduction in an impurity band.

This impurity band conduction can be explained on the model proposed by Mott (1956) and Conwell (1956) who assume that there are both donor and acceptor atoms present with densities N_D and N_A respectively where $N_D - N_A \gg N_A$. At low temperatures all the acceptor states will be filled by donor electrons and the overlap of the donor atoms is great enough for a hole on an ionized donor to jump to a neighbouring neutral donor, and the theoretical predictions of this model agree reasonably well with experiment.

If there are no acceptor impurities present, the number of electrons in the impurity band just equals that of the donor impurity atoms and, as pointed out by Mott (1956), correlation effects will inhibit band conduction unless there is a large overlap of the orbitals associated with adjacent impurity atoms. Erginsoy

(1952) has suggested that the excited states and not the ground states form the impurity band, and this should account for the finite slope of the resistivity curve at low temperatures, but the calculations of the lower band edges of the excited states for hydrogen-like impurities by Erginsoy (1952) and Baltensperger (1953) show that the excited states bands are close to the edge of the conduction band, giving too large an activation energy for the conduction process. Also there is a further objection; Fritzsche (1955) showed that conduction in an excited states band would be extremely small as the excited states cannot be treated as ordinary acceptor states. An excited state can only be occupied if the ground state of the impurity atom is empty. This limits considerably the number of excited states available for conduction as at low temperatures most of the atoms are in their ground state.

Most work on impurity band theory assumes that the impurity atoms are distributed regularly throughout the material, whereas in practice the impurities are quite randomly distributed, but Aigrain (1954) has shown that randomness makes the band approximation valid for a much lower density of impurities.

Pearson and Bardeen (1949) attempted to explain the variation of activation energy (ϵ_1) with impurity concentration by interpreting the decrease to be due to the electrostatic attraction of other ionized donors for an electron which has escaped from its own donor. This potential energy of attraction reduces the energy required for activation. However, on this model it is the density of ionized donors which controls the reduction and not the density of impurity donors (ionized or not) as required by the experimental results.

Pincherle (1951) and Lehmann and James (1955) have considered the effect of the free carriers (electrons from ionized donors) on the activation energy. The free carriers will tend to screen the field around the impurity centres, and the greater the number of free carriers the greater is the screening effect. The number of carriers available for screening depends on the impurity concentration and on the temperature. As the temperature is reduced, the number of carriers is reduced and the activation energy tends to the unscreened value. At relatively high temperatures (above 150°K) the reduction is almost constant and quite large, but does not account for all the reduction in activation energy observed.

A minor contribution to the lowering of the activation energy is due to polarization effects. A free electron in an impure material gives rise to a larger polarization than in the pure material due to the higher dielectric constant caused by the neutral donors. This has the effect of lowering the edge of the conduction band and hence the activation energy. Approximate calculations by Castellan and Seitz (1951) show the effect to be very small.

§ 2. THE MODEL CONSIDERED HERE

In this paper, we calculate the effect of the interaction of impurity atoms in pairs. If a slight overlap exists between the orbitals of adjacent impurity atoms and one of these atoms becomes ionized, the remaining electron will spread out over both impurity centres and thus its kinetic energy will be lowered. This reduction in kinetic energy must be subtracted from the ionization energy of a single impurity atom in order to find the ionization energy of the pair.

To calculate the magnitude of this effect, we thus have to obtain: (i) the energy of a hydrogen molecular ion in a medium of dielectric constant κ for a series of internuclear distances; (ii) the energy of a hydrogen molecule in a similar medium also for a series of internuclear distances. In (2) we assume a random orientation of spins at temperatures of interest and thus obtain a mean energy by taking three-quarters of the triplet energy and a quarter of the singlet energy. Fortunately, this second correction term need not be known with such accuracy as the first quantity.

We shall consider the case of phosphorus impurities in a medium of silicon, where the normal activation energy is 0·045 ev and the dielectric constant is 11·7.

A phosphorus atom has one more positive charge than a silicon atom, so it can be considered as a single positive charge embedded in a continuous medium with an electron bound to it. When the electron is far from its parent impurity atom, it will be moving slowly and it will polarize the surrounding medium, and the effective dielectric constant will be the static one (κ). When it is near to its parent atom, it will be moving quite rapidly and will only partially polarize the surrounding medium and the effective dielectric constant will be much less. Therefore, for the potential between the impurity atom and its donor electron, we use an expression of the form:

$$V = -\frac{e}{\kappa r}\,[1+(\kappa-1)\,\mathrm{e}^{-\gamma r}] \qquad \ldots\ldots(2)$$

where r is the distance between atom and electron, and γ is some suitable damping factor chosen so that the activation energy will have the correct value. The medium will also reduce the effective mass of the electron m^* and in this case $m^* = 0{\cdot}25m$ (which is the accepted value for silicon).

We use modified atomic units throughout the calculations: the unit of length $r_0 = \hbar^2/m^*e^2 = 2{\cdot}12$ Å, the unit of charge $e = 4{\cdot}80 \times 10^{10}$ e.s.u., the unit of energy $= e^4m^*/\hbar^2 = 6{\cdot}8$ ev. The Schrödinger equation for a single impurity atom becomes

$$\left[-\tfrac{1}{2}\nabla^2 - \frac{1}{\kappa r}\,(1+(\kappa-1)\,\mathrm{e}^{-\gamma r})\right]\psi = E\psi \qquad \ldots\ldots(3)$$

where we choose ψ of the form

$$\psi = \frac{a}{\pi^{1/2}}\exp(-r) + \frac{b}{(\pi\kappa^3)}\exp(-r/\kappa). \qquad \ldots\ldots(4)$$

The values of a and b are found by a variational process and the value of γ for the correct activation energy is $\gamma = 1{\cdot}3$.

§ 3. HYDROGEN MOLECULAR ION IN A DIELECTRIC

Let the two atoms A and B be separated by a distance R, and let the distance of the electron from the atoms be r_A and r_B, then the Schrödinger equation of the system is

$$\left\{-\tfrac{1}{2}\nabla^2 + \frac{1}{\kappa R} - \frac{1}{\kappa r_A}\,[1+(\kappa-1)\exp(-\gamma r_A)] - \frac{1}{\kappa r_B} \times [1+(\kappa-1)\exp(-\gamma r_B)]\right\}\psi = E_{H_2^+}\psi. \qquad \ldots\ldots(5)$$

Dickinson (1933) found for the case of the ordinary hydrogen molecular ion that the energy of the system was given fairly accurately by assuming the wave function was made up of 1s and 2p functions. In this case we take a wave function of the form

$$\psi = c_1(\psi_1(r_A)+\psi_1(r_B)) + c_2(\psi_2(r_A)+\psi_2(r_B)) \qquad \ldots\ldots(6)$$

where $\psi_1(r_A)$ and $\psi_1(r_B)$ are the solutions to the hydrogen atom in a medium of variable dielectric constant given by (4) and

$$\psi_2(r)=\frac{\alpha^{3/2}}{\pi^{1/2}}r\cos\theta\exp(-\alpha r) \qquad \ldots\ldots(7)$$

where θ is the angle between $\mathbf{r}$ and $\mathbf{R}$.

The spread parameter α is varied to give the minimum value of the energy of the system. Ideally, there ought to be a variable parameter in the S functions, but the correct S function for minimum energy will only be slightly different from the function given in (4), the variation in the p function being the greatest.

The minimum value of the energy in terms of α was then found analytically, and then the energy was minimized with respect to α numerically for a series of values of R. Values of the energy were computed for values of R between 10 and 50 modified atomic units and an approximate expression for the energy of the system $E_{H_2^+}$ is given by

$$E_{H_2^+}(R)=E_\infty+0{\cdot}0159\exp(-0{\cdot}197R)-0{\cdot}00277\exp(-0{\cdot}0409R). \qquad \ldots\ldots(8)$$

E_∞ is the energy of an isolated impurity atom.

The last term on the right-hand side of (8) is larger than the second term for values of $R>12$ atomic units, and hence in all realistic values of R, the electron will be more tightly bound than in the case of an isolated impurity atom.

§ 4. THE HYDROGEN MOLECULE IN A DIELECTRIC

Labelling the atoms A and B, and the electrons 1 and 2, r_{A1} and r_{B1} are the distances of the first electron from atoms A and B respectively. r_{A2} and r_{B2} are the distances of the second electron from A and B respectively, and r_{12} and R are the separation of the two electrons and the separation of the two atoms.

We evaluate the energy of the hydrogen molecule in a medium of variable dielectric constant using the model of Heitler and London (1927), using wave functions of the form

$$\Psi=A[\psi(r_{A1})\psi(r_{B2})+\psi(r_{A2})\psi(r_{B1})] \qquad \ldots\ldots(9)$$

$$A^2=1/(2+2\Delta^2) \qquad \ldots\ldots(10)$$

$$\Psi_A=B[\psi(r_{A1})\psi(r_{B2})-\psi(r_{A2})\psi(r_{B1})] \qquad \ldots\ldots(11)$$

$$B^2=1/(2-2\Delta^2) \qquad \ldots\ldots(12)$$

where

$$\Delta=\int\psi(r_{A1})\psi(r_{B_1})\,d\tau. \qquad \ldots\ldots(13)$$

Here the one-electron wave functions are given by Eqn (4). The Hamiltonian of the system is taken to be

$$-\tfrac{1}{2}(\nabla_1^2+\nabla_2^2)+\frac{1}{\kappa R}+V(r_{12})-V(r_{A1})-V(r_{A2})-V(r_{B1})-V(r_{B2}) \qquad \ldots\ldots(14)$$

where

$$V(r)=\frac{1}{\kappa r}[1+(\kappa-1)\exp(-\gamma r)]. \qquad \ldots\ldots(15)$$

Using these two wave functions ((9) and (11)) we get two values of the energy E_S and E_A corresponding to the symmetrical and antisymmetrical space wave functions

$$E_S=2E_\infty+\frac{1}{\kappa R}+\frac{E_{11}+E_{12}}{1+\Delta^2} \qquad \ldots\ldots(16)$$

$$E_A=2E_\infty+\frac{1}{\kappa R}+\frac{E_{11}-E_{12}}{1-\Delta^2} \qquad \ldots\ldots(17)$$

where $$E_{11}=\iint\psi^2(r_{A1})\psi^2(r_{B2})[V(r_{12})-V(r_{A2})-V(r_{B1})]\,d\tau_1\,d\tau_2, \qquad \ldots\ldots(18)$$

$$E_{12}=\tfrac{1}{2}\iint\psi(r_{A1})\psi(r_{A2})\psi(r_{B1})\psi(r_{B2}) \times[2V(r_{12})-V(r_{A1})-V(r_{A2})-V(r_{B1})-V(r_{B2})]d\tau_1 d\tau_2; \qquad \ldots\ldots(19)$$

E_S is a singlet state and corresponds to an attraction between the two atoms and E_A is a triplet state and gives rise to a repulsion between the atoms at all values of R. The integrals containing $V(r_{A1})$, $V(r_{A2})$, $V(r_{B1})$ and $V(r_{B2})$ are easily evaluated from the table of two-centre integrals tabulated by Coulson (1942). The integral in $V(r_{12})$ for the coulombic term E_{11} is evaluated by standard methods.

The part of the exchange term in r_{12} is

$$\iint\psi(r_{A1})\psi(r_{A2})\psi(r_{B1})\psi(r_{B2})V(r_{12})\,d\tau_1 d\tau_2$$
$$=\frac{1}{\kappa}\iint\frac{1}{r_{12}}\psi(r_{A1})\psi(r_{A2})\psi(r_{B1})\psi(r_{B2})\,d\tau_1 d\tau_2+\frac{\kappa-1}{K}\iint\frac{1}{r_{12}}\psi(r_{A1})\psi(r_{A2})\psi(r_{B1})\psi(r_{B2}) \times\exp(-\gamma r_{12})\,d\tau_1 d\tau_2. \qquad \ldots\ldots(20)$$

The first term contains 16 integrals which can be evaluated by the method of Sugiura (1927) by changing to elliptic coordinates and expanding r_{12} in terms of the associated Legendre functions. The second term cannot be evaluated analytically, but its contribution to E_{12} is very small ($<1\%$ of E_{12}) and can be roughly estimated from the relative values of the two terms in the integral $\iint\psi^2(r_{A1})\psi^2(r_{B2})V(r_{12})d\tau_1 d\tau_2$. As in the case of the molecular ion, values of the energy were computed for values of R between 10 and 50 modified atomic units, and an approximate expression for the energy in these units is

$$E_{H_2}(R)=2E_\infty+0{\cdot}0717\exp(-0{\cdot}0255R)+0{\cdot}0219\exp(-0{\cdot}133R). \qquad \ldots\ldots(21)$$

The electrons are not so tightly bound, in this case, as an electron on an isolated atom. The energy required to remove an electron from the molecular system will be

$$E_{H_2^+}-E_{H_2}=-E_\infty+0{\cdot}0159\exp(-0{\cdot}197R)-0{\cdot}00277\exp(-0{\cdot}0409R) -0{\cdot}0717\exp(-0{\cdot}255R)-0{\cdot}0219\exp(-0{\cdot}133R). \qquad \ldots\ldots(22)$$

When computing the amount of reduction in activation energy, it is necessary to consider all the pairs a given atom can make, therefore we must integrate over all possible pairs. Assuming that the impurity atoms are distributed with constant density throughout the material, the reduction in activation energy ΔE is given by

$$\Delta E=8{\cdot}4\times10^{-20}\rho\ \text{ev} \qquad \ldots\ldots(23)$$

where ρ is the density (centres/cm^3) of impurity atoms.

This model of considering the impurities in pairs will only hold at low concentrations, when the probability of finding two centres close together in a region of the material is much greater than the probability of finding three centres close together. The linear variation of ΔE with ρ predicted by (23) contrasts with the $\rho^{1/3}$ law arising from the theory of Pearson and Bardeen (1949). However, the experimental results published by them are not sufficiently detailed to determine the power law in the low density region. The results of Debye and Conwell (1954) are also insufficiently detailed in this region to make a comparison possible.

§ 5. DISCUSSION

At 10^{17} centres/cm^3 the reduction in activation energy is 0·008 ev which compares with 0·009 ev in the case of Pearson and Bardeen, and the activation energy becomes zero at about 5×10^{17} centres/cm^3 on this simple model. However, this approximation can only be considered valid at low densities and will always give values that are high. At high densities, when one electron is excited in a given region of the material, it is not correct to look upon the reduction in activation energy as the spreading of an electron over two centres, but rather to the spreading of $x-1$ electrons over x centres, where x at high densities is much greater than 2. As the density is reduced, the two-centre model will be more correct. At low concentrations using this model, the reduction in activation energy agrees approximately with the results of Pearson and Bardeen (1949) although more recent results show that their zero concentration activation energy is too high.

Hence, at low concentrations, the reduction in activation energy can probably be regarded as due to a combination of the effect discussed here with the screening effect of Pincherle (1951), and at high densities, as a combination of screening and the formation of an impurity band.

Some Physical Properties of the γ and δ Phases in the U–Zr System

By R. D. BARNARD†
University of Nottingham

Communicated by L. F. Bates; MS. received 10th May 1961

Abstract. Electrical resistivity and magnetic susceptibility measurements are reported for U–70 and 74 at. % Zr in both the γ and δ phases. Negative temperature coefficients of resistivity were found in the metastable γ phase of U–70 at. % Zr, and also in the δ phase of both alloys between 90° and 870°K. The Pauli weak spin paramagnetism, exhibited by both specimens, always increased with temperature.

The results support the view that the δ phase is primitive hexagonal and not an ordered form of the body-centred cubic γ phase. The anomalous resistivity behaviour may be a consequence of the band structure of the alloy.

§ 1. INTRODUCTION

RECENT measurements of the resistivity of metastable γ body-centred cubic U–Mo and U–Nb alloys (Chandrasekhar and Hulm 1958, Berlincourt 1959, Bates and Barnard 1961a, b) have shown an abnormal feature between 4·2 and 500°K, namely, a monotonic decrease of resistivity with increasing temperature. The accumulation of additional data (Hall effect, electronic specific heat, and magnetic susceptibility) particularly for the U–Mo system has furthered our understanding of the electronic structure of these alloys, and a collective electron model now seems appropriate for their description. With this model the resistivity behaviour may be explained, provided that the density of states at the Fermi surface is a sensitive function of energy. The existence of similar resistivity behaviour in γ U–Nb alloys (Bates and Barnard 1961 b), despite the difference in the conventional valency of Nb and Mo, has led to a similar conclusion about the position of the Fermi surface in the density of states–energy spectrum.

This behaviour is not unique in metastable uranium alloys; alloys of Ti–V (Brotzen *et al.* 1955), Ti–Mo (Yoshida and Tsuya 1956), and Ti–Nb (Ames and McQuillan 1954) also show this phenomenon in the quenched body-centred cubic phase, and again no explanation in terms of localized electrons is appropriate. Similar anomalous behaviour has also been reported in other alloy systems; some Fe–Cr (Newmann and Stevens 1959) and Th–Ce (Newmann 1958) alloys exhibit negative temperature coefficients of resistivity over small temperature ranges, but they are thought to be associated with the scattering of electrons by localized moments. Such alloys also show anomalies in the magnetic susceptibility in the same temperature ranges.

The extension of magnetic and electrical observations to the U–Zr system arose naturally from the previous investigations on uranium alloys, for once again the γ phase can be retained at room temperature by quenching alloys of suitable composition. A further investigation of the same properties of the δ phase was performed in the hope of resolving the conflicting views held concerning its crystal structure.

§ 2. THE CRYSTALLOGRAPHY OF THE γ AND δ PHASES

The phase diagram of the U–Zr system is now well established, although disagreement exists between various authors on some of its finer details. There is, however, complete agreement that solid solution exists between γ body-centred cubic uranium and β body-centred cubic zirconium, and the stability of the δ phase is now established (Holden and Seymour 1957). The γ phase can be stabilized at room temperature by quenching alloys in a composition range between about 50 and 80 at. % Zr, but the rapidity with which the δ phase forms often results in two-phase mixtures. Solubility limits of the δ phase have been variously reported; Knapton (1957, unpublished) reports a solubility range of 63–79·5 at. % Zr at 600°C, but Duffey and Bruch (1958) give the limits as 66 and 72 at. % Zr. Studies in this region are complicated by the pronounced effects of oxygen and nitrogen on the δ phase solubility limits, and by the nature of the γ–δ transformation. The δ phase was first thought to be an ordered structure of the γ form (Mueller 1955), but Boyko (1957) considers the structure to be more appropriately indexed as primitive hexagonal. This structure is partly ordered with zirconium atoms located at the (0, 0, 0) positions, while zirconium and uranium atoms are located randomly at $(\frac{1}{3}, \frac{2}{3}, \frac{1}{2})$ and $(\frac{2}{3}, \frac{1}{3}, \frac{1}{2})$ positions. The random distribution of uranium and zirconium atoms allows a considerable range of composition. For U–70 at. % Zr, the δ–γ phase change temperature is about 605°C (878°K).

§ 3. EXPERIMENTAL DETAILS

Two alloys of composition U–70 and 74 at. % Zr were used in this investigation, both being within the δ solubility limits. The alloys were prepared at the Atomic Energy Research Establishment, Harwell, in an argon arc furnace from uranium and zirconium samples whose principal impurities are shown in the Table.

Chief Impurity Contents (parts per million) of Uranium and Zirconium

	C	Fe	Al	Si	N_2	Cr	Mn	H_2	O_2	Cu	Ni	W	As
Uranium	800	100	65	25	20	5	10	10	50	—	—	—	—
Zirconium	—	—	—	—	50	4	3	300	200	150	10	200	50

The alloys were homogenized for two weeks, at 1000°C, in the γ phase region and then rapidly water-quenched to retain the γ phase in metastable equilibrium. Metallographic observations performed on the two alloys after the susceptibility and resistivity examinations showed U–74 at. % Zr to be mainly δ phase and U–70 at. % Zr, though predominantly δ phase, contained considerable amounts of impurity, especially at the grain boundaries.

Details of the apparatus for the measurement of magnetic susceptibility and electrical resistivity over the ranges 293–1200°K and 90–1200°K respectively have been described elsewhere (Barnard 1960).

§ 4. Experimental Results

4.1. *Electrical Resistivity*

The resistivity–temperature relation of U–70 at. % Zr is shown in Fig. 1. Observations were first taken with temperature increasing from 90°K with the specimen in the metastable γ state; the onset of precipitation of the δ phase is clearly indicated at 375°K, where there is a marked discontinuity in the slope of the resistivity–temperature curve. Readings were continued as the temperature and degree of precipitation increased until, at about 878°K, the γ phase was re-established with a discontinuous decrease of resistivity. Of course, little value can be attached to the observations taken while the γ phase was decomposing, as these were time-dependent as well as temperature-dependent, and they are included in Fig. 1 merely to show the marked effect of δ precipitation. In the stable γ region, where the resistivity was almost temperature-independent, the heating and cooling curves were identical, showing that equilibrium was established in this phase. A tentative interpolation shown by the broken line in Fig. 1 has been made between the metastable and stable γ regions of the resistivity curve, thus giving the probable variation between 90 and 1200°K of γ U–70 at. % Zr. Slight temperature hysteresis was observed on cooling through the γ–δ phase change temperature, after which further cooling was accompanied by a steady *increase* in resistivity down to 90°K.

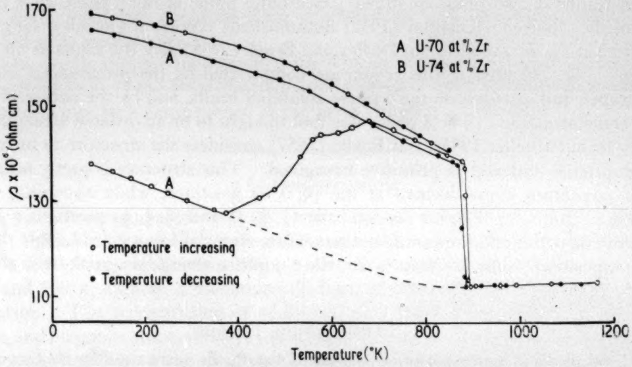

Fig. 1. Electrical resistivity plotted against temperature of U–70 at. % Zr in the metastable γ, stable γ and δ phases and U–74 at. % Zr in the δ phase.

It was at first thought that this remarkable behaviour might have been due to insufficient time being allowed for the phase change γ–δ to be completed. It was therefore decided to follow the resistivity changes of U–74 at. % Zr at 875°K while the γ phase decomposed to the δ phase. Between 5 and 30 hours after the decomposition was started by reducing the temperature from 900 to 875°K no change in the resistivity occurred, and so the δ phase was considered to be in equilibrium. Resistivity values were then taken as the temperature was reduced to 90°K. The variation is shown in Fig. 1 together with values taken on heating afterwards. Cooling and heating curves are identical.

From information on the thermal expansion of U–70 at. % Zr in the δ phase (Knapton 1959, private communication), corrections were calculated for the resistivity values, but their effect was so small that the graphs are here plotted without correction. The similarity between the forms of the resistivity variations of δ U–70 at. % Zr and U–74 at. % Zr seems to indicate that the δ phase was in equilibrium in the former case also.

The absolute value of the resistivity of δ phase U–70 at. % Zr at 273 °K was $161 \pm 2 \times 10^{-6}$ ohm cm, compared with the value $184 \pm 2 \times 10^{-6}$ obtained by Loasby (1958) who also investigated the same properties of the δ phase but only over the limited temperature range 90–293 °K. However, Loasby observed a similar temperature dependence of resistivity. The greater purity of materials in the present alloys may account for the lower resistivity.

4.2. *Magnetic Susceptibility*

Figure 2 shows the temperature variation of the susceptibility of U–70 at. % Zr in the metastable γ, stable γ and δ phases and also of the δ phase of U–74 at. % Zr. The observations on the former specimen were taken, like those of the resistivity, first in the metastable γ and then in the stable γ region. The variation for U–70 at. % Zr shown in Fig. 2 indicates that in the stable γ region the susceptibility is only weakly dependent on temperature, whilst strong temperature dependence holds for the metastable γ state. In this respect the behaviour is similar to that of the uranium-rich γ U–Mo and U–Nb alloys. The effect of precipitation of the δ phase is clearly accompanied by a decrease in susceptibility; this precipitation in the metastable γ U–Zr alloys is much more rapid than with U–Mo or U–Nb alloys, and marked effects occurred in the present sample at temperatures as low as 100 °c.

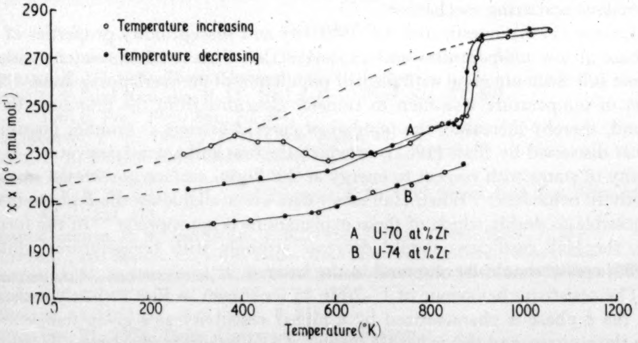

Fig. 2. Magnetic susceptibility plotted against temperature of U–70 at. % Zr in the metastable γ, stable γ and δ phases and U–74 at. % Zr in the δ phase.

With U–70, 74 at. % Zr in the δ phase there appears to be an increase in slope of the susceptibility–temperature graph at about 560 °K. This is at precisely the temperature where the resistivity–temperature curves of the δ phase alloys show a decrease in slope (Fig. 1). These effects are considered later in the discussion of the δ phase.

§ 5. Discussion

Both the susceptibility and resistivity behaviours of γ U–70 at. % Zr are qualitatively similar to those previously reported with the uranium-rich γ U–Mo and U–Nb alloys (Bates and Barnard 1961 a, b). With no other physical property data on γ U–Zr alloys available for correlation purposes, it is hazardous to discuss the possible electronic structure of these alloys. However, the properties presented here seem to indicate that a collective electron model, with a band structure at the Fermi surface at least qualitatively similar to those of the U–Mo and U–Nb alloys is appropriate. It is to be noted that a negative temperature coefficient of resistivity in γ U–Mo alloys is found up to 30 at. % Mo, and with γ U–Nb alloys up to 60 at. % Nb, but this behaviour is present in a γ U–70 at. % Zr specimen. The extension of the anomalous behaviour may well be associated with decreasing electronic contributions from the solute atoms (Mo, Nb, Zr have conventional valencies of 6, 5, 4 respectively).

As far as the author knows, this is the first example of the persistence of a negative coefficient of resistivity characteristic of the δ phase over a wide range of temperature of some 800°K in a metallic alloy in an equilibrium phase. Between liquid oxygen temperature and 800°K there is a 17% decrease in resistivity; this property may have useful applications in low resistance circuits whose total resistance is required to be constant with temperature. Thermal conductivity measurements on the δ phase may be extremely interesting in view of an anomalous scattering mechanism.

Loasby (1958) investigated the resistivity and susceptibility properties of the δ phase at low temperatures and suggested that these were consistent with an almost full Brillouin zone with a small population of an overlapping zone. The effect of temperature was then to transfer electrons from the first zone to the second, thereby increasing the number of current carriers. Another possibility is that discussed by Blatt (1961), in which the first and second derivatives of the density of states with respect to energy at the Fermi surface govern the unusual resistivity behaviour. When Hall effect data are available on the δ phase it will be possible to decide which of these explanations is appropriate. In the former case, the Hall coefficient should decrease strongly with temperature, while a small increase should be observed in the latter.

The resistivity behaviour of U–70 at. % Zr shown in Fig. 1 clearly indicates that the δ phase is characterized by a higher resistivity at a given temperature than the γ phase, and this is hardly typical of a superlattice structure. However, it is theoretically possible, although unusual in practice, for a superstructure to exhibit a higher resistivity than the parent disordered structure. For, if the increase in order of the superlattice which alone results in a lower resistivity is accompanied by a sufficiently large decrease in the number of effectively free electrons, produced possibly by the new faces of the Brillouin zone, then a higher resistivity will ensue. In the present instance, this situation appears improbable, since the near equality of the susceptibilities of the δ and γ phases at 0°K is indicative that no severe electronic change takes place although, obviously, a small change must take place to give the different temperature dependences of susceptibility. It seems, therefore, that the physical properties so far investigated favour the hexagonal structure rather than the superstructure description of the δ phase.
